It may be of some interest and perhaps benefit to such institutions to read the following description of a method which is successfully employed by myself and, no doubt, by many other ship surgeons. It is a well-known fact that much of the opposition which is arrayed against vaccination is caused by the inoculation of disease into one person from another through the medium, in times now happily past, of the crust, and later by the vaccination knife or by using the same applicator to apply the virus to all arms. To my mind there are but few things which could and should cause more feelings of remorse to the conscientious physician than the knowledge, or even suspicion, that he had through any avoidable means inoculated a trusting patient, especially a child, with a loathsome disease.

When a number are to be vaccinated, as in a school or barracks, and the same knife is used for all, the danger of such an "accident" is very great, even though an attempt be made to sterilize the knife after

each scarification — which, I fear, is seldom done. Thus an innocent person becomes sorely afflicted, and another stumbling-block is placed upon the barrier raised against vaccination. A disease in one person may thus be inoculated into not only one other but several otherwise healthy people.

The readers of the MEDICAL RECORD are doubtless aware that steerage passengers on the transatlantic liners are vaccinated by the ship's surgeon as early in the voyage to the United States as practicable. The rules state that "all adult persons should be vaccinated who have not been successfully vaccinated within the past six years, except children under ten years of age who bear good evidence of successful vaccination." A scar upon the arm of an adult practically means nothing: and as a correct history of past vaccinations is difficult to obtain, usually all, except small children with good marks, are vaccinated —upon the theory that "If you don't need it, it will not hurt you: and if it does hurt you, you needed it."

The vaccine furnished to the surgeons of the Holland-America line is put up in small tubes of glass hermetically sealed at each end. Each tube contains sufficient vaccine for fifteen inoculations, is of the best quality, and is handed to the surgeon on board ship as late as possible before sailing, usually within the hour of departure, in order that the vaccine shall be as fresh as possible. The vaccination is done as soon as practicable after leaving port, and is performed in the following manner: The ends of the glass tubes are clipped off with shears, and the vaccine is turned from them into a small butter dish or watch crystal, and a little clean glycerin is added to it. For scarifying I use only needles. Any kind of a steel needle may be used, provided it be new and clean. The ones which I use are common sewing-needles of French manufacture, and come in tubular telescopic paper boxes, each containing about twenty-five needles of assorted sizes. There are many variations in the thickness of skins, and an assortment of needles is desirable. The dish containing the virus, and the needles, with all the points in one direction, are placed on a proper support within easy reach of the surgeon. The people to be vaccinated are formed into line, with arms prepared. The surgeon stands facing the patient, holds a needle between the thumb and first two fingers of his right hand, with the point toward the ulnar side. The fourth and fifth fingers are closed against the palm of the hand. He grasps the patient's arm firmly with his left hand, which draws the skin taut, and with a few rapid strokes of the needle, usually five, makes as many scarifications in the skin, parallel to the long axis of the arm. This is usually sufficient, but if not a few rapid strokes may be made at right angles to the others. A little bleeding, but not much, should result. The needle is then reversed between the thumb and first finger by a sweep of the second finger in closing, so that the point of the needle points toward the palm of the hand. The end of the needle containing the eye is then dipped into the virus and applied to the scarifications. The needle is then thrown overboard.

The eye of the needle will take up a good-sized drop of the vaccine, much in the same manner as a pen does ink.

The pain caused by the scarification, though a little acute, is so quickly ended that it is much more easily endured than is the scraping of a knife. I have scarified an infant's arm and applied the virus before the child realized what was going on enough to cry out or struggle. The preparation of the arm before and the dressings after the vaccination may be carried out as desired.

The advantages of this method over that of the knife are the simplicity and rapidity of the operation; the perfect sterilization which may be given the needles; and, above all, the absolute impossibility of inoculating one arm from another, as the part of the needle which has been in contact with the arm of one never comes in contact with the virus or the arm of another. Of course a new needle is used for each person, but the expense of them is comparatively nothing. When a large number are to be vaccinated, one will be surprised at the rapidity with which it may be efficiently accomplished by this method.

V. A. CHAPMAN, M.D.,
Surgeon of S.S. Werkendam.

AT SEA, September 24, 1898.

MISTAKEN IDENTIFICATION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: By identity is meant the determination of the separate or distinct existence of a person, drawn from a series of facts, some of them obscured, perhaps by trickery or fraud, and all of them more or less varied by circumstances. When the recognition of a person is the object of a judicial action, the forensic application of the term is to be considered. Medico-legally, the consideration of personal identity is one of great importance, embracing, as it does, questions which affect cases of both a civil and a criminal character; in fact, it may constitute the most important evidence of any presented.

Cases of mistaken identity have frequently arisen, and medical literature fairly teems with instances which go to show that innocent persons have been often made to suffer because they had the misfortune to resemble others.

The difficulty of identification is very much increased in those cases in which the body of a person has been subjected to mutilation after death, or in which severed portions of the same body have been removed to a distance, or even destroyed.

Murderers often dispose of the mutilated remains of a dead body, with a view to escape detection. In the brutal murder of his mistress, Cæsar, the New York negro, who was some few years ago convicted and sentenced to death, mutilated the remains in a horrible manner and then removed the severed portions to a distant part of the city, for the evident purpose of avoiding the suspicion that was soon cast upon him.

The identity of the living may usually be established by the direct evidence of those who have had such acquaintance with the person in question that they have a perfect recollection of his personal appearance. This kind of evidence is, however, often very defective, for the reason that instances do occur in which the most confident identification of persons has afterward proved to be of no value whatever. In the celebrated Tichborne and Guerre cases illustrations are afforded of the extreme difficulty of deciding this question. In the former instance eighty-five witnesses swore that the claimant was Sir Roger Tichborne, even the latter's mother and family solicitor being among the number. The claimant's case, however, was lost on the cross-examination. The uncertainty of identification is also well shown in the Martin Guerre case, which was tried in the year 1560 before the parliament of Toulouse, and is recited at length in "Celebrated Crimes" by Dumas. This personage, Martin Guerre, had been away from his home for a period of about eight years, when an individual named Du Tilh appeared and represented himself as the long-absent man. So strong was the resemblance that his statement was universally accepted by all of Guerre's family, including his wife, sisters, and two brothers-in-law, among whom he had lived unsuspected for three years, having two children by Guerre's wife. Some

circumstances, however, occurred to cause suspicion in regard to his true character, and he was arrested on a charge of fraud. Upon his examination he gave perfectly satisfactory answers to the most minute inquiries in relation to Guerre's former life. Some one hundred and fifty persons were examined during the proceedings, of whom between thirty and forty testified from a lifelong acquaintance that the prisoner was Martin Guerre, while about the same number swore positively that he was Armand Du Tilh, whom they well knew, and over sixty, who knew them both, declared that they were unable to say which the prisoner was. Finally, however, the real Martin Guerre appeared upon the scene, when immediately he was recognized by the four sisters who had previously testified that Du Tilh was their brother. They admitted their error and acknowledged the distinction. There being now no doubt of the guilt of the prisoner, he was condemned and executed. From these two most astonishing examples the fact is demonstrated that appearances are not conclusive evidences of personal identity, simply because they convey different impressions to different observers. This goes to show that a large proportion of people are untrained in minute observation.

The false identification of the living and the dead body has been a matter of much concern for centuries, relegating evidence by circumstance to an uncertain niche in criminal jurisprudence. The present mystery of the Yellow Mill Pond bids fair to be a case of repeated mistaken identifications. The police authorities of the world have ere this been put on their mettle in solving cases of this kind; men have been hanged in the past for the murder of persons who later appeared upon the scene alive and well. In the present celebrated case, the person identified as dead turns up alive, inspects a grave dug for her, glances at the floral tributes to her funeral—in fact, comes home in the nick of time to attend her own funeral. Her appearance throws this mystery into the slums of an almost fathomless and never-to-be-solved mystery. Remarkable coincidences, a distracted father, a dentist, an undertaker, are the factors which led to the false identification of the body. The father's solemn oath seemed to clinch the identity of the dead form. Perplexity surrounded the efforts of the authorities within a short time, for lo, behold! the girl doubly and triply identified as dead turns up alive at her home. Although the features of the dead and the living girl are dissimilar as regards the head, nose, forehead, and hair, still the distracted father recognizes his daughter by marks on the face and head. He finds a scar on one side of the parting of the hair—a scar three-fourths of an inch long on the head—and a pockmark, resulting from chicken-pox, over the eye; he remembers that his daughter has the same distinguishing marks, but he admits that the general appearance, the shape of the forehead, and the nose of the dead girl do not resemble the corresponding features in his daughter; still he stakes his life on it that the mutilated body lying before him is the body of his absent one. From the photograph of the head of the dead girl he recognizes more strongly than ever his lost child. The strongly locked, rigidly contracted jaw of the head of the mutilated form is forced open for the father to inspect the teeth, the difficulty of which I will leave to any one versed in the care of the body after death—a difficult feat in almost all cases. The now almost irresponsible parent with the aid of a chart, and with the assistance of the undertaker, recognizes his daughter more strongly by means of the teeth.

The characteristic features of filled and of removed teeth, believed to be possessed by his daughter, are transmitted by telephone, with the help of the dentist's chart, and correspond exactly. He returns home with the body, believing it to be that of his missing child. According to the dentist and the father, the teeth of the dead head tallied exactly with the chart, and consequently with the teeth of the missing girl; the chart was prepared by the dentist who attended the teeth of this missing young woman, and consequently he ought to know. The condition of the teeth in the dead body showed that the two centre teeth were filled with gold, the centre tooth on the right side of the mouth was filled on both sides; the next tooth to that on the right side of the mouth was filled on the inside; the one on the left side of the centre was filled on the inside. Two of the back teeth on the left side of the upper jaw were gone. Back tooth, front of wisdom tooth, filled with white filling; stomach tooth, on lower jaw, filled with gold on right side; the next back tooth was filled. The feet of the dead girl were exact counterparts of the feet of the missing one, but the hair did not compare favorably; in thickness and length it did, but in color it was entirely different, redder than the hair of the missing girl.

Shades of Martin Guerre! more a case of distracted father than a case of mistaken identification. And still this case will be seized upon by the astute criminal lawyer to gull the ever gullible jury into the belief that his client is guiltless of crime, simply because mistakes in identification are frequently made, and will be made as long as the emotions have full play in man. I venture to say that in very few cases can a positive identification be made and sworn to. No less than ten innocent men have been labelled "Willie Tascot," and each identified positively as the murderer of a Chicago millionaire—yes, identified by more than one person; even the height, features, filling of teeth and birthmarks corresponding. Still each of these men turned out the victim of circumstances. Men have been indicted for crime and placed on trial, simply because they were "identified" as the guilty one, and in every case the real culprit turned up later. Men have been tried for murder, the supposed victim making his appearance alive and in court before the end of the trial, as was the case in the trial of Buckson in 1851. A person may disappear mysteriously from his or her usual haunts. A nude body is found in the water; it is identified by certain marks, scars, tattoos, and peculiarities of the teeth. Later, the identified party makes his appearance in the flesh. How many persons have taken part in their own wake, simply through a mistake in identity? Recently, in our own courts, the real cuprits have appeared and pleaded for the release of others, imprisoned unjustly through false identity. At a time when theft was punishable by death in England, a man was hung as the criminal; simply another case of false identification.

The "mail-coach case" in France was the cause of the guillotining of two persons through false identification. A positive and hurried identification should be frowned upon, as it rightly was by the authorities in the now celebrated Yellow Mill Pond mystery. The father completed his identification in an hour. This hour of positivism will give food to the criminal advocate, in the defence of clients, for centuries to come. The authorities did well in refusing to deliver the body to the distracted father until he had made affidavit to his positive identification. The undertaker in the case had buried more bodies than any other man in the State, and was well qualified to judge of the changes in appearance, after death, by a photograph, by the features, and by marks. He asserted positively that there could be no mistake. The dentist, standing beside the telephone, converses with the undertaker, evidently an observant man, at the side of the dismembered corpse at the morgue. The dentist tells

the undertaker across the 'phone that the first right upper front tooth is filled on each side; of course, he refers to the teeth of his former patient, the missing girl, and he wishes the undertaker to compare his description with that of the dead body. He telephones, furthermore, that the teeth on either side are filled on the sides nearest the first tooth. The undertaker telephones back that this description tallies exactly. The dentist's chart shows, furthermore, that in the lower jaw the left side of the fifth right tooth was filled; this also shows in the head of the dead. A white filling shows in the upper jaw on the left side, next to the wisdom tooth; two upper teeth are missing on that side and one upper tooth is absent on the other side. Remarkable coincidences, but simply a case of mistaken identity. Stronger evidences could not have been brought forward than these peculiarities in the teeth. Still when the missing and supposedly dead daughter returns it is found that her nose is *retroussé*, and that her teeth are in all respects dissimilar from those of the body in the morgue. Was ever identity twisted as it was in this case? And still the same thing will recur for ages. The only actual coincidence of resemblance between the prodigal daughter and the unfortunate in the morgue was the pockmark over the eyebrow.

Circumstantial evidence has had a remarkable setback. Dentists with elaborate charts will not be looked upon with favor by juries for a long time to come. As for long-distance telephone identifications —well, the less said the better. Seldom has there been such a case of mistaken identity—birthmarks identical, fillings in the teeth sworn to as the same, the father stakes his life upon the correctness of his identification, the dentist folds his chart, and the body is shipped to the suffering parents, only to be returned again to the morgue as a silent argument of the unreliability of hasty and improperly conducted identifications. The confidence of the public as jurors has been shaken as regards identification of dead bodies. The criminal lawyer will be on the alert in incorporating this now famous case in his defence of criminals. Father, undertaker, photograph, dentist, even the mother, all wrong. Still accused persons have been sent to prison—ay, to ignominious death—on less positive testimony than this. Trials for murder and other crimes, when the question of identification is involved, will echo this case, as showing the unreliability of positive identification in the living or in the dead. "Circumstances do not lie," I heard the eloquent Fellows say in the trial of the Arab, Ben Ali, for the murder of "Old Shakespeare;" but circumstances in this now mysterious case of the Yellow Mill Pond have brought forward—what? A monstrous example of false identity. And when the mistake is discovered, what do we find in its place, what has it brought to life? Simply a love affair between two ordinary persons.

Still, we do not identify any more positively in our great city of New York. I will mention examples. The body of an unknown is found, removed to the morgue, and in many cases is identified by ten or more persons, as was illustrated in the Colonnade Hotel case. How easy it is to be deceived is not comprehended at its proper worth. The changes produced by death invariably increase the liability to error—so much so, that the identification of a dead body by a single person is unconvincing, unless supported by circumstances. Love of notoriety is the foundation for some of these mistakes, but in the majority of cases people go to the morgue and honestly believe that they have found their beloved ones at last. These are to be distinguished from that class of "born liars" who will identify anything, from an army mule to a thirteen-inch shell.

It is not so very long ago that an officer in this city, who had brought a female prisoner to the police court, identified the wrong woman in court, and found out his error only after the wrong woman had been sentenced and committed to jail. In the same courtroom, within twenty-four hours after, another police officer identified as his prisoner a man who was sixteen years older than the man he had arrested. A remarkable case of deception in this city was that of the man who, believing his stepson dead, found out, two years later, that he had been living in the same house with him all that time, alive and well. Certainly a slap for those who identify by features only. In July, 1897, the body of a woman lay in the morgue; death was caused by drowning. She was thrice identified, each time falsely. A few years since a woman identified each of two bodies as the body of her husband. They looked so much alike, and so much like her missing husband, that she did not know which one to bury. In describing him to the police, before these bodies were found, she said that her husband carried a small harmonica and a peculiarly shaped match box. The first body found had in its pockets a harmonica and a match box. She was preparing the body for burial when another body was fished out of the water, in the pockets of which were a harmonica and a match box exactly like those found on the other corpse. She was debating which body to bury when an acquaintance told her that he had met her husband at a parade. Her husband did not return, so she buried both bodies, to make sure that he received proper interment, in case either corpse was his. A woman and all her children identify a body at the morgue as husband and father. A wake is held, all arrangements for the funeral are completed. The woman is summoned to the morgue, the funeral is stopped; she finds her husband at the morgue—another case of mistaken identity. A colored man returns to his home alive and well, after his wife had supposedly buried him a year before. He disappeared from home; a body was found in the water; it was identified by his wife as his, it was buried, and $491 insurance money was collected. In Brooklyn a boy absented himself from home; in the mean time his parents buried the body of a boy, thinking it to be their son. At dinner, one evening, their missing boy returned alive and well, and was warmly greeted with a sound thrashing. Another body with well-preserved features was found floating in the river. It was positively identified by mother and son. The identification was completed, in that an old-time scar was found over the right eye. After the body was buried, the real husband and father returned alive to his family.

In Tidy the following case is cited: The body of an old man was found on the bank of the Dee, at Drumoak. The left ear and the first finger of the left hand were wanting, the mutilation being apparently of long standing. Two young women claimed the body as that of their father, who had been in the habit of leaving home for weeks at a time, and who had lost his left ear and left forefinger. On the return of the daughters and friends of the supposed party from his funeral, the boatman of a ferry which they had to cross asked them for whom they were mourning, and on receiving their answer laughingly informed them that he had only half an hour before ferried their father over, alive and well—which on reaching home they found to be true.

JUSTIN HEROLD, M.D.
173 EAST EIGHTIETH STREET, NEW YORK.

Kissing has come to be regarded as so dangerous a pastime in Columbus that the board of health will supply any applicant with a disinfecting lip wash, to be used before and after.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 8, 1898:

	Cases.	Deaths.
Tuberculosis	135	147
Typhoid fever	102	36
Scarlet fever	55	8
Measles	33	3
Diphtheria	60	14
Cerebro-spinal meningitis	0	1
Laryngeal diphtheria (croup)	4	8
Chicken-pox	10	0

Plague Statistics.—In Calcutta among male Hindoos the proportion of reported deaths to reported cases has been 86.2 per cent.; among female Hindoos, 72; among Hindoos of both sexes, 84; among male Mohammedans, 85; among female Mohammedans, 88; among Mohammedans of both sexes, 86; among male Eurasians, 54; among female Eurasians, 73; among Eurasians of both sexes, 63; among males of all classes, 83; among females of all classes, 76; and among persons of all classes and both sexes, 82 per cent. The figures upon which these percentages are based are in many instances, particularly in the female group, too small to permit of any sweeping conclusions as to racial susceptibility to the plague poison, but attention may be called to the remarkably low mortality among Eurasians.—*The Lancet.*

League in Italy against Knife.—Through her associated workingmen's clubs Rome has taken an initiative as laudable as it is opportune. She has organized a "Lega contro il Caltello" (league against the knife), the instrument carried in contravention of the law by every peasant and artisan and the medium of the homicides, four thousand and upward annually, perpetrated in Italy. The latest meeting of the league was held on September 11th, when a "statuto" was compiled, embodying the "sense" of previous meetings in a series of final resolutions. Its membership is by this time reinforced by an enormous number of "adhesions," and if, as is more than likely, it becomes the parent of other "leghe" on similar lines in the provinces, Italy will have taken a step long expected of her by contemporary Europe toward clearing her character of the stigma which has hitherto been attached to it for "priority in crimes of blood."—*The Lancet.*

Colored Photography, which will be of such value in medical writings, has again been announced as an assured fact. This time the discovery was made in Chicago.

Inordinate Sympathy.—A physician, in an article illustrating the evil custom of talking to an invalid about his pains, says that once he requested a mother to mark a stroke upon a paper each time that she asked a sick daughter how she was. The next day, to her astonishment, she made one hundred and nine strokes. A three-months' visit away from home was prescribed.

The Idiotic and Feeble Minded.—The total number of idiotic and feeble-minded persons in the United States on June 1, 1890, was 95,609. Of these 52,962 were males and 42,647 females; 84,984 were whites; 42,277 males and 33,620 females were born in the country; foreign whites, 4,875 males and 4,212 females; negroes, 5,788 males and 4,799 females; the remainder, Chinese, Japanese, and Indians, 22 males and 16 females. In the census of 1880 there were 76,000 feeble-minded persons in the United States, showing an average increase of 2,000 a year. In 1870 the number of idiots was 24,395; of these 22,766 were born in the United States. Dr. Fernald estimates that, taking the country as a whole, there is one feeble-minded person for every 500 persons in the United States, while Dr. Ireland is of opinion that as a rough estimate this proportion holds good in those countries which have a census.

Hospital Arrangements in the Soudan.—The arrangements made by the army medical department are most elaborate and complete. They have been made by Surgeon-Colonel Macnamara. A medical officer is attached to each battalion, and one also to the cavalry and to each battery of artillery; then from each battalion, etc., are drawn thirty-two trained men, who retain their arms and can be otherwise used in emergency, whose business is to pick up and give first aid to the wounded and convey them to the field hospitals, which will be at convenient distances behind the brigades in some sheltered position. Behind each brigade are to be five field hospitals, each with one medical officer and accommodation for twenty-five men. These five field hospitals act as one, but are made sectional in order that the sections may be detached to follow any battalion that may be acting independently of the brigade. In all these there is accommodation for one hundred and twenty-five wounded in the field hospitals of each brigade. There is also a senior medical officer with each brigade. From the field hospitals the wounded are to be conveyed as soon as possible, after treatment, to barges moored off the river bank, where there will be accommodation for two hundred men. There will be other hospital accommodation on the river bank. At the Atbara, ample and special accommodation has been provided. A hospital has been built of mud bricks, with walls some three feet thick and a lofty roof, the wards being ceiled with matting and thickly thatched with Dhurra straw. It is probably as cool a place as there is in the Soudan. Here is accommodation for two hundred men, but on so generous a scale that if necessary another fifty or more could without any cramping be added to the inmates. Men reaching this hospital get proper hospital clothing and bedding, and have sheets to their beds. Six medical officers are in charge. There is another base hospital lower down the river, at Abadeah. Fifteen miles north of Berber is another big mud-brick hospital, with accommodation for three hundred men, who will be looked after by eight medical officers.—*London Daily News*, August 26th.

The World's Suicides.—The number of suicides throughout the world is said to be about one hundred and eighty thousand yearly. The greatest number happen in June, the fewest in September, and nearly one-half between 6 A.M. and noon.

Night for Growth.—A scientific writer says that night is the time which nature utilizes for the growth of plants and animals; children, too, grow more rapidly during the night. In the daytime the system is kept busy disposing of the waste consequent on activity, but while asleep the system is free to extend its operations beyond the mere replacing of worn-out particles; hence the rapid growth. This is why invalids need so much rest and sleep.

Mosquito Destroyers.—The natural enemy of the adult mosquito would appear to be the various species of dragon-flies, and there is evidence that a large flight of these insects, which are called in some parts of the United States "mosquito-hawks," is capable of

clearing localities of mosquitoes, even when the pest has been most severe; but the dragon fly, even if it could be used in large numbers, which does not appear to be possible, attacks the pest at too late a stage. Far more hopeful means of fighting mosquitoes are those directed to the abolition of its breeding-places or the destruction of the larvæ. It is true that measures of this kind are not everywhere feasible, but in many places there is no reason why the mosquito plague should not be at least very much diminished by the draining of ponds and marshes and the use of kerosene on the surface of the water.—*British Medical Journal.*

Faith Murder is Manslaughter.—A man and his wife, members of an English sect of faith curers called very appropriately "peculiar people," were held not long ago by a coroner's jury on a charge of manslaughter for neglecting to obtain medical advice in the case of one of their children, who died of bronchitis.

Health Reports.—The following statistics concerning small-pox, yellow fever, cholera, and plague have been received in the office of the supervising surgeon-general of the Marine Hospital service during the week ending October 8, 1898:

		Cases.	Deaths.
Small-Pox—United States.			
Alabama, Cedarville	August 1st to September 29th	50	
Michigan, Detroit	September 24th to October 1st	5	
Mississippi, Cooway	September 28th	3	
Small-Pox—Foreign.			
Belgium, Antwerp	September 3d to 10th	1	1
Ghent	September 10th to 17th	..	1
England, Southampton	September 10th to 17th	5	
India, Calcutta	August 20th to 27th	..	1
Madras	August 27th to September 2d	..	1
Japan, Awamori Ken	August 17th to September 11th	53	16
Russia, Moscow	September 3d to 10th	2	
Odessa	September 10th to 17th	3	
Warsaw	September 3d to 10th	10	
Yellow Fever—United States.			
Louisiana, Bowie	October 6th	1	
Delogny	October 6th	1	1
Franklin	To October 6th	375	7
Taylors	To October 6th	100	11
Orwood	To October 6th	79	4
Waterford	To October 6th	2	
Jackson	To October 6th	41	4
Oxford	To October 6th	52	6
Edwards	To October 6th	6	
Water Valley	To October 6th	10	
Harriston	To October 6th	142	4
Fayette	To October 6th	1	
Madison	To October 6th	3	1
Port Gibson	To October 6th	1	1
Woodville	To October 6th	1	
Clinton	To October 6th	1	
Starkville	To October 6th	3	
Hermanville	To October 6th	2	
Yellow Fever—Foreign.			
Mexico, Tampico	August 18th to 25th	..	12
Cholera.			
India, Calcutta	August 13th to 20th	..	1
Calcutta	August 20th to 27th	..	4
Madras	August 27th to September 2d	..	63
Japan, Tokyo Fu	August 17th to September 11th	7	4
Awamori Ken	August 17th to September 11th	1	
Fukushima Ken	August 17th to September 11th	3	2
Kanagawa Ken	August 17th to September 11th	4	3
Plague.			
India, Calcutta	August 20th to 27th	..	4

Books Received.

HOW TO AVOID TUBERCLE.

BY TUCKER WISE, M.D., L.R.C.P., M.R.C.S.,

MONTREUX, SWITZERLAND,

FORMERLY PHYSICIAN TO THE WESTERN GENERAL DISPENSARY, LONDON, AND INFIRMARY FOR CONSUMPTION, MARGARET STREET.

TUBERCULOSIS is by far the most destructive of all diseases to which the human race is subject, but if simple means for lessening its prevalence were made known widely throughout crowded communities, and became popular in the light of a social duty, there is no doubt that pulmonary consumption, and with it many forms of tubercle, would be rendered much less frequent among all classes of the population than is the case at the present day. Many persons will fall into a grave error if they think they are practically free from contracting the disease, provided their family descent shows a good record of health. Any one and every one is liable to be attacked at any period of life, and it becomes among civilized and educated nations a matter of the utmost importance for the population to make themselves personally acquainted with the means of maintaining a healthy condition of body to resist the disease.

From European statistics we may cite France, where the method of registration is more complete and exact than in England. It has been computed in that country that one out of every six deaths occurs from tubercle, and the pathological records of the morgue show that from forty to fifty per cent. of persons who live to middle age have tubercle in some form or other. In England the proportion, as near as can be judged, is that one person in every seven dies from the disease, and that about one-third of the whole population get it, more or less.

As the malady is not brought under the immediate notice and observation of private persons unless one of the family should be afflicted with it, the prevalence and importance of tubercle are completely underestimated. To illustrate how blind the general public becomes on such a matter, it may be mentioned that the French formerly termed it the "English disease" —probably forming the pseudonym from the illustration presented on the Riviera of English consumptives in search of health—little knowing that their own country, France, afforded an equal or perhaps higher percentage of the disease.

Much can be done on the part of the individual in avoiding tubercle; and even at the commencement of bacillary infection, when tubercles are being formed, personal hygiene and systematic treatment frequently result in permanent cure. Later on, when the streptococcus of pus accompanies the tubercle bacillus in the lung, it becomes a more serious and prolonged affair, but not then hopeless.

The personal directions for avoiding consumption and diminishing the tuberculous virus, are not of an impracticable, onerous nature, nor are the precautionary measures difficult to carry out; but if complied with as far as means and station in life permit, we may be assured that many healthy persons would be protected from the disease, and sick ones saved from reinfection.

Pulmonary tuberculosis or tubercles in the lung, commonly called in the later stages phthisis, decline, or consumption, arises:

(1) From living in an atmosphere containing putrefiable organic matter, such as that given off from the lungs and skin. These vapors, which contain epithelium and fatty particles, rapidly putrefy and become deleterious to health in furnishing a medium for the growth and preservation of various poisonous and dangerous micro-organisms, the most common being the bacilli of tubercle and the micrococci of pus.

(2) By a minute germ or microbe—the tubercle bacillus—entering the human body by the lungs or by the stomach, and occasionally by the skin, if the latter be diseased or injured. This micro-organism is found largely in the expectoration of infected persons; in house dust; in the flesh and milk of diseased animals, as well as in excrementitious matters thrown off by them—such as pus, mucus, dejections, etc.

Although tubercle in many instances cannot be regarded as an incurable disease, it is widespread throughout the world, and varies in intensity with the density of the population. It prevails chiefly among those who breathe and live in a close, tainted atmosphere, or who drink tuberculous milk, or eat food contaminated with bacilli. Overcrowded houses, narrow, ill-ventilated streets, and closely built towns show a high percentage of tubercle, and the disease attacks the lower animals as well as human beings.

Farmers, gardeners, fishermen, and farm laborers, all of whom are much in the open air, suffer least of all; but clerks, drapers, printers, and persons engaged in sedentary labor or dust-producing occupations fall victims to the disease in large numbers; also those in a higher station of life who breathe used-up, stale air, either in shop, bank, office, counting-house, or home. In the agricultural districts the mortality figure due to phthisis is less than half that of London, and the figure for respiratory diseases is still lower,[1] showing that the common feature in relation to the increase of the malady is vitiation of the air in which man lives.

The conditions of predisposition to contract tubercle are: Anæmia; malnutrition and debility (arising either from some acute illness, nervous depression, excesses, or bad habits of any kind, or from obscure causes); abrasions of the mucous membrane from frequent bronchial irritation or catarrh; injuries and open wounds; heredity—chiefly in the direction of weak, small, inactive lungs, or faults in tissue, glands, or blood (it is doubtful if the bacillus of Koch is transmitted from parent to offspring); imperfect chest formation (accidental, acquired, or hereditary); obstruction of the air passages from injuries, malformation, or disease; a weak, thin epithelium (either acquired or inherited), with an inability in the mucous membrane to resist invasion and penetration by microbes; tubercles in the lung are very apt to occur after measles, when there has been much shedding of the epithelial covering in the mucous tract, and also after whooping-cough; abscesses, decayed bone, enlarged glands which

[1] Lancet, January 22, 1898. Supplement to the annual report of the registrar-general.

become caseous, pleurisy, pneumonia, or carbuncles often precede tuberculous disease in the lung.

The two objects to be held in view in combating and avoiding the disease are (*a*) to cultivate invulnerability, (*b*) to destroy or suppress the bacillus. Plenty of fresh air and sunlight, good surface and subsoil drainage, nutritious food and proper clothing, dryness and cleanliness of dwellings, a steady life and judicious exercise—all contribute, as can be well understood, in establishing a healthy invulnerable condition of body toward tuberculosis.

The Dwelling.—If attainable, select a house facing south, with large windows, situated on a dry soil and in a slightly elevated airy position, but not wind swept. Damp, shut-in, ancient houses, with stale paperings remaining in layers on the walls, decayed woodwork, and dark cellars, are the very worst dwellings to inhabit, either in town or country. While close attention is usually bestowed on house drainage (and very rightly, too), the sanitary state of the basement of many houses is often neglected, and no account taken of the mouldiness which may be present, nor the accidental accumulations of fetid litter—as old packings and straw, waste paper, rags, cast-off clothes, lumber, and odds and ends, which often are forgotten and decompose for months in cupboard and cellar without being brought to light or knowledge. The effluvia from such decaying rubbish are aspirated by the warmth of the house into the atmosphere of the upper rooms, are absorbed by the aerial dust, and breathed unknowingly by the inmates.

Every cellar, cupboard, and dark room should be ventilated and kept fresh, as well as the space beneath the flooring of kitchen and basement rooms. Dark, inclosed, stagnant air teems with bacteria and leaks gradually into the house atmosphere. Simply sprinkling carbolic acid about only gives a sense of false security. No amount of any aerial disinfectant, of a strength that could possibly be respired, will touch bacilli or destroy their pestiferous properties as long as the cultivating conditions of stagnation, gloom, warmth, and dampness remain. It is only by airing, lighting, and cleansing dark corners that bacteria are kept down in numbers and their virulence is diminished.

In every house there is a varying amount of floating dust, composed of germs, epithelium, fungi, and débris from the friction of clothing, furniture, paper, carpets, curtains, etc.; specks of carbon from fires, gas, lamps, and candles. We have only to observe a beam of sunlight entering a room to perceive the myriads of microscopic particles which accumulate in the atmosphere we breathe indoors.

Ventilation.—The ordinary estimate of what the necessary purity and cleanliness of our breathing-atmosphere should be, falls far short of the proper standard. Many persons consider that, unless they detect offensive odors or oppressive heat in the house, the air is quite fit for respiration and no dangerous properties can be present. This is altogether a false notion, based on want of knowledge. A person may live or sleep in a room where the air has not been renewed sufficiently for health, and yet perceive no vitiation of the atmosphere whatever; as the olfactory sense gets dulled and insensitive by reason of the very gradual increase of impurity that takes place. On the other hand, the unhealthy effects of rebreathed air are too insidious and imperceptible to strike the attention.

The crude, open-window system for the renewal of air in occupied rooms, although an excellent and efficient plan of ventilation in warm, calm, and temperate weather, or in dry cold climates, has its disadvantages, and does not commend itself generally for adoption in winter time, except to persons who have trained themselves to open-air exposure.

In cold and windy weather ventilation of dwelling-rooms by tubes or open apertures is objectionable and liable to give chills; indeed, the majority of people will not have it at any cost. They prefer to take the risks of bad air. I have found, however, that in these cases a wire-gauze blind meets a great deal of the difficulty, and, provided the room has an open fireplace, it can be effectually ventilated without draughts and alternating currents of chilly air. The gauze blind fits into the window and is hooked to the frame. It can be removed for cleaning or renewing the gauze when choked or worn out. The window sash is opened a few inches, according to the outside temperature or direction of the wind. The homely muslin window blind is a substitute either for wire gauze or coarse bunting, if economy is desired, provided the material be affixed to the window frame and not to the sash itself. In this way the sash can be raised, while the muslin keeps out the coarser dust and blacks, and admits the air from outside, but not nearly so freely or effectually as wire gauze.

To get rid of the imperceptible cloud of dust which accumulates in all rooms, admit the air and light through open windows to every part of the house daily for at least an hour, longer if convenient, and insure continuous ventilation of dwelling-rooms, bedrooms, and nurseries, night as well as day, by means of the wire-gauze blind and partially open window, commencing with an inch and gradually increasing the opening to six inches or more, according to circumstances.

All nurseries and bedrooms occupied by delicate persons should have large windows and a southern or southeastern aspect if possible.

Churches, schools, classrooms, lecture halls, large dormitories, courts of justice, theatres, and crowded rooms of every sort require artificial ventilation and frequent cleansing. A musty odor indicates the presence of putrescent organic matter.

Furniture.—Thick, heavy curtains, stuffed furniture of velvet pile, rep, cretonne, etc., carpets which cover the whole extent of the floor, are fertile sources of dust. Dark papering in a room absorbs the light which would otherwise be reflected on to the inmates.

Curtains should be made of a washing-material light in color. Carpets, if fitted to cover only the central area of the floor, can be more readily taken up and broomed in the open air and sunlight.

Dusting.—All dust should be carefully removed with damp dusters, and not be flicked off the cornices, furniture, and ornaments with a feather brush or dry duster, to be set floating in the atmosphere until most of it settles again. The ordinary "dusting" process and "brushing the carpet" are most objectionable and unhealthy proceedings, unless there is a strong current of air to carry the floating aerial particles out of the windows free from the house; even in that case it is an unwholesome occupation for the servant. Sprinkle the carpet with wet tea leaves, insure a thorough draught, and use an American carpet sweeper.

Breathing.—Learn to breathe habitually through the nose and not by the mouth. Children ought to be taught this habit when they are young. The nasal passages act as a filter for the inhaled air. Much atmospheric impurity and even disease germs, which would otherwise enter the throat and lungs, then get arrested and expelled in the nasal mucus. Hold the body erect and avoid constrained positions of the chest, or a habit of shallow, listless breathing when at rest. Take a long-drawn sigh at intervals, to expand and contract the lungs, and so preserve chest elasticity and capacity.

Clothing.—Full, deep breathing is promoted by wearing easy-fitting clothing, which should be of porous, light, but warm texture, especially loose about the waist and lower ribs, that the diaphragm may not be impeded in its action. Woollen underclothing and

flannel nightdresses or pajamas are healthful. Close-fitting waistcoats, tight trouser bands, tight sleeves under the armpits, corsets, low-necked dresses, and thick veils are bad.

Let children be dressed equably, not layer on layer of clothing over the chest while they go barelegged. By too much coddling, overclothing, and inordinate fear of air and draughts, and confinement indoors, a delicacy and tenderness of the epithelial covering of the skin and respiratory passages are engendered. Susceptibility to tubercle may arise in consequence of this. The epithelial scales have under these circumstances missed the healthy stimulus to proper growth given them by cool fresh air and ozone.

Exercise.—No definite amount of physical exertion can be named to suit all alike, as each individual has his own capacity; but exercise in the open air and walking up hill should not be shirked by any one in health. Town dwellers ought to get out beyond the town limits at least once a week, to breathe the air of the country and obtain sunshine. Children should be encouraged to move about when out of doors, and not be dressed up in stiff clothing that might impede the free motion of their chests and limbs or curtail the desire to play.

Diet.—It is not expedient in the present paper to enter into the question of dietaries or the various contradictory theories and fads relating to food. One point is plainly impressive, viz., that the carnivora suffer but little from tubercle except under extreme conditions of confinement, but most herbivorous and granivorous animals are very susceptible to the disease and contract it largely. The inference to be drawn from this is that nitrogenous diet—flesh, etc.—produces a state of nutrition less favorable to attacks of tubercle than a non-nitrogenous dietary consisting mostly of an excess of starch in some form or other.

There is no doubt that many young persons (especially girls between the ages of ten and twenty) eat largely of sweets, pastry, cakes, biscuits, and buns, to the exclusion of nutritious animal food. Their appetites are impaired for the regular meals, and they get improperly nourished and fall into a debilitated, anæmic condition, inviting tubercle. In the present age man is designed, by the formation of his teeth, stomach, intestines, and the quantity of gastric juice secreted (from eight to ten pints in the twenty-four hours), to eat a fair quantity of animal food—and he has done so, with few exceptions, from time immemorial, and will always do so. It is the most concentrated nourishment he can obtain to supply the nitrogen which is essential to life. Therefore beef, mutton, poultry, game, fish, eggs, and milk—all properly cooked—ought to be consumed in moderate quantities to build up the muscular tissue; starchy foods, as oatmeal porridge, macaroni, semolina, rice, tapioca, bread, potatoes, peas, beans, etc., butter, and fats, for the production of animal heat and formation of bone and adipose tissue; fresh vegetables and ripe fruits for the salts and acids they contain, which are essential to maintain the purity of the blood.

Fluids.—About three pints of fluid is an average quantity for an adult person each day, either in the form of tea, coffee, milk, etc., ale, wine, or water; and the habit should be cultivated of taking this chiefly toward the end of a meal or even after the meal is finished, that the acidity of the gastric secretions may not be weakened before digestion has begun. Spirits, unless well diluted, are bad for any one, except taken under medical advice. Children may be allowed pure water to drink from time to time, if thirsty; and the habit of taking a morning cold bath should be gradually acquired and continued throughout the active part of life.

The Principal Sources of Direct Infection and how to Avoid it.—The designation, "infectious disease," which is now applied to tuberculosis, tends to impress the public mind with an apprehension that in personal contact with the sick the disease may be "caught" in the same way as other infections. If this exaggerated idea gained extension, the lives of many harmless sufferers would be rendered unendurable without advantage to any one.

Alarm on the subject of infection from person to person may be considerably modified by the knowledge that the bacillus of tubercle is not very tenacious of life when outside the body. Unless it has organic impurities to feed on, its virulence is soon destroyed by sunlight and fresh air; and, lastly, actual transference of bacilli to the individual must take place either through the medium of the air breathed or food consumed. Neither the breath nor perspiration of a sick person has been found to convey the disease. The real dangers of direct infection are the following, and the precautions necessary for meeting them are described in the ensuing paragraphs.

(1) From dried expectoration containing tubercle bacilli, which has disintegrated or become pulverized into fine floating particles.

(2) From the flesh and milk of diseased animals, especially the cow. Milk is by far the most important and dangerous.

(3) From excrementitious matters thrown off by diseased house pets, as cage birds, tame rabbits, dogs, and cats.

The actual scare at this moment with a section of the public has regard almost solely to domiciliary contact with consumptive persons. Comparatively little heed is given to the dangers lurking within the house itself, irrespective of infected persons who may, by cleanly habits, be quite innocuous to others. Accumulations of dust, want of air and light, have already been mentioned; but dirty food, animals or birds affected with tubercle, if kept within doors, may become dangerous foci of disease.

Expectoration.—The treatment of expectoration and discharges requires the most careful attention and scrupulous cleanliness. Expectorated matter and pus from wounds must not be allowed to soil the clothing, bedding, walls, carpets, mats, floor, or any part of the house. A spit cup or flask, specially made for the purpose, must be used with some fluid disinfectant, such as carbolic acid, to keep the flies off. The patient should expectorate into this or into a slop vase containing water, so that the contents may be thrown down the water closet.

By dried expectoration, when the bacilli are virulent, tuberculous pulmonary disease not only may be eminently infectious to others, but also may reinfect the patient himself who happens to inhale or swallow particles of it, such as arise from soiled handkerchiefs, pillow cases, carpets, etc., and also from the moustache or beard. For occasions of emergency, cheap handkerchiefs or squares of linen may be used; but they must be burnt soon after use before the expectoration gets dry, and not be sent to the wash. The storing and sorting of such soiled linen can pollute the air.

It may be considered vulgar to spit, even into a handkerchief, but it is far worse to swallow expectoration when coughed up into the mouth. Never do this, or the bowels may become infected. There is some risk, too, that small portions of tenacious sticky mucus might, during the act of swallowing, enter the Eustachian canal in the throat and cause serious trouble to the internal ear.

On no pretext or excuse should any one spit about the house, or in railway carriages, cabs, etc. As it is impossible to prevent spitting out of doors generally, let every one overcome by necessity expectorate in the

roadway or gutter, where the light and air will kill the germs; not on the pavement, where ladies' dresses sweep up the dirt and carry bacteria home to their wardrobes.

No one should kiss a consumptive person on the lips, nor use the same drinking-utensils, forks, and spoons, unless they have been properly washed in boiling water.

A man who has a chronic cough with expectoration ought to shave the beard and upper lip. In such cases it is a cleanly proceeding, if nothing else.

Clean spittoons ought to be in more frequent use than they are, especially in hotels, theatres, and public halls, clubs, offices, schools, etc.

Wash any cups, vessels, flasks, or objects contaminated by sputum, in boiling water. Heat at boiling-point kills infection.

Clear the house of mice, that they may not contaminate food.

If circumstances do not admit of a person affected with tubercle occupying a separate bedroom, let a large airy room be selected, with separate beds; the window should be kept partially open day and night, the room scrubbed out once a fortnight, and the ceiling and walls cleaned and colored yearly.

It is desirable that patients should learn to sleep on the affected side, if painless, in order to keep the lung at rest as much as possible, and prevent the secretions draining into the sound lung.

Before occupation of a room previously inhabited by a consumptive during an illness, precautionary measures should be undertaken thoroughly to purify and disinfect the room, by leaving the windows open, scrubbing with hot water and carbolic soap, recoloring the ceiling, and washing or varnishing the wallpaper and woodwork. The furniture, bed, and bedding should be exposed for some days to the sun in the open air, unless treated with superheated steam.

Milk.—Cows' milk, especially in towns, ought always to be sterilized by heat a short time previous to use. This is better done in a double saucepan, as the flavor of milk is impaired by direct boiling. It is not enough that milk be boiled and then stored in the pantry, cupboard, or dairy, as it can be recontaminated by atmospheric dust. Milk cultivates bacilli readily, and many diseases are conveyed by it—as typhoid and scarlet fever, diarrhœa in children, diphtheria, and tuberculosis to an enormous extent among infants and young children. If pure milk can be obtained direct from a healthy cow—that is, an animal free from tuberculous disease—the nutritive value of this fresh unstored milk will be found superior to that of any boiled or preserved milk; as it is a more natural product and will contain organic glandular extracts, which in the case of sterilized milk have been impaired or destroyed by heat.

Storage of Food.—The provision made by nature in the digestive tract against bacillary poisons when swallowed with food is generally effectual in protecting the body; but there is a large number of children and young persons who are vulnerable or become so incidentally, either from enfeeblement of the acid digestive secretions, or from repeated and constant injection of bacilli, or from a weakened and abraded mucous membrane. The cleanliness of food, therefore, demands every precaution. Care in this respect with regard to milk, cream, cheese, butter, cold meats, jellies, pastry, and confectionery, seems to be utterly neglected in many instances when undoubtedly polluted air can introduce micro-organisms on these substances, which prove excellent mediums for cultivating bacilli or maintaining their virulence. We have only to inspect with the naked eye the objectionable methods adopted by confectioners, bakers, cookshops, restaurants, and railway stations, in the temporary preservation of eatables, to observe that cold food is exposed to large accumulations of atmospheric filth; and there is no doubt that tubercle bacilli are frequently deposited on such food without being rendered inert by the cooking-process, as would be the case if the food were hot. Flies may convey the disease from expectoration to food, or from ulcerated wounds and excrement of domestic animals or cage birds.

Cooking.—As tuberculosis occurs among cattle and poultry, the flesh of these should be well cooked. Heat destroys the dangerous properties of stray germs.

Household Pets.—There are other animals besides the bovine race prone to tubercle, which come in close contact with man and even live under the same roof with him. Placed under such unnatural conditions of life as are entailed by confinement indoors, they frequently get diseased; and, although absolute proof is incomplete, there is a strong suspicion that diseased cage birds communicate tuberculosis to a serious extent among human beings. From cases that have come under my own observation and investigation, I am of opinion that they are a fruitful though unsuspected source of tubercle in many a household. As about four hundred thousand canaries are said to be imported yearly into this country, the distribution of tubercle by this bird alone, when disease attacks it, must be considerable. Animals that come in contact with man are:

Bovines, tuberculosis frequent.

Pigs, tænia common; tuberculosis occasional.

Rats, susceptible to cancer; tubercle rare.

Mice, occasionally tuberculous.

Rabbits, guinea-pigs, highly sensitive to tubercle.

Dogs, tænia common; cancer and tubercle occasional.

Cats, sensitive to diphtheria; tubercle more frequent than in the dog.

Horse, donkey, sheep, goat, rarely affected with tubercle.

Fowls, pigeons, doves, canaries, parrots, all cage birds, tuberculosis (chiefly intestinal) a common disease.

Tuberculous disease begins in such an insidious manner that it cannot be discovered with facility in the lower animals. A pet canary or parrot may distribute bacilli right and left for months without arousing suspicion. The same danger, lessened in degree, exists in respect to fowl roosts adjoining a house, to tame rabbits and guinea-pigs. In fact, a household is safer in regard to health without any of these pets, except, perhaps, the cat and dog properly fed and looked after, and in case of suspected illness sent off at once to the veterinary surgeon.

No infected person with expectoration ought to marry, nor should consumptive domestics be employed in the house. No consumptive mother should suckle an infant or have it to sleep with her.

Sores, boils, carbuncles, skin eruptions, children's teeth, enlarged glands, blocked nasal passages, should all be carefully attended to, especially in the young.

Persons who have been once attacked by tubercle must lead a careful life after recovery, avoiding late hours, crowded assemblies, close rooms, irregular meals, and fatigue or excesses of any kind. If an outdoor occupation can be selected, so much the better. In any case, the preceding rules relating to diet, clothing, and hygiene must be carefully observed.

To maintain health and ward off a recurrence of the malady, the following vital points may be summarized to impress them upon the attention: (1) A generous dietary of nitrogenous food. (2) Free ventilation of dwelling and sleeping rooms by open windows with wire-gauze blind. (3) Adequate house heating in winter. (4) Boil all milk or cream previous to use. (5) Try and obtain eight hours' sleep every night; if

not sound sleep, contract the hours to seven and rest in the day. (6) If debilitated with weak digestion, take rest in the recumbent position a quarter of an hour before and after meals. (7) Wear the loosest clothing possible, especially around the waist and lower ribs, to afford absolute freedom in respiration. (8) Take systematic daily exercise in the open air on foot. (9) If means and station in life admit of a long holiday from time to time, live during fine weather in a tent in the open air or in a summer house for most of the day; and, if unemployed, pursue a hobby to occupy the mind.

September, 1898.

IMPRESSIONS AND CONCLUSIONS BASED UPON A STUDY OF FIVE THOUSAND CASES OF SKIN DISEASE TREATED DURING THE YEAR.[1]

By CHARLES WARRENNE ALLEN, M.D.,

NEW YORK,

ATTENDING SURGEON (DEPARTMENT OF THE SKIN), GOOD SAMARITAN DISPENSARY.

GENTLEMEN: Having been notified by the chairman of your committee on statistics that my report for the year had been received by him at too late a date for incorporation in the annual report, I decided that, instead of presenting a paper of a different nature for this meeting, I would make, as it were, a minority report of my personal statistics, and give certain impressions which the study of the cases has made upon me.

The diseases giving over one per cent. of the total number and showing the largest number of cases are, in the order of greatest frequency, as follows: Eczema (including all varieties), 985; impetigo contagiosa, 444; pediculosis capillitii, 365; vaccinia, 331; dermatitis "pediculosa," 210; urticaria, 170; scabies, 164; dermatitis (traumatica), 142; acne, 141; favus, 139; intertrigo and intertrigal eczema, 127; tinea circinata, 124; tinea tonsurans, 92; furuncle, 97; syphiloderma, 84; dermatitis calorica (including burns), 75; erysipelas, 72; abscess, 70; verruca, 67; pediculosis corporis, 59; pruritus, 58; psoriasis, 58; erythema multiforme, 54.

Statistics must, of necessity, be somewhat misleading, though I recognize their importance and the value which this society's work has been to us all. We should not lose sight of the fact that many cases are counted over again, some perhaps several times, in making up the society's yearly statistics. No class of patients more than ours runs about from one institution to another, and from one physician's office to another, and naturally they become registered during the course of the year by more than one member. Take, for example, the single instance of favus. Out of my one hundred and thirty-nine cases—an unprecedented number for this country—I can point to but two supposed cures, and, with the exception of perhaps a dozen at the present time under treatment, all the patients have disappeared from observation. Many have entered institutions such as the Randall's Island hospital, from which institution they may figure in the returns from other members. Many children allow the hair to grow after a very inadequate course of treatment and enter private schools. Their exclusion from the public schools is chiefly responsible for the unusual number falling under my observation. Almost all had brought the disease to this country from Europe; a few gave a history of its having developed here. One at least passed the quarantine officers after the law excluding favus went into effect. I have advocated the establishment of a favus school for these children, to keep them apart and under treatment. The best results in treatment have come from close cutting of the hair, epilation, chrysarobin applications alternating with ammoniated mercury ointment; occasionally formalin in solution or ointment. In instances of scattered small areas involving the scalp, perhaps only about a single hair follicle, the diagnosis may be made by finding beneath the crusts, which are not at all characteristic, a minute yellow granule, which when picked out of the depression in the reddened skin and spread upon a slide is found to be a mass of mycelium and spores in a state of pure culture.

Acne varioliformis gave nine instances; two were quite aggravated, causing a disfiguring redness of the face and leaving deforming cicatrices. Unguentum hydrargyri ammoniati is the remedy *par excellence*, but new outcroppings must be watched for and aborted by timely use of the remedy. In one instance it occurred as a unilateral affection. In a girl of seventeen years there was a history of its having existed from early childhood, in association with necrotic lesions on the hands and pernio.

Alopecia areata gave nineteen instances, one beginning as small areas of baldness gradually coalescing and becoming generalized, until to-day scarcely a hair is to be found upon the whole body's surface. Several instances were associated with seborrhœal dermatitis. In several adults groups of large bald areas, clinically corresponding to this affection, were studded over with broken-off hairs, most suggestive of tinea tonsurans, but careful search failed to show any fungus. Culture experiments were also negative. Formalin solutions, used even up to the full forty-per-cent. solution strength, acted well in several instances.

Dermatitis venenata was treated thirty-seven times. One instance involved nearly the entire body, and was followed by a severe attack of acute nephritis with marked general anasarca. Recovery under hospital care.

Dermatitis pediculosa was the term under which was recorded a large number of patients, chiefly children, whose scalp, neck, back, and sometimes the face or other parts were the seat of irritation due to pediculi capitis, and in which the extent and degree of skin involvement seemed to call for something more than the simple diagnosis of pediculosis capitis.

Erysipelas.—I have on two previous occasions endeavored to interest this society in questions relating to erysipelas. My statistics were then drawn from family and hospital practice and dealt with a more severe type. The seventy-two patients here included, with the exception of a few children, all presented the facial type. All recovered, so far as I am aware, usually within from forty-eight to seventy-two hours. There is only one point I now wish to make, but I believe it a most important one. Scarcely one of these subjects failed to give a history or evidence of preceding nasal affection, and the skin manifestations almost always began upon the side on which the nostril was involved. Every patient was treated by thorough intranasal swabbing, upon both sides, with a fifty-per-cent. watery solution of ichthyol. Ichthyol collodion was applied over the skin. In some instances the adhesive band was applied about the forehead. In scarcely a case did the scalp become involved, and then not extensively. Pseudo-erysipelas, as the term is here employed, is meant to designate an inflammatory condition of the arm following vaccination, of which thirteen instances were recorded. Extension of the process does not reach beyond the elbow or above the arm, as a rule. There is roughness of the skin rather than the smooth surfaced erythema of erysipelas before vesiculation occurs. In other respects the process is clinically much the same

[1] Read before the American Dermatological Association, June 1, 1898

as that of true erysipelas. True erysipelas not infrequently follows vaccination, as shown in a number of instances in this collection.

Erythema multiforme, seen mostly in children (fifty-four patients), showed, in all instances in which the temperature was taken, fever ranging from 100° to 101.5° F. (a symptom not always noted in the books). Aside from the erythemas prodromal to the exanthemata there is a large class, in all probability of infectious origin and associated with digestive defects, which latter alone need correction by intestinal antiseptics to cause the rash to disappear. The joint and muscular pains often present, as well as fever and other subjective symptoms, point to an infectious origin for many instances. Its occurrence as an occasional sequela of vaccination points in the same direction.

Erythema Nodosum.—From a clinical standpoint this should not be included as a form of erythema multiforme. It seems to stand by itself. So many of the ten patients seen have been young adults or children who have but recently landed from emigrant vessels, that I have come to look upon the hardships of a steerage voyage as having some causative influence. The temperature is at times as high as 104.5° F., remaining at 104° F. or but little below this point for several days, despite energetic use of salicylates, which is the best treatment I know of. There is not uncommonly a history of articular pain in one or more joints, antedating the eruptive lesions by a week or less. I believe it to be an infectious process closely allied to rheumatism.

Zoster.—In the forty-one cases there were few presenting special interest. The youngest subject was two and one-half years, while the youngest given by Cantrell in his statistics (*The Philadelphia Medical Journal*, March 26, 1898) was three years. In almost all cases the lesions were varnished with a three-percent. methylene blue in collodion. Even in the aged with considerable pain the lesions dried up rather promptly under this local treatment and the pain disappeared. The statement has recently been made that zoster should cause a suspicion of the presence of phthisis. This I could not verify in a single instance.

Impetigo, to judge from this year's experience, almost always has pediculosis capitis as an etiological starting-point.

Intertrigo in infancy, whether associated with seborrhœal eczema of the scalp, originating in irritating dejections, or assuming the form and outline of eczema marginatum and suggesting a mycotic process, disappeared more rapidly under methlyene-blue solution than any other single remedy I have ever employed. Many instances showed superficial ulcerations in the groin, folds of the neck, or elsewhere, and under the blue solution these, too, always did well. An interesting instance of disseminated tinea circinata in the region of the groins raises a point of differential diagnosis.

Folliculitis abscedens was the diagnosis in twenty cases. The subjects were all young children or infants at the breast, and the affection occurred mostly during the heat of summer in connection with miliaria. The scalp, face, and neck were mostly involved in some, while in others the region of the buttocks and thighs was more largely implicated. Some lesions attain enormous proportions, but it is found that these patients do better under medical treatment and local applications than when subjected to surgical measures. Indeed, in one case referred to the surgeon, in which the lesions were opened and dressed under the most approved antiseptic methods, fatal erysipelas developed. All other cases recovered, so far as my records go.

Lupus Erythematosus.—One of the four instances treated was cured by electrolysis. The lesion consisted of a single patch, involving one side of the nose in a woman.

Molluscum epitheliale gave twenty-four instances. In our last report there were ten, and in the combined statistics but nine and one-half per five thousand. One of the growths upon the cheek of a young girl was the size of a hickory nut, and the surrounding infiltration caused it to look but little like the clinical picture of this affection.

Morbilli.—This diagnosis was entered but once, for the reason that the affection is not treated in the skin class. I would like, however, to state that in many cases examined in the pre-eruptive stage I was enabled to verify Koplik's sign, which, I think, is one of great value, not only in detecting measles at an early period but in differentiating from rubella and morbilliform erythemas. In one instance I was struck with the marked inflammatory change which had suddenly occurred in the eruption of papular eczema (lichen simplex type), which had been under treatment for some days. On taking the temperature it was found to be 105° F. The catarrhal symptoms were slight and there were no eruption of measles and none of the usual clinical signs upon which the diagnosis could be established. An inspection of the buccal membrane, however, removed all doubt by the discovery of minute pearly points upon a red base.

Pediculosis "pubis" of the eyelids in children was treated in four instances.

Pityriasis Maculata et Circinata (Rosea).—Thirteen instances. These cases uniformly show a temperature extending in its range from 100° to 104.5° F. At times the eruption is intensely itchy and becomes highly inflammatory. One was followed by very extensive desquamation in rather large but thin flakes. The face is often involved. In one instance it occurred in secondary syphilis, making an interesting differential study. The affection is probably more often mistaken for syphilis than for anything else, and some instances surely suggest the combined large macular with the small or miliary, papular, secondary rash, but the grouping of the latter is lacking and the characteristic central desquamation and peripheral extension of the lesions of the pityriasis rosea remove any doubt. One instance was in a child of four years.

Psoriasis.—Fifty-eight cases. Anthrarobin and chrysarobin ointments and combinations with collodion were almost wholly relied upon for external application. A number of patients relieved of the eruption in the early part of the year turned up again with renewed outbreak toward its close. Iodothyrin was given an extended trial in about twenty instances, but without results which would lead me heartily to advocate its employment, unless possibly in obese subjects.

Prurigo is worthy of note from the fact that no less than fifteen instances were recorded. They occurred mostly in children, some of whom had been but a short time in this country, but all giving a history of the affection's existence from very early life. A question mark should be placed after about five of these, as not having been sufficiently long observed to establish a positive diagnosis, or as being in the first stages of persistent or recurrent urticaria, pruritus, and thickening before papulation. There were, as I remember it, but two adolescents in the number. Prurigo mitis was recorded twice. One presented the appearance of persistent or chronic cutis anserina or nutmeg-grater condition of the entire surface, along with urticarial wheals and papules.

Scabies.—One hundred and sixty-four cases. For the past four months I have employed Dr. Sherwell's favorite remedy, consisting of dry powdered sulphur, and I must say that the results have been excellent. The pruritus is more quickly arrested by it, I believe, than by other means usually employed, and, if faith-

fully persisted in, it effects a cure within a comparatively short time.

Syphilis gave but eighty-four instances, for the reason that cases are also treated in other departments of the institution. I believe that under the intramuscular-injection method better results are obtained than by the older plans. It is only exceptionally that men object, though many women absented themselves from the clinic after the initial injection, which, by the way, is usually the one to give the most inconvenience.

Tinea circinata, or ringworm of the body, gave one hundred and twenty-four instances, or fifteen less than the number of favus cases. During the first half of the year I employed chrysarobin dissolved in ichthyol and water, which worked well, but more recently I have applied a strong solution of formalin, which acts still more promptly, but must be used with some care to prevent irritation of the skin, and is open to the objection of giving decided pain. It should, as a rule, be applied by the physician himself.

Tinea tonsurans gave but ninety-two instances. Some were interesting from the fact that in the same family several distinct clinical forms of trichophyton disease existed at the same time. Thus in one group of three children one sister presented the bald or alopecia-areata form of ringworm of the scalp, a second sister showed a single acute ring of tinea circinata upon the face, and the brother, who was the first to be affected and the last to recover, presented upon the wrist and back of one hand rings of vesico-pustules. He also had disseminated ringworm of the scalp in small areas and disseminated scaly plaques upon the ears, neck, and upper half of the trunk. The coexistence of the typical round, dry, scaly, furfuraceous plaques on the scalp, studded with broken-off hairs, with either rings or irregular scaly patches on the skin surface, has not been uncommon, pointing to an identity of fungus for both clinical forms.

Tinea Versicolor.—In the forty-seven cases observed, several points have impressed me: (1) That a large proportion of the subjects were young women, many of whom came from Austria; the proportion of Austrians to Poles treated at the institution being very small. (2) That many gave a history of recurrence after apparent cure. (3) That several had lesions extending upon the neck and even to the sides of the cheek over the lower jaw. One had a patch upon the brow. (4) That tincture of iodine or Lugol's solution brings out the fainter and at times almost imperceptible lesions by staining them a deep mahogany color, which contrasts markedly with the staining of the adjacent normal skin. (5) That in a certain rather large proportion of instances, especially in women, a patch hidden by the hairs of the pubic region escapes observation and treatment, and that recurrence is often due to this fact. (6) That treatment must be persevered in after the surface appears free from lesions, because the origin of each separate round plaque is perifollicular and perhaps intrafollicular, and unless remedies are employed which penetrate, or are employed in such a way that they are made to enter the follicular openings of the skin, new punctate lesions will be seen to arise about the follicular openings.

Vaccinia deserves a passing word in explanation of the large number of over three hundred instances recorded, from the fact that such cases are not generally so frequent in skin classes, although much interest attaches itself to the generalized eruptions and sequelæ. The majority were what might be designated "bad arms," *i.e.*, deep indolent ulcerations, many with surrounding infiltration, crateriform, chancriform ulcers, etc. Some lesions presented more the features of inoculated variola than those of vaccinia, with development of vesicles upon the arm at a distance from the point of inoculation. In several instances there was secondary accidental inoculation by scratching. Twice typical vaccinia was implanted upon a post-auricular eczema and ran the same course as upon the arm.

Among the generalized eruptions:

Roseola vaccinica or erythema was observed a number of times. The papular form was also common (a week or thereabouts after inoculation). The most interesting was the vesicular. Some instances were diffuse, some grouped, and lesions occurred also on the mucous membrane of the mouth and tongue, but not in groups of two or three vesicles as in varicella.

Many lesions were papulo-vesicular, a vesicle developing upon the apex or in the centre of a flat maculo-papule, the borders of the latter taking on a shiny or waxy raised border unlike anything seen in varicella. This central vesiculation rapidly flattens, desiccates, and subsequently desquamates. Some instances I put down as of varicella type, so closely did the lesions simulate chicken-pox. They developed about the twelfth day, and usually showed no coincident lesions in the mouth.

As sequelæ, as well as before local vesiculation had occurred, I found urticaria and erythema multiforme quite frequently present. Generalized scarlatiniform erythema was not very commonly observed. Erysipelas developed upon the arm after vaccination (sometimes as late as the fifth or sixth week) in a number of instances attributable to secondary or subsequent infection. Pseudo-erysipelas, already mentioned, an extending erythema of limited degree, was quite frequent.

Impetigo contagiosa was rather infrequent. I show a photograph of two instances of persistent impetigo at the site of the vaccination long after all trace of the vaccinia proper had disappeared.

Pemphigoid lesions were noted in several instances. Large bullæ were presant upon the feet, hands, back, chest wall, etc.; some with clear contents, others purulent.

Keloidal scars, even of mild degree, were rarely seen to follow even the deepest ulcers.

Verruca.—Warts are auto-inoculable, and hence hetero-inoculable. Of the sixty-five patients treated, several were of members of the same family. The history was frequently given of one (the largest) "seed wart" coming first and others developing afterward, and that a second child showed the growths subsequently to the one presenting the parent wart. This is the same history as is usual in molluscum contagiosum. The contagiousness is seemingly proven by the fact that once wholly removed, other new warts do not continue to develop. Interesting instances were those in which a little girl with abundant warts upon the hands and wrists showed a group of fifty lesions surrounding the right eye, with none upon the opposite side; a young man with forty upon one palm; a young girl with the hands covered (several of "seed" variety), and about twenty on the inside of the mouth (buccal membrane). Most efficacious preparations for local application were found to be: acetic acid, 1; sulphur, 2; glycerin, 3; or salicylic acid with acetic acid and cannabis indica in collodion. Trichloracetic acid was also used with good effect.

Among rare cases may be mentioned two of psorospermosis and one of rhinoscleroma.

612 East Sixtieth Street.

Fibroid Tumors.—I wish once more to express the opinion that the next advance in the treatment of fibroid tumors will be the general adoption of early operation and the more general substitution of myomectomy for hysterectomy, as being the most conservative treatment of these growths.—Charles P. Noble.

THE MEDICAL ASPECTS OF CAMP MANAGEMENT AT CHICKAMAUGA.[1]

By H. A. HAUBOLD, M.D.,

ASSISTANT SURGEON, EIGHTH REGIMENT, NEW YORK VOLUNTEERS; VISITING SURGEON, HARLEM HOSPITAL, NEW YORK.

Much can be said of Chickamauga Park, much has been said that is true, and much, very much more that is untrue. A little of what is true I shall try to say to-night.

It is quite impossible to exclude from a subject of this sort all references to its military side. Medical men, even those in the army, are notoriously ignorant of the military necessities of a campaign against the enemy, and it would seem well that this is so. The care and treatment of the sick and injured and advice to the commanding officers on sanitary questions are their allotted field. Mark the word "advice." The medical officer is in no way and at no time directly responsible for the sanitary condition of an encampment. He simply advises the commanding officer, and that individual is the responsible person.

I repeat, "And it is well that this is so." Medical officers have the singular and unwarranted desire to help and render easier the lot that has befallen the poor devils that come under their observation. It is also a peculiarity on the part of commanding officers to be devoid to a considerable extent of this desire, and, therefore, it is well for the surgeon to be ignorant of military necessities. It eases his conscience. So if I should make use of any harsh phrases, if what I say should reflect discredit upon the heads of any department in the army, it must be accredited to my own ignorance of military necessities. I am still an officer in the volunteer army. Somewhere in the rules and regulations governing this body it is made an offence, I believe, of some gravity, to offer criticism of your superior in bars, or leaves, or eagles, or stars, or what not. Still I entered the volunteer service preeminently as a medical man. With myself the occurrences that came under my observation have left impression only as regards the lessons I learned as such. It is these that I shall offer you, interspersed with some deviations, the perhaps inevitable accompaniment of the more or less emotional if not dramatic impulses that always escort everything pertaining to war.

Imagine, if you can, scant woodland, no underbrush, no shrubbery, some open fields, grassless, dust covered, sun baked; a mud-stained shallow creek, and its equally mud-stained shallower tributaries—and this is Chickamauga Park, the domicile of more than forty thousand men for several months. Camp Thomas, Chickamauga Park, Ga., is reached from Chattanooga, Tenn., over an intervening distance of about eleven miles, by means of a single-track, so-called rapid-transit railroad. Over this all troops, cavalry, artillery, and infantry, all rations, supplies, and ordnance were transported. The journey itself is picturesque enough. The trains take their way through a valley, on the one side of which the famous Lookout Mountain towers, from whose summit the Confederate commanders flashed signals into seven States during the war of the rebellion; and on the other lies Missionary Ridge, where the late General Grant had his headquarters at that time.

Still this does not compensate for the inadequacy of the railroad accommodations. It is the deficiency in this particular that was no doubt responsible for the much-talked-of delay in delivery of necessary supplies.

My regiment, the eighth infantry, New York volunteers, reached Chickamauga Park on May 24, 1898. What I am enabled to relate dates from that time. For reasons that will appear later, it is of importance to state that the park had been occupied by troops of the regular army for some time (several weeks) before the volunteers arrived.

As to the further description of the camp (I have already described its general appearance), Chickamauga Park is in the northern part of Georgia, five or six miles south of the Tennessee border line. The soil consists of clay chiefly. There is much surface rock. Indeed, for the greater part of the space that came under my observation, it was impossible to dig trenches more than three or four feet in depth for the receipt of fæces. This made the digging of new sinks necessary every few days, and, as the surface space allotted to each regiment was small, it ultimately became a serious question as to where they were to be dug. This question is always a difficult one to solve in an encampment that is older than two or three weeks. They should not be dug too near the tent ground; still many soldiers are afflicted with intestinal disorders that make frequent visits to the sinks necessary at night; and when the goal that the poor fellow is trying to reach when he has a violent pain in his abdomen is too far off he is apt to stop by the wayside. It is easy to see the menace to health under these conditions. Remedy—move the camp before it gets beyond three weeks old.

Again, the rocky nature of the substrata made absorption or percolation of the contents of the sinks into the earth impossible, and when the first violent rainstorm occurred the newly closed fæces basins were washed out by the water. No rain fell for weeks, and during this period of time the thin layers of earth superimposed upon the rock became dry and powdered, to such an extent, indeed, that tent pegs were made to hold with difficulty, and it was not uncommon to have tents fall as a result of their pulling out. Much of the surface of the park was what is called dry creek, *i.e.*, gullies in the rock. In the intervals between rain storms these were perfectly dry, but when the rain fell they became filled with rushing torrents of water, several feet in depth, and indeed in some situations were quite impassable. It is easy to see from this that the contents of the shallow sink trenches were washed out into the general waterflow and spread over large surfaces in the park. In a short time the water, clarified by sedimentation, collected for a time in the deeper portions of the creek bed, and lay there, a tempting-looking extract of fæces.

Of course it was impossible to keep the men from drinking of this; indeed, it was a temptation that few could resist. This is more readily understood when the appearance and character of the water supplied through the supply pipes are borne in mind.

This brings me at once to the consideration of the very important question of the water supplied the troops. I do not wish to be understood as making positive claim that the source of water supply was infected at the point where it was drawn. The engineering department of the army holds that Chickamauga Creek was tapped at a point nearer its source than where drainage from the camp could possibly enter, and that chemical and bacteriological tests were made, satisfying them that the water was good and not infected. This latter point may be dismissed with the statement that I have had opportunity to observe the testing of water quite frequently, and that I am as a result reluctant to attach importance to it. Still this is a matter of opinion.

But this is nevertheless true: that for the first few days my regiment was in camp the water supply did not reach our regimental camp; that water was drawn for drinking-purposes from Chickamauga Creek at points where infection was possible through contamination from drainage from the camp sinkholes of other regiments; that the water supplied later through

[1] Read at the October meeting of Lenox Medical and Surgical Society.

the pipes was of the color of mud and altogether repulsive to every one; and that during my stay men and horses bathed in the creek at various points both above and below where it was tapped.

Chickamauga Creek is the natural drain of the park. Everything soluble ultimately reached it. It empties into the Tennessee River some distance above the point at which the town of Chattanooga draws its water supply. (Incidentally, watch this place for typhoid fever next spring.) Again, the water was led through a six-inch pipe laid on the surface of the ground. It was here daily kissed by a broiling Georgia sun. Of course, it always had the temperature of the air. Contrast this warm, nauseous mud soup to the clear, cool extract of fæces I have referred to, and it is not difficult to see why the men in their unfortunate ignorance preferred the latter. It is true the men were warned against drinking anything but the regular water; it is also true that cast-iron rules were formulated, prohibiting them from bathing in the creek; but it is impossible to impress a thirsty or an overheated soldier with rules of hygiene.

This brings me to the consideration of the one and really only grave disease that menaced the lives and health of the troops, *i.e.*, typhoid fever. It is hardly necessary to state that the first cases were imported —whether by the regular troops who first occupied the camp or by the volunteers, it is difficult to say. I have no precise knowledge of the condition of the regular troops. The various theories held by some, that typhoid was caused by the fruits, pies, etc., vended by hucksters, or the result of the untrained volunteer sleeping on the ground, are sufficiently absurd to be dismissed with this mention. The source of infection is, I think, easily recognized in the water the men drank. I do not maintain that this necessarily applies to the general water supply. This would be too grave a statement to make positively, yet it is my opinion that it does. But the pools of rain water and the wells and springs that were discovered after the first great rainstorm certainly were infected. Infection was also carried by flies. Never has mortal man seen such vast numbers of this vermin as infested Chickamauga Park. Myriads of them infested the sinks and myriads infested the food. It is easy to see how readily these insects could carry infection under the circumstances. Later came the dust as an element of infection. As I said, the contents of the sinkholes was spread over the ground by the rainwater; then dried out under the benign influence of the sun; converted into dust under the feet of tramping men, horses' hoofs, mule carts, etc.; carried everywhere by the wind. So you see it is not difficult to understand why typhoid fever raged as it did.

If the deductions made in the sciences are true, typhoid fever is a preventable disease. To prevent first its occurrence, and later its spread, is a gigantic undertaking, if not an impossibility, in a camp whose existence extends over several months or even weeks. The conditions that preclude its occurrence are more or less ideal; they exist only in well-regulated towns or cities. They could never have been made to obtain in Chickamauga Park. This fact was recognized long before the epidemic had assumed any magnitude. Discussions regarding it were held by medical officers in the presence of commanding officers. In truth, this statement was made by the writer during the latter week in June in the presence of a general of division and several of his staff: "There are one, two, three, or more cases of typhoid fever in the hospital from every regiment in your division; while the total number of cases is not yet large, they mean a common and widespread source of infection, and there will be a large number of cases on record in a very short time." The medical history of the camp proved this soon enough. In an adjoining division the number of typhoid-fever cases at that time had reached a considerable number—I think seventy odd, and new cases were coming in daily. The troops were not moved out until September.

It may have been a military necessity to keep the troops where they were, but from a scientific standpoint the infected area should have been abandoned, since remedy of the evils was impracticable. One reason why this was not done that has been adduced can be answered by the medical officer—that of expense. Pensions far exceeding in amount the cost of moving the troops from Chickamauga Park will ultimately be paid for the remote sequelæ of typhoid fever.

The character of the epidemic was virulent. Some of the men died from the acuteness of the disease. Temperatures ran high—105°, 106°, and 107° F. Delirium was often maniacal, suggesting sudden invasion of the blood by large quantities of toxins. Beyond these, none of the symptoms deserves special mention. In a general way it may be said that the cases were rather more severe than we usually see in New York City. In this connection it should be borne in mind that most of the men were at a time of life when resistance to disease is greatest, *i.e.*, between eighteen and thirty years of age; that their physical condition was good at the time of their enlistment. This, I think, makes it fair to conclude that the epidemic was of a malignant character.

As to treatment, there is little to be said except in a negative way. It is to be borne in mind that medicinal treatment of typhoid fever is of little value. Even in large towns and cities it is difficult to procure the conditions necessary to the rational treatment of this disease, except in well-equipped hospitals. Naturally these could not possibly be placed at the disposal of the patients in a field hospital. None of the so-called abortive or curative methods was attempted in the wards of the hospital to which I was attached. The knowledge of the pathological history and morbid anatomy of the disease precludes indulgence in these wild absurdities. The treatment attempted was, in a general way, fluid diet, abstraction of heat, stimulation, and rest. Intestinal disinfection was attempted by the administration of insoluble disinfectants, on the theory of lessening tympanites only. No idea was entertained that the typhoid bacteria could be reached in the glandular structures of the submucosa of the gut. In cases in which constipation existed, calomel was employed in small doses frequently repeated, with the double intent of laxative and disinfectant. When hemorrhage existed, this latter method was of course not used. Refinements of treatment were not indulged in, and, indeed, necessities were frequently impracticable, for the reason that the materials and apparatus were not furnished. Tubbing was rendered impossible, because we had no tub; wet packing was used but did little service, for the good and sufficient reason that the water from the pipes was of about the temperature of the air. The nearest standpipe was several hundred yards from the hospital tents, and the water from it was dragged over the intervening distance in barrels. An effort was made to procure water from Crawfish Spring, distant about three and one-half miles; indeed, mule carts were employed in hauling it; but when it ultimately reached us it, too, had become quite warm and, though better than that from the pipe, it was still of too high a temperature. Ice was as rare as were diamonds. Two hundred pounds a day was allotted us; this was carted over hot, dusty roads, in slowly rumbling mule carts, and much of it dripped by the wayside. Later more was supplied from private sources, but never did we have sufficient in quantity to be of much service. Milk—the sheet anchor in the nourishment of cases of continued febrile diseases—

was supplied in cans and placed in a trench dug in the ground, which we used as a refrigerator. In the afternoon the ice gave out; the milk soured, and was rejected by both patients and stomachs.

The nursing, while not skilful, was rather better than one could expect under these trying circumstances. Some of the men had been trained nurses in New York and other large cities. All of them are only to be commended for their prodigious efforts. I am referring now to the much-abused hospital-corps man, not the delegate from private charities. Our boys were soldiers, drilled in the hot sun at "litter drill" and "the school of the soldier" for part of the day, lectured to in first aid to the injured, quizzed, sworn at, and bedded on the ground at night, when they weren't doing duty as night nurses. I did not see a single inhumane or culpable act performed by any member of the corps attached to the hospital of the first division, third army corps. I never saw one of them drunk; but I did see fatigue, pallor, gauntness, and self-sacrifice constantly. And this applies to all, from the senior sergeant to the detail at the mule corral. Never have I seen a single man hesitate to obey an order. Some of them were woefully lacking in training, but never in willingness. Often have I seen a tall, slim youth, standing wearily in line at retreat, straighten up when his name was called, detailing him for night work, at the end of a long, insufferably hot day; and later seen him go resolutely about his work in the dim light of a hospital tent.

These things made the care and treatment of our patients extremely difficult. While it is true that ideal treatment of typhoid fever in field hospitals is impossible, it is also true that some of the conditions were the result of lack of judgment in executive departments. Water, ice, and milk—these three things were obtainable, and we had neither of them in sufficient quantity nor of proper quality. Look once upon the spectacle of a patient, gaunt, emaciated, delirious, with sordes on the tongue, lips, and gums so thick that articulation is impossible, motioning inco-ordinately at his mouth with trembling, transparent hands, and then know that the ice was melted, the water warm and mud stained, and the milk sour, and you will agree that, after all, tremendous effort should have been made to effect a remedy in executive departments. I make no apology for this statement, nor do I offer any qualification. War and misery have gone hand-in-hand as long as history has existed. Nothing will ever part them. But they should not meet first in camps of mobilization.

Regarding pharmaceutical supplies, large quantities of more or less useful drugs were issued and distributed. The method of organization of the hospitals was good enough in theory, but gave rise to delays that might have been avoided. It would lead me too far to go into this extensively. The general impression among regimental surgeons was that the division hospital was not a desirable place to send their patients, and they were right. Still it was quite impossible for them to obtain all they wanted for each regiment, when the division hospital had nothing itself except in drugs, and these were issued as rapidly as possible.

The food furnished the troops was badly selected. Bacon, beef, potatoes, bread, hardtack, tomatoes, onions, beans, and coffee were the chief articles issued. No one questions the heat value of these articles of food, nor is there any doubt that they contain the three classes of substances necessary to maintain life. But there was not enough variety, and, as intestinal disturbances were exceedingly common, the diet offered was not very conducive to health. Of course, some of the food stuffs furnished were convertible into either cash or some other article of diet. But in the confusion of matters it was impossible to obtain either, so the saving clause in army regulations that makes rations convertible was of no service. There certainly was not enough fresh meat furnished, and the bread, while well prepared from a baker's standpoint, was too porous. On the whole, the food was not of a good quality.

There were, of course, many minor hardships and discomforts that were without doubt attributable to ignorance on the part of various officers, and in many cases in the men themselves. But this has to do with the system of organization, and is not properly discussed here.

Intestinal disturbances of various kinds existed very largely, and presented much variety as to severity. Most of them were simple diarrhœas, although there was some dysentery. In some instances they were attended with rise of temperature and other general symptoms of the absorption of toxins into the blood. Grave cases with bloody and mucous stools occurred, and were not readily amenable to treatment—due in part to the fact that milk and readily digested food, such as eggs, rice, etc., were not obtainable.

As regards venereal diseases, these did exist to a considerable extent; they are the invariable accompaniment of all military encampments. Still it is not true that they were more prevalent than one would have a right to expect. One writer, a surgeon on a general staff, tells us, in an article in the *Journal of the American Medical Association*, that eighty per cent. of the surgical cases at Chickamauga Park were venereal. When it is remembered that the troops were not under fire and that surgical cases were rare, the misleading character of his statement is sufficiently apparent.

One word as to climate. The air is dry; the temperature very high, often rising higher than 100° F.; still the nights were cool. Not a single case of insolation occurred during the time the troops camped in the park.

On July 8th I went to bed with typhoid fever; my experience stopped on this date. Some of my associates followed me at short intervals. I offer no eulogy upon the efforts of the medical man. It would be inconsistent with the history of things ever to expect favorable comment upon them, and surely under the circumstances it would be unwise to offer one myself.

ANTISEPSIS VERSUS ASEPSIS IN COUNTRY PRACTICE.[1]

By W. B. KONKLE, M.S., M.D.,
MONTOURSVILLE, PA.

Conditions determine appliances—determine their applicability and practicability. *Vice versa*, any given appliance presupposes the conditions essential to its employment. Hence, in the abstract, an appliance can approach perfection only proportionately as the related conditions represent the ideal. In practice, however, that is most perfect which most nearly harmonizes with and fulfils the requirements of the circumstances and indications present. The elegant patent-leather shoe might be considered the most finished product of art as to footwear; but the high-topped stoga boot clearly discounts it in a log camp. The latest style of harvester is a splendid machine in a smooth, even field; but it would look woefully out of place on a sideling new ground: in competition with it here the old cradle would majestically maintain its pre-eminence.

That in the abstract, and in practice as well where corresponding environments prevail, aseptic methods mark one of the highest attainments of the healing art,

[1] Read before the Lycoming County (Pa.) Medical Society, September 8, 1898.

is a proposition that no one should doubt—that no one could successfully dispute. But let us survey and scrutinize the conditions presupposed thereby and prerequisite thereto. I need not detail or describe these, for all can understand and appreciate them. The civilization of the dawn of the twentieth century exhibits no more lustrous, no more inspiring picture than that of the model operating-room, with its ingenious design, its elaborate yet accurately systematized paraphernalia, its admirably organized personnel, its superb discipline.

But let us reverse our gaze, and contemplate other scenes painted from life. A woman in her thirteenth labor at full term: a veritable veteran, with one of those magnificent pelvises upon whose merits dear, venerable Elerslie Wallace used to love to linger, and with one of those vulvas of awful dimensions and infinite dilatability, through whose august portals a twelve-pound baby comes sweeping like a canalboat out of a lock. A consummately easy case for the doctor—barring the conspicuous absence of nearly everything ordinarily supplied for use on such occasions, and barring also the battle with flies and contact with multiform filth of various degrees of antiquity. The next day the doctor finds, in a cup in which he had left some sugar-coated pills, a squad of bedbugs studying pharmacy—more bedbugs than pills. Recovery is prompt and uneventful, of course. But imagine the introduction of aseptic obstetrical practice in that forbidding atmosphere!

Again, the doctor is called ten or a dozen miles into the backwoods region to care for a man whose hand has been lacerated by a shingle machine. A neighbor must take charge of the ether when the operation begins; two or three other neighbors must assist; the one man present trained for such work must keep his eye on all, and simultaneously be doing all possible for a pair of hands to execute. The wound progresses very satisfactorily and the result is creditable. But fancy an attempt to construct the complicated and delicate mechanism of aseptic surgery out of such material and upon such a soil!

These are extreme situations, one will say. That is admitted. They are simply adduced for the more forcible presentation of the point asserted. Let it be remembered, however, that between this emphasized position and the limits of condition appropriate for the application of asepsis there is a wide intermediate territory, throughout the whole extent of which the method must prove disappointing. In this regard anything short of perfection is altogether imperfection.

Another will say that even under unfavorable circumstances favorable results follow this method. I would reply that under such circumstances favorable results as frequently follow no method at all. These apparently exceptional instances indicate only that injurious germs were not in the locality or that the tissues have been more than ordinarily resistant. Indeed, it seems that nature has in this way vouchsafed some compensation to the poor man separated from the best ministrations of our art.

Against the attempt to apply asepsis beyond the bounds of the conditions necessary to its success I would protest. To preserve a semblance without an essence is the merest cheat. Let there be no ape-like going through the motions simply with the idea that duty has been done by such adherence to unreal forms. Let asepsis take its place where it will be a fact and not a delusion.

This protest is made the more earnestly—derives its practical importance, indeed—from the consideration that an ineffectual attempt at asepsis may forestall a most beneficial application of antisepsis. Antisepsis may be of the highest value where asepsis would be impotent. If we may not exclude germs, the expediency of waging war against them still remains.

To antiseptic methods were due many of the successes of the old days of medicine. Our forefathers had learned, partially at least, to nonplus a foe, vaguely conjectured, perchance, but not then revealed. The balsams and essences of former generations were none the less useful because no rational comprehension of their *modus operandi* was entertained. Antisepsis is to-day a science; and the light of science always guides more clearly and accurately than the *ignis fatuus* of empiricism. In the trustworthy germicides at his command the physician wields a weapon of genuine efficiency, inestimably valuable by reason of the possibility of its application under all conditions. Appropriately to the last degree falls this weapon into the hands of the country doctor.

Progress of Medical Science.

Syphilis of the Stomach.—Professor Dieulafoy draws the following conclusions: (1) Syphilis of the stomach is not so rare as is generally supposed. (2) The syphilitic lesions of the stomach occur in various forms; for example, hemorrhagic erosions, ecchymoses of the mucous membrane, gummous infiltration of the submucosa, circumscribed gummata, ulcerating gummata and their resulting cicatrices. (3) Here, as in all cases of loss of substance of the stomach wall, the acid gastric contents probably finish what the initial ulcerative process began. (4) The symptoms of syphilitic ulceration of the stomach may simulate all those of simple ulcer—pain over the xiphoid cartilage and vertebral column, vomiting of food, hæmatemesis, melæna, irritability of the stomach, cachexia. (5) The syphilitic nature of the stomach affection cannot be diagnosticated from any of the previous symptoms. If symptoms of ulcus rotundum occur in a syphilitic patient, then we are justified in surmising that the stomach lesion itself is of a syphilitic nature. (6) We must never forget to seek for a previous syphilitic history in patients with ulcus rotundum or exulceratio simplex. (7) This being the case, the treatment suggests itself—mercurial preparations and the iodide of potassium. (8) The recognition of the syphilitic nature of certain ulcers of the stomach is all the more important, on account of the fact that we are enabled to cure a certain number of patients who otherwise might fall into the hands of the surgeon.—*Le Bulletin Médical*, April.

Immunity against the Bubonic Plague.—Dr. S. K. Beinarowitsch (*Arch. des Sciences Biolog.*, March) after numerous experiments with animals concludes as follows: (1) The antipest serum, if injected directly under the skin, produces but a passive and transient immunity against the plague; the duration of this immunity is, to a certain extent, directly proportionate to the amount of serum injected. (2) A serum dose equivalent to one-one-hundredth the weight of the animal produces immunity against a fatal inoculation of the plague bacillus for a period of two weeks; with a smaller dose the period of immunity is decidedly shorter. (3) An animal which on account of a serum injection has acquired a passive immunity against the plague bacillus will with an injection of virulent plague bacilli acquire a certain degree of active immunity. (4) The ability to acquire an active immunity and the duration of the same stand in inverse proportion to the amount of the serum injected before inoculation with the bacillus of the bubonic plague. (5) The attainment of an active immunity

on the part of the animal depends upon the appearance of a reaction after the inoculation of the pest bacillus.

Rubeola or German Measles.—Dr. Pulawski (*Gazeta lekarska*, 19–20, 1898) as a result of the study of two epidemics makes the following statements: The disease sets in abruptly without any previous prodromal symptoms. The period of incubation is about two weeks. During the entire course of the disease the temperature is normal or only slightly elevated. The eruption is similar to that of measles, with this exception, that it is somewhat smaller and lighter than the latter. The eruption appears first on the face and neck, then on the chest and back, and finally on the extremities. The eruption is accompanied by itching, and desquamation is entirely lacking or appears only on the face. In concluding, the author states that, contrary to the teachings of Henoch, he considers rubeola a distinct and separate disease, and summarizes as follows: "(1) The clinical picture of rubeola resembles that of measles, it is true; but still it has its own characteristics which are repeatedly seen. (2) Rubeola patients can cause the spread of this disease only, and not that of measles or scarlet fever. (3) Rubeola does not protect against the other acute exanthematic diseases, and *vice versa*. (4) Rubeola occurs not only in sporadic cases but also in epidemics."

The Amœbæ from a Parasitic and Culture Standpoint.—Dr. Robert Behla in a recent book on this subject makes the following statements: (1) In the oral cavity of human beings amœbæ, according to their pathological significance, whether they be a separate species or only reproductions of other organisms, have thus far not been demonstrated. (2) Up to the present time they have not been found in the nasal secretion of human beings. Experiments with animals are lacking. (3) Amœbæ are not mentioned among the parasites of the human ear. (4) The mucus of the human eye does not show amœbæ. (5) They are also absent in the expectoration of the respiratory apparatus. (6) The Italian investigators, Celli and Fiocca, have seen amœbæ in the gastric contents of human beings. On numerous occasions Behla found amœbæ in the stomach of recently slaughtered cows, and, in addition, infusoria which unquestionably came from the drinking of contaminated water. (7) More frequently the intestines of human beings contain amœbæ. The amœba coli Loesch, which has been substantiated by various investigators, deserves especial mention on account of the extraordinary interest to which it has given rise in reference to dysentery. (8) Amœbæ in the uro-genital apparatus of human beings. Baelz has demonstrated in the bloody urine of a tuberculous patient, twenty-three years of age, an amœba which resembles the amœba coli. Furthermore, Jürgens has demonstrated amœbæ in small mucous cysts of the male bladder, and Posner has also made mention of amœbæ in the urine and female uro-genital apparatus. (9) The amœbæ are also present in the vagina. (10) Fleyner has reported amœbæ in an abscess at the floor of the mouth. The case occurred in a man, sixty-two years of age, who at some previous date suffered with dysentery. (11) Nencki, Tieber, and Wyzni Kiewicz report the existence of amœbæ in the various organs —liver, spleen, kidney, etc.—of sick cattle. (12) Behla found amœbæ in the secretion of an extensive suppurating ulcer of the lower thigh.—*Memorabilien*, August.

Bromoform Poisoning.—Dr. Müller, in the *Münchener med. Wochenschrift*, September 20th, reports a case of a child, two years old, suffering from whooping-cough, who swallowed about four grains of bromoform during its mother's absence from the sick-room. A few minutes later the child appeared intoxicated, and following the administration of lukewarm water and tickling of the pharynx it vomited. Soon it fell into a deep slumber, broken by repeated convulsions, beginning with respiratory spasm and cyanosis of the face. A copious supply of milk was at once administered. Two hours afterward the child was in a state of collapse with scarcely perceptible breathing, cyanotic face, fluttering pulse, cold hands, contracted pupils with absence of reaction to light, and muscles paralyzed. Death occurred in about five hours following the ingestion of the dose, with respiratory and cardiac paralysis. The characteristic clinical picture is that of asphyxia, undoubtedly caused by the action of the blood poisoned with bromoform upon the respiratory centre. The post-mortem examination revealed the following conditions: The pupils equal and of medium size. The stomach contained some food particles which had a faint odor of bromoform. There were only a few hemorrhagic spots and slight congestion of the mucous membrane without loss of the lining epithelium. The duodenum and upper half of the jejunum had a deep odor of bromoform; the mucous membrane was injected; the solitary glands and Peyer's patches were intensely swollen; the upper part of the jejunum was already reddened. Farther along, the reddening became less marked, the outer coat was grayish, and the mucous membrane was pale. The liver was normal in size. The upper surface was bluish-red. There were a few hemorrhagic spots in the left lobe. Cross-section revealed a glistening bluish-red surface, from which there exuded a profuse, thin dark blood. The kidneys were large, brownish-red, glistening, and sanguineous. The thinness of the blood was a striking feature. Only in the right heart were there a few small clots. The left ventricle contained a small amount of thin dark blood. The epithelium of the epiglottis was reddened. There was a grayish-red mucus in the trachea. The injection of the mucous membrane was more marked lower down and most marked at the bifurcation of the trachea. The tongue was pale. There were a few hemorrhagic spots, about the size of a grain of mustard seed, on the left lower lobe of the lung under the pleura. The surface was dark bluish-red, the cross-section was cherry red. Upon pressure there exuded from the bronchi a copious whitish mucus. The mucous membrane of the bronchi was markedly injected. The veins of the dura contained very thin dark fluid blood. The vessels of the pia were sharply outlined, having been filled with blood of a similar character. They formed swellings as if they were artificially injected with wax. The brain substance also showed numerous hemorrhages and was wet and succulent. Chemical examination of the different portions of the body revealed the presence of bromoform in various quantities. From the stomach, intestines, and their contents there were obtained 1.165 gm. of bromoform. This also was present in the blood and various organs, although not in measurable quantities. When it is considered that of all these organs only small portions were taken and examined, it must be concluded that bromoform had doubtlessly accumulated in the body in large quantities. The most important points in the case were the thinness of the blood, the dark red color, and the unusually marked injection of the vessels of the brain and its meninges. Of less importance was the irritation of the mucous membrane of the small intestine. This being the only reported case of death from bromoform poisoning in which autopsy was made, we have given the post-mortem changes at some length.

Alcoholism in Children.—Dr. Combe, of Lausanne (*Annal. de Méd. et Chirurg. Infant.*), summarizes as follows: (1) A wetnurse who is accustomed to drinking

wine may continue the same to moderation during the period of nursing. (2) A wetnurse who has not been in the habit of indulging in alcoholics must not receive any during the entire course of the nursing period. (3) An alcoholic mother must not nurse her child. (4) Nervous children and those who are suffering from an organic nervous disease must refrain absolutely from alcoholic drinks. (5) Very young children must never receive any alcoholic drinks, except in cases of acute diseases in which alcohol is indicated. (6) Total abstinence should be insisted upon until at least the sixth year. From the sixth to the twelfth years children may occasionally drink a small quantity of very diluted wine. (7) Total abstinence is indicated in the case of older children who are wayward, lazy, and weak in memory. (8) Hereditary alcoholism favors idiocy, epilepsy, and insanity.

On the Treatment of Catarrhal Symptoms with Guaiacol Carbonate.—The good results obtained by Dr. Hoch with creosote in the treatment of catarrhal symptoms in children following measles and whooping-cough, suggested to Dr. Nied, of Vienna (*Allg. Wiener med. Zeitung*, No. 22, 1897), the use of guaiacol carbonate in catarrhal affections. He has treated twelve female patients, varying in age from twenty-three to seventy-five years, some suffering from acute bronchitis, others from influenza. Doses proportionate to the severity of the symptoms were ordered; in mild cases he gave 0.5 gm. of guaiacol carbonate on the first day, morning and evening, and on the second and succeeding days 1 gm. twice daily. In other cases he prescribed on the first and second days 1 gm. morning and night, and on the third and subsequent days 1.5 gm. In more severe cases he gave twice daily 1 gm. on the first day, 1.5 gm. on the second, and 2 gm. on the third and following days. A beneficial result was usually apparent on the second day, at the latest on the fourth day, and manifested itself in a return of the lost appetite and a marked loose expectoration. The mucus usually disappeared in from fourteen to twenty days.

Blood and Histological Examination in a Case of Malaria Pernicioso-Comatosa.—Dr. Nicolaus Jancso, of Klausenburg, reports (*Deutsches Archiv für klinische Medicin*, Bd. 60, Heft 1) a case of acute pernicious malarial fever. In the histological examination he found in all the organs black pigment particles, most abundant in the spleen, next in the bone marrow and in the liver. The spleen presented the appearance of acute inflammatory hypertrophy. The pigment particles were most numerous in the cells; the connective tissue contained but little pigment. In the bone marrow the fat cells appeared as though dispersed in the lymph canals. A large portion of the cellular tissue contained pigment, grouped especially about the nuclei of the cells. The liver was of a dark, brownish-black color, and held a large amount of pigment located chiefly in the capillary blood cells, in the endothelium lining the blood-vessels, and in the so-called cells of Kupffer. In all the other organs the quantity of pigment was proportionately small. In blood taken from the finger tip Jancso found only small parasites of the amœboid-movement variety and half-moon forms, without division; on the other hand in the spleen and bone marrow there were large numbers of parasites in the stage of division. The brain was anæmic, and but few parasites could be demonstrated in the blood contained in the capillaries of the gray substance. From this the author concludes that the coma of pernicious malaria is not always due to the plugging up of the cerebral capillaries with parasites or pigment, but is frequently a result of the toxic action of the chemical products liberated by the malaria plasmodium.

Enanthemata.—At the annual meeting of the American Pediatric Society, held in Cincinnati in the beginning of June, Dr. F. Forchheimer, of Cincinnati, read a paper on what he considered to be a characteristic enanthem of German measles. According to the extract published in *Pediatrics* the enanthem is a macular, distinctly rose-red eruption upon the velum of the palate and the uvula, extending to, but not over, the hard palate. The spots are arranged irregularly, not crescentically, are of the size of large pinheads, and are very little elevated above the level of the mucous membrane. He studied the eruption in twenty-two cases. In no case had he seen the exanthem when there was not present a suggestion of the enanthem. The enanthem is very short lived, fading away within the first twenty-four hours. It is the same eruption which is found upon the skin, characterized by the size of efflorescence, its arrangement, the absence of great infiltration, and, above all, by its color, a pure pinky-rose-red, almost exactly the same as the "roseola" of typhoid fever. During the process of involution there are sometimes left pigmented deposits, usually of a yellowish or yellowish-brown color, in the form either of spots or of streaks. The difference between this enanthem and those of scarlet fever and measles is as follows: in scarlet fever the enanthem appears from twelve to twenty-four hours before the eruption. It appears on the pillars of the fauces in the form of characteristic puncta, then rapidly spreads over the mouth in the form of a scarlet-red coalescing eruption, which ends in desquamation, producing the strawberry tongue. In measles the enanthem begins upon the soft palate, from thirty-six to forty-eight hours before the exanthem, in the form of purplish papules arranged crescentically. Some of the subsequent speakers said that their experience confirmed that of Dr. Forchheimer.—*Lancet Editorial.*

Clinical Studies with Spleen and Thyroid Extract.—Drs. Charles A. Bois and Neil T. Kerr (*British Medical Journal*, September 10th) sum up the results of their investigations of this matter by stating their convictions as follows: "(1) That the most general result of this treatment is physical improvement. (2) That its action on the mental state is undoubtedly evident in a fair proportion of cases, especially of adolescents, sometimes direct, at other times owing to improved physical conditions. (3) That it materially assists in rendering thyroid treatment efficacious, the patient, after a course of spleen treatment, being more susceptible to the action of thyroid. (4) That when it fails there may be a defect in the preparation of the extract. We have found that capsules of the liquid extract are best. The desiccated spleen, which is usually employed for tablets, must necessarily lose some of its active properties. (5) It is best given at least half an hour before meals. In conclusion, it is not necessary to say more than this: That if a collective investigation of the treatment were taken up and persevered with, spleen extract would prove itself well worthy of a place in the treatment of mental disease."

A Simple Method of Estimating the Quantity of Urea.—Dr. Buckner (*Münchener Zeitschr. für Biol.*, No. 2) suggests an easy method by which the proteid metabolism can be calculated with some degree of probability by comparatively simple operations. If it be granted that, as Buckner holds from many check experiments, when the salts in the urine are about normal in amount, especially the chlorides, the urea forms one-half of the total solids, unless some abnormal constituent is present in excess, the specific gravity will give the approximate percentage of solids. A qualitative test for chlorides with nitrate of silver will show whether they are increased or not, or if present

in a small amount, and from this the total amount of salts may be reckoned in proportion. As an example, a normal urine, 1,000 c.c. in the twenty-four hours, had a specific gravity of 1.0285; total solids (28.5 × 2.33) =6.64 per cent.; chlorides, precipitate normal; no abnormal constituents. The urea, therefore, was estimated at 3.32 gm. per cent. Liebig's method showed 3.41 gm. per cent.; Kjeidahl's process, 1.81 gm. of nitrogen, or equal to 3.89 gm. of urea per cent., which will give a figure very similar to the others if the nitrogen of the uric acid and other nitrogenous constituents be subtracted. In a case of diabetes passing 2,250 c.c. urine per diem, with a specific gravity of 1.038 and containing 4.8 per cent. of sugar, the total solids will be 199.1 gm. in the whole day's urine (38 × 2.33) × 2.25, the sugar, 108 gm. On subtracting the figure for the sugar from the total, 91.1 gm. remains, the half of which, 45.55 gm., corresponds to the amount of urea excreted. As 1 gm. of urea represents 2.9 gm. of albumin, or 13.7 gm. of flesh, the excess lost by the diabetic over the normal man amounts here to 170 gm. of flesh. The method appears to afford a means whereby a sufficiently accurate determination of proteid metabolism may be worked out from very simple every-day clinical manœuvres. Of course, allowance has to be made for the nature of the diet.

The Policy of Depopulating Cities Infected with Yellow Fever; if Undertaken, how Best to Accomplish it.—Dr. Felix Formento (*New Orleans Medical and Surgical Journal*, October) draws the following conclusions: (1) General depopulating of towns and cities infected with yellow fever, however desirable, is not practicable. (2) Voluntary exodus of individuals and families is to be encouraged at the first breaking out of the disease. (3) During an epidemic, depopulating should be carried out under special sanitary precautions. (4) Depopulating of houses in which first cases occur, by removal of the sick to properly constructed hospitals, and of the well to special camps of observation, and thorough disinfection of houses, he considers the most efficient measures for the stamping out of the disease at its birth. (5) Isolation of the sick and destruction or disinfection of discharges from bowels, and of all contaminated material, with disinfection of the premises, are the best means of limiting the disease. (6) All measures of repression of an arbitrary character are to be applied to a limited number of cases only. If they fail they should be discontinued, as they are an additional burden to the sufferings and hardships of the people.

Modern Treatment of Tuberculosis.—Dr. Charles Denison (*Journal of the American Medical Association*, September 24th), in summing up this paper, advances the following conclusions: (1) As the whole is greater than a part, the combined method is superior to any given branch of the treatment. The individualizing process, and the adaptation of all methods to the needs of a given case, is the preferable plan. (2) The seasonable change of residence to a well-selected high-altitude climate, with its dryness, sunshine, possibilities of outdoor life, and its stimulating qualities, gives the best possible resistance to the advance of consumption. (3) Exercise is most essential and necessary to promote both cell activity and the needed mechanical distention of the air-cells. (4) Local treatment and proper inhaling-methods bear important relation to exercise, cell stimulation, and the climatic effect of the high-altitude method. (5) A great and most valuable addition to our curative means comes through the skilful determination of the proportion of infection, in order to the establishment of the balance between bodily resistance and the disease. This balance is the key to the as yet preferable—the direct—method of specific treatment. (6) It is a mistake to overwhelm the body with frequent injections of undetermined animal serum, thereby producing either a severe reaction or a possible cumulative toxæmia.

Snakebites and their Treatment.—Dr. B. Merrill Ricketts (Cincinnati *Lancet-Clinic*, September 3d) draws the following conclusions: (1) The copper-head, the coral, and the rattlesnake are the only serpents in the United States which possess fangs, at the base of which is a sack containing a poisonous fluid. (2) The result of inoculation depends upon the dose, and the size of the human being or animal. (3) Most of the authentic cases of death by bite of these serpents have been among children. (4) No authentic record of death, as the result of the bite of any of these snakes, has been found in the adult man by the writer. (5) If death does not result within a few hours, it is not the venom but other agencies that produce it. (6) The bite of the cobra is not so deadly as is generally supposed. (7) Overstimulation from alcohol and other agencies is, he believes, oftener the cause of death than virus inoculation. (8) The effect upon the body is more severe if the virus is injected into blood-vessels. (9) There seems to be no subject which is surrounded by so much uncertainty and exaggeration.

Trichinosis.—Dr. T. R. Brown (*Journal of Experimental Medicine*, vol. iii., 1898) gives an account of investigations made by him on trichnosis, with special reference to the increase of the eosinophilic cells in blood and muscle, the origin of these cells, and their diagnostic importance. From these observations he concludes as follows: (1) That there is a marked decrease in the percentage of eosinophilic cells in the blood in trichinosis. (2) That this decrease may be used as a diagnostic sign in this disease. (3) That this disease in its sporadic form is more common than has hitherto been supposed, as shown by the discovery of the three cases which were described, within a comparatively short period, at the Johns Hopkins Hospital. (4) That a systematic examination of the blood should be undertaken in cases with indefinite intestinal, muscular, or articular symptoms, in the hope that in some at least of the hitherto doubtful cases a diagnosis may be reached.

Bacteriology of the Blood in Disease.—Drs. James and Tuttle ("Report of the Presbyterian Hospital"), after much investigating, adduce the following conclusions: (1) The attempt to cultivate bacteria from the blood of living persons is useless unless carried out in a painstaking way, and with thorough antiseptic precautions, and with blood drawn directly from a vein. (2) The number of diseases in which this procedure is useful is small. (3) In malignant endocarditis it is of great value; in other septic diseases, of moderate value; and in typhoid fever it may, on rare occasions, prove of some use. In other morbid conditions its usefulness has not yet been proved.

The Agglutinating or Sedimenting Properties of Serums and their Relation to Immunity.—Dr. Herbert E. Durham (*British Medical Journal*, September 3d) concludes his discussion on this topic as follows: "The actions of normal and heterologous serums (clumping and protective) may be left on one side as hardly germane to our subject. We have evidence that when agglutinins are present, inhibitory and protective properties are also to be found. Hitherto an agglutinin free from these other substances has not been obtained. Agglutinins act within the living body by causing clumping, as well as in the test tube. Destruction of agglutinins occurs in an actively immunized animal after infection with the homologous bacterium. There is no definite relationship between the limit dilution

at which clumping can be recognized and the limit dilution at which complete effect is produced upon a given amount of the bacteria. From the latter some clew as to the preventive efficiency of a serum may be obtained. Lastly, although in future experience the association of agglutinins with protective substances may be shown to be fortuitous, yet it will always have attached interest from the fact that the now well-established method of serum diagnosis in typhoid fever and other diseases owes its birth to this association. The knowledge that protective qualities are acquired by the blood of typhoid-fever patients led to the probability that the clumping property would also be developed. This resulted in Gruber's world-famous suggestion that this agglutinating property should be worked out in typhoid and cholera patients."

The Nature and Significance of Leucocytosis.—Dr. Robert Muir, in a discussion on this subject before the last annual meeting of the British Medical Association (*British Medical Journal*, September 3d), interpreting the phenomena, says: "(1) The local leucocytosis is a most important means of defence; (2) the proliferative changes in the bone marrow are the means by which the leucocytes concerned may be supplied in large numbers at any given place of need; (3) the leucocytosis in the blood is an indication at least that this supply is being maintained. We may also mention that the vascular arrangements in the marrow are such as, on the one hand, to permit a ready action upon its cells of chemotaxic substances circulating in the blood, and, on the other hand, to allow a free and rapid passage of the cells into the blood. It is to be noted that chemical substances must be the means by which a general leucocytosis is brought about, and therefore it is not surprising that it can be produced when there is no local inflammatory change. Whether in such a case the leucocytosis really acts as a means of defence by combining with toxins in the blood (for example, in the leucocytosis following injection of diphtheria toxin) must still be considered an open question. Another question worthy of study is whether, and if so to what extent, degenerating or broken-down tissues act as chemotaxic agents in the production of a general leucocytosis."

Diphtheria Treated with Antitoxin Serum in University Hospital during 1896 and 1897.—Drs. Sidney Martin and G. Bertram Hunt (*British Medical Journal*, September 3d) draw the following conclusions: "(1) The great reduction seen both in our total and tracheotomy mortality can be due only to the treatment with antitoxic serum, for the examination of the cases reveals no other factor capable of producing this result. (2) The full benefit of antitoxin was not obtained until fairly large doses (on an average between 7,000 and 8,000 normal units) were employed; the mortality then fell from 28 per cent. in the first antitoxin year to 17.7 and 17 per cent. in the next two years. Each case of diphtheria should have an initial dose of not less than 6,000 normal units. (3) Since antitoxin has but little effect on the mortality when given after the fourth day, it should be administered as soon as the patient is seen, without waiting for the bacteriological diagnosis, and the full dose should be given immediately in one injection, not in divided doses on successive days. (4) Not only does antitoxin reduce the mortality, but it also distinctly lessens the severity of the disease in patients who recover. This is best shown by the effect on the duration of the fever, which in our series lasted only four days in a very much larger proportion of antitoxin than of pre-antitoxin cases. (5) The effect of antitoxin is chiefly seen in its specific action on the diphtheritic membrane, as shown by the cessation of its spread and more rapid clearance, and also by the greatly lessened mortality of such cases, in which the chief danger is from extension of membrane, the mortality of tracheotomy cases especially being reduced from 65.5 to 26.4 per cent., a greater reduction than was seen in the other cases."

Acetonuria.—Von Jaksch distinguishes the following forms: (1) The febrile; (2) diabetic; (3) carcinoma which has not yet produced inanition; (4) inanition acetonuria; (5) psychoses; (6) auto-intoxication; (7) digestive disturbances, especially the gastro-enteritis of children; (8) chloroform narcosis.

"Railway Spine."—These are the cases that bring two types of expert witnesses, one side swearing that the man is seriously injured, the other side testifying that the symptoms are fraudulent and only assumed for the purpose of mulcting the railway company. The examination of such patients must be conducted with great care, and while it is necessary to be guarded against so-called "litigation symptoms," fairness and justice demand that all real symptoms should carry due weight. The following suggestions may be of value: (1) Do not rely upon a single symptom, but weigh all the symptoms. (2) Study the manner of the patient, and test his truthfulness or studied attempts to exaggerate his complaint. (3) Exclude all pains the existence of which cannot be confirmed by any physical evidence, and which rests mainly upon the unsupported statements of the patient (Dercum). (4) Admit all pains the signs of which are evoked without any previous warning or suggestion (Dercum). (5) Pay special attention to every symptom which is beyond the control of the patient, as temperature, deformity, persistent rigidity of muscles, vomiting, sweating, bloody urine, etc. For estimating the value of pain as a symptom, Dercum recommends a method of examination which is often of great value. Superficial tender spots are tested by injecting at one of the painful areas either cocaine, or, as suggested by Keen, simple cold water. If the pain is genuine, the injection relieves that particular spot, while the others remain tender.—Dr. J. W. MacDonald, "A Clinical Text-Book of Surgical Diagnosis and Treatment," page 509.

Treatment of Migraine.—Dr. Henry Hanford (*The Edinburgh Medical Journal*, September), in an article on migraine and the vasomotor theory, speaks of the treatment as follows: "It is well known that when with headache the extremities are cold, some relief is obtained by warming the hands and feet at the fire. In many cases the recumbent position is required in addition. In a large class of patients the attack may be cut short by many hours by going to bed, applying hot bottles to the extremities, and taking hot drink (as soon as the stomach will retain it)—some hot tea or milk. A glow soon pervades the surface, and the spasm is relaxed. Relief so obtained is not very liable to relapse. After a few hours the ordinary duties of life may be resumed, and, although sleep is the best completion of the cure, its place may sometimes be taken by a good dinner. I believe this treatment, when it can be carried out, to be far superior to any drug treatment, although it may be aided by a good dose (thirty to sixty grains) of bromide of potassium. It is a curious fact, and may be taken as the exception which proves the rule, that a few patients find that the recumbent position aggravates their pains, and often prefer to spend the night in an armchair rather than go to bed. And also, in the later stages, moving about sometimes seems to hasten the end of the attack more than remaining quiescent."

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, October 22, 1898.

ETHER NARCOSIS.

THE comparison of ether with chloroform as an anæsthetic continues to be a subject of interest, and, in Europe especially, contributions to the journals upon this subject are frequent and often the results of long series of observations and experiments. In this country the popularity and reputation of ether seem to be fixed, and chloroform is almost everywhere regarded with some suspicion, in spite of some of its very attractive qualities. The very generally recognized disadvantage which ether has is undoubtedly the increased secretion of mucus and saliva which occurs during its administration. In the *Archiv für klinische Chirurgie*, B. 57, 1898, Hölscher gives some conclusions upon the action of ether, which are based upon a series of experiments upon animals. His paper is long, and his conclusions are that the ether vapor has very little irritant effect upon the broncho-tracheal mucous membrane; that the tracheal râles during ether narcosis are caused by the aspiration of the secretions, salivary and mucous, from the mouth; that the affections of the air passages following ether narcosis are caused by this aspiration; and that the increase in the flow of saliva depends largely upon local irritation by the vapor, but that central influences also play a part in this process.

It is a good thing to bear in mind that the secretions from the mouth are responsible for the tracheal râles, for it puts the prevention of the condition within the range of easy possibility, and also imposes a distinct responsibility upon the anæsthetizer. Of course patients are very variable in their behavior during etherization in regard to the amount of secretion and the character of the respiration, and in some it would be practically impossible to prevent the flow of some of the saliva and mucus into the trachea. It is probable, however, that it is only when the secretions reach the bronchi and their large branches that there is any great danger of pulmonary involvement. When the secretions do reach the large bronchi or the bronchioles and cause a bronchitis or a broncho-pneumonia, the consequences are apt to be serious, especially in elderly or alcoholic patients.

Extreme care on the part of the anæsthetizer, both as to the amount of ether given and in keeping the mouth clean and the head and jaw in the correct position, is the only thing which can give us security from unpleasant experiences in a certain number of instances of the administration of this anæsthetic. The dangers in the use of chloroform depend upon inherent poisonous qualities in the drug, and can be guarded against only by watching with extreme care the amount given and its effect upon the circulatory apparatus. Even with the greatest care cases will occur in which, on account of some latent cardiac trouble or of personal idiosyncrasy, alarming or fatal symptoms will develop, with very little time for satisfactory treatment.

In the case of ether, the dangers depend largely upon causes which are mechanical and can be prevented by mechanical means, leaving out, of course, any such event as the overwhelming of the patient with the drug, which should never occur and can occur only from carelessness. If the whole bronchial mucous membrane were pouring out an excess of secretion during etherization, it would be a very difficult matter to give the drug successfully; but if the secretion comes almost entirely from the mouth, it must be an easy matter to control.

In operations with tracheotomy, the presence of the tube in the trachea is irritating and causes an extra secretion of mucus in the trachea; and if this secretion becomes muco-purulent and the inflammation extends downward, the consequences are self-evident. In ordinary etherization we have not this source of irritation, and whatever sepsis is introduced must come from the mouth.

A PLEA FOR REVISION OF SCIENTIFIC NOMENCLATURE.

MUCH dissatisfaction has long been felt at the inadequacy of the language of scientists correctly to express their meaning. Instead of using clear and comprehensive terms in the vernacular, Greek and Latin are resorted to, and in consequence long-winded hybrid words are concocted by the coiners, which tend only to confuse and perplex their audience. This fact has been greatly in evidence at the recent meeting of the British Association, so much so, indeed, that protests have been freely circulated in the press and an alteration in the present methods has been strongly advocated. The London *Times*, in an article commenting upon the matter, has this to say: "For the general encouragement of science, however, or, more properly speaking, for the encouragement of scientific methods of thought, the stimulus of public opinion is urgently required, and this stimulus the meetings of the association may do much to create. They would do more, we may venture to suggest, if the leaders of science would themselves become sufficiently literary to avoid offending the ears of scholars by a laborious, unintelligible, and unnecessary nomenclature. There was something to be said, no doubt, for the general use of Latin as the language of the learned common to men of all nations. There is nothing to be said for the modern jargon of illiterate Greek compounds used to express ideas which might be better and more correctly expressed in any modern tongue. No foreigner

would be assisted to comprehend a paper read before the association, mainly in English, because it contained such words as 'enantomorph,' "hyphomycetons,' 'peltation,' 'cleistogamy,' or a score of others which could be mentioned, the meaning in all these cases, as gathered from the presumed derivation, being more or less vague and general, while the application is in each case quite specific, precise, and usually such as the derivation will neither justify or permit. Men of science who are imperfectly acquainted with English, but who have retained from their school days some small smattering of Greek, make up such words as those above referred to, and then proceed to define the meaning which they attach to them and which other folks are expected to remember. The whole process is a mistake—and a serious one—which the leaders of scientific thought and inquiry would do well to set themselves to correct. The resulting vocabulary tends to bring science into disrepute with scholars, who are inclined to 'stare and gasp' at the verbal monstrosities submitted to their notice, and who may be excused for thinking that knowledge which can be expressed only in unintelligible verbiage is hardly worthy of their attention." We trust that the leaders of science will take to heart the wise if somewhat ponderous words of the *Times*, will cry "*Peccavi!*" and resolve to amend the errors of their ways.

CHRISTIAN SCIENTISTS AND FAITH HEALERS IN GREAT BRITAIN.

Judging from accounts received, it would appear that the Christian scientists and others of the same race are quite as numerous and as successful in gaining converts by their pernicious teachings in Great Britain as here. The fact is also made clear that in both countries the law is powerless to check the imposture; at least such is the case in England, where the Christian scientists, faith healers, and the rest of the brotherhood are legally entitled to undertake the treatment of patients, either personally or by correspondence, and to fleece their victims to the utmost extent; but with one reservation—a healer is liable to a charge of manslaughter, should a patient die while under treatment.

The exact legal position occupied by the quack fraternity was, according to London *Truth*, thus defined by an eminent authority in answer to a question as to why some of the professional organizations did not look out for a chance to prosecute some of the mind-healing sisterhood. The legal luminary begins his interpretation of the English law on the matter by affirming that donkeys and dogs are better protected from the machinations of quacks and frauds than is any human being, and then proceeds as follows: "Any outsider who calls his place a veterinary forge commits an offence against the veterinary act, which provides that no person who is not a member of the Royal College of Veterinary Surgeons can take or use a title or description which will lead any member of the public to believe that by going to his, the advertiser's, establishment such member of the public would procure skilled advice or assistance. And yet a quack may call himself doctor, or, if fortified with a worthless diploma, style himself M.D. with impunity. The reason is that, while under the veterinary or the dentists act the mere fact of using a title or description of the character referred to, whether such title relates to the individual or to his premises, is an offence in itself, under the medical acts a man cannot be held guilty of the offence of calling himself doctor or M.D. or surgeon, unless by so doing he wilfully and falsely pretends that he is a registered man. The courts have again and again held that whether or not a man so falsely pretends is a question of fact for the magistrate. The courts have also held that when a man has a foreign diploma giving him the title to call himself M.D., the educational value of which may be practically worthless, he cannot be held falsely to pretend that he is an M.D. Had the words 'wilfully and falsely' been omitted from the medical act, and the phraseology been the same as in the veterinary and dentists acts, conviction of an offender would be easy. . . . Until the medical acts forbid practice in every shape and form by unregistered persons, it would be hopeless to expect to secure a conviction under these acts. No man in his senses would suggest that these pseudo-Christian quacks are wilfully and falsely pretending to be registered practitioners. Even the fools who seek their aid do not believe this. At the same time there is a grave difficulty in the way of prosecuting for false pretences. The defence would call a number of dupes who would swear to a cure having been performed on themselves." Therefore, in Great Britain and in many parts of America the only way of checking the evil is by enforcing the law against the healer who may be implicated in a case which terminates fatally. This view of the matter should be earnestly impressed upon the relatives of the dupes who have fallen victims to their fatuous folly, as well as on any physician who may chance to be concerned in the affair. In every instance of a like nature the doctor should stoutly refuse a death certificate, regardless of the social standing of the deceased or whatever the desire of the relatives to avoid a public scandal.

It would also undoubtedly act as a deterrent to the increasing custom of seeking relief at the hands of these impostors, if the lay journals were, like London *Truth*, freely to ventilate the subject and endeavor so to educate the weak-minded members of the community that they might see and turn from the errors of their ways before it was too late.

American Academy of Railway Surgeons.—The following officers were elected for the ensuing year: *President*, Dr. W. W. Grant, Denver; *First Vice-President*, Dr. J. F. Pritchard, Manitowoc, Wis.; *Second Vice-President*, Dr. J. P. Lord, Omaha, Neb.; *Secretary*, Dr. T. B. Lacey, Council Bluffs, Iowa; *Treasurer*, Dr. C. B. Kibler, Corry, Pa.; *Editor*, Dr. Fred J. Hodges, Ashland, Wis. The next meeting will be held at Omaha, Neb., in October, 1899. The committee of arrangements is J. P. Lord chairman; T. B. Lacey, and Fred J. Hodges.

News of the Week.

Tetanus was the cause of considerable medical interest in the neighboring districts of Jersey during the past week. In one instance it proved fatal, in the case of a six-year-old Hackensack girl, within six hours of her injury; and in the case of a man in Passaic, in whom intracerebral injections of antitoxin were tried for the first time in this country, the beneficial effects were said to be almost instantaneous and very pronounced.

Wintergreen Poisoning.—A rare instance of poisoning from oil of gaultheria occurred during the past week in Bellevue Hospital, the first in the history of the institution, it is said. The drug was taken by the patient as a cure for drunkenness. The quantity consumed was not definitely made out, it being, according to the man's statement before he became unconscious, ten cents' worth. Some years ago there occurred in the wintergreen-distilling region of Pennsylvania a similar death, in which an insurance company raised the question of intent on the part of the insured. It was shown, however, that in the process of production a watery fluid was obtained which the workmen drank with impunity, but the oil was considered dangerous and the supposition was that a mistake had been made in the two liquids, making the suicide non-intentional.

Resolutions Adopted by the Public Health Association.—The following is the substance of several resolutions adopted at the recent meeting of the American Public Health Association.

Offered by Dr. George H. Rohé: "*Resolved*, That the association reaffirms its indorsement of the creation of a national department of public health."

Presented by Dr. A. L. Gihon: "*Resolved*, That a committee of seven be appointed by the chair to wait upon the President of the United States, with a view of obtaining a bacteriological commission to go to Havana to study the cause and prevention of yellow fever."

Offered by Dr. A. Walter Suiter: A resolution urging the complete discontinuance of the use of the long-tube nursing-bottle.

Offered by Dr. U. O. B. Wingate: A resolution recommending the appointment of a committee for the purpose of presenting a definition of the term "epidemic," for the guidance of health authorities in executing such laws as call for the declaration of the presence of an epidemic.

Offered by Dr. Henry B. Horlbeck: A resolution urging upon the United States government the necessity of establishing a leper colony, similar to such institutions as now exist in Canada and Mexico, where lepers can be segregated.

Small-Pox in Ohio.—There has been during the past summer an epidemic in a town near Toledo, Ohio, which the local physicians called chicken-pox. There have been more than two hundred cases of the disease with no deaths, but the persistence of the epidemic and the fact that sporadic cases of small-pox were constantly appearing at various places in the neighborhood finally aroused suspicion, and the attention of the State board of health was called to the disease. An investigation showed that the epidemic affection was really variola, and measures have now been taken to control it. The churches and schools have been closed, all persons ill with the disease are isolated, and general vaccination has been ordered, under pain of arrest.

Prof. A. Jacobi, M.D., LL.D.—At the recent commencement of Ann Arbor University, Ann Arbor, Mich., the degree of LL.D. was conferred on our distinguished townsman, Prof. Abram Jacobi. An honor most worthily bestowed.

Lives Lost in a Hurricane.—Reports of the damage caused on the Georgia coast by the hurricane which passed over that region in the first week of October show that one hundred and twenty lives were lost and property was destroyed to the value of over $1,000,000.

A Death from Sunstroke occurred in the first week of this month in Akron, Ohio.

The Yellow-Fever Situation in the South has materially improved during the past week, owing to the advent of frosty weather, and it is now confidently anticipated that the governor of Mississippi, the treasurer, and other State officials, and the supreme court judges will soon emerge from their hiding-places—such of them, at least, as have not died of fright—and resume their interrupted duties. Two new cases were discovered the first of the week at Meridian, but the cool weather has so quieted the fears of the people that the usual panic did not occur. Quarantine has been abolished in many of the towns in Mississippi, and the poor negro reconcentrados are allowed their freedom to seek food and shelter. There were twenty new cases of yellow fever in Louisiana and eight deaths on October 15th and 16th, and twenty-two cases and two deaths in Mississippi, a total to date from the two States of two thousand and five cases and one hundred and eleven deaths.

Obituary Note.—Dr. Nathan Smith Lincoln, of Washington, D. C., died in that city on October 14th. He was born at Gardner, Mass., on April 3, 1828, and was graduated in arts from Dartmouth College in the class of 1850. He studied medicine under his uncle and namesake, Dr. Nathan R. Smith, of Baltimore, and received his medical degree from the medical department of the University of Maryland in 1852. He began practice in Baltimore, but removed in 1854 to Washington, where he resided to the time of his death. From 1857 to 1874 he was connected with the Columbian University, occupying successively the chairs of chemistry, theory and practice of medicine, anatomy and physiology, and chemistry. During the civil war he was surgeon-in-chief of the hospitals established in Washington under the quartermaster's department. He was for a number of years attending surgeon to Providence Hospital and later became consulting surgeon to many of the hospitals in the capital. He was a

member of the American Medical Association, and also of the American Association for the Promotion of Science.

Leech against County Society—Action without Merit.—An action to recover $10,000 damages brought against the County Medical Society in 1895, and also against Mr. W. A. Purrington as its counsel and Clarence W. Meade, police justice, was finally disposed of on October 10th. The action grew out of the arrest on the society's complaint in 1893, of one Leech, upon the advice of counsel that the medical law, notwithstanding its change by the revision of that year, made practice of medicine without license and registration a misdemeanor. The plaintiff some time before trial desired to discontinue the action without costs. The County Society, which had with plaintiff's consent amended its answer, agreed to this. Mr. Purrington and Judge Meade, however, refused to let the plaintiff discontinue unless he paid costs. This they did upon the ground that such consent on their part would imply some possible merit in his action, or a possible admission by them that their acts as counsel and magistrate were unauthorized by law. The trial judge held that the complaint stated no cause of action, but allowed the plaintiff permission to move at special term for an amendment, on condition of paying the defendants Meade and Purrington costs amounting to $210, but directed that if this amendment were not applied for within twenty days, the court directed the complaint should stand dismissed, with full costs and extra allowances of five per cent. to each defendant. Thereafter the plaintiff again asked Messrs. Meade and Purrington to allow him to discontinue, and they consented to do so, upon condition that he pay additional costs in amount of $100, which he did, thus fully admitting their contention that his action was without merit.

The Associated Physicians of Long Island.—The second regular meeting of this society, the establishment of which was recently mentioned in these columns, was held at Patchogue on Saturday, October 8th, under the presidency of Dr. William Browning, of Brooklyn. The following was the programme of the scientific session: 1, "Laryngeal Diphtheria," by Dr. Pedro F. Francke, of Far Rockaway; 2, "The Use of Digitalis in Chronic Organic Cardiac Disease," by Dr. William B. Gibson, of Huntington; 3, "The Treatment of Fractures of the Spinal Column," by Dr. Algernon T. Bristow, of Brooklyn.

The Yale Medical School.—The vacancy caused by the retirement of Dr. Lusk, of the physiological department at the Yale Medical School, has been filled by the appointment of Dr. Moore, formerly instructor of physiology in the University College Hospital, London.

Fatal Accident in an Insane Asylum.—The boiler in a wing of the asylum for dangerous and criminal insane at Iona, Mich., exploded on October 10th, killing one man and badly injuring three others.

Diphtheria prevails to an unusual extent in the lower wards of Elizabeth, N. J. Several cases are reported daily, but many families in which the disease exists endeavor to conceal the cases, and the work of the health board in stamping out the threatened epidemic is greatly impeded.

The Filth of Havana.—Dr. W. F. Brunner, sanitary inspector of the Marine Hospital Service, has made his first report from Havana since the war began. He says that the city is even more filthy than it was before, if such a thing can be imagined. There is not a great deal of yellow fever, simply because there is but little material for the disease to feed upon, but pernicious malaria, dysentery, and typhoid fever are raging. The deaths for the week ending October 6th were five hundred and thirty-six, which is larger than for any single week during the past year. There are still some reconcentrados, whose deaths from starvation help to swell the roll of mortality in that wretched Spain-ridden city.

Professor Ogston, senior surgeon to the Aberdeen Royal Infirmary, has resigned after thirty years' connection with this institution, on account of the pressure of professional and other duties.

Spread of Typhoid Fever by Flies.—In view of the reports concerning the spread of typhoid fever in camps through the medium of flies, and of the experiments demonstrating the possibility of this, as set forth in a letter by Dr. M. A. Veeder in a recent issue of the MEDICAL RECORD, the board of health of the village of Lyons has adopted the following regulation: "All water-closets, vaults, or other receptacles liable to infection by typhoid or dysenteric material, shall be properly inclosed with tight walls and such doors, screens, and covers as may be necessary to make their contents inaccessible to flies."

Public Medical Relief.—The French legislature passed a law in 1893, providing that every citizen who is without resources shall be entitled to receive gratuitous medical assistance. Under this law, a list is drawn up, in every commune, of the persons entitled to this relief, the total number of such representing about 3.5 per cent. of the population. Of these, about one-fourth availed themselves of the privilege of free medical assistance during the past four years. The cost to the State for medical attendance, drugs, and nursing, was 13 francs (about $2.50) for each patient, and the total expense to the State about $1,000,000.

Wanted: An Absorber.—Separate post-graduate medical schools will be abolished, only when they are incorporated with a complete but separate plant, as an integral part of a university. This idea was set forth by the president of the New York Post-Graduate Medical School, in his inaugural address at Chickering Hall, in October, 1882. It is impossible to teach undergraduates and graduates together in any considerable number, and the same teachers cannot give the time necessary in addition to their own duties for post-graduate instruction. The two departments will always be required.

Dr. Charles H. Chetwood has been appointed visiting surgeon to the Bellevue Hospital.

The Sixth International Otological Congress will be held in London, on August 8, 9, 10, 11, and 12, 1899. President, Dr. Urban Pritchard, professor of otology at King's College, London. The meetings will, by permission, be held at the Examination Hall of the Royal College of Physicians and Surgeons, Victoria Embankment. The subject chosen for special discussion is "Indications for Opening the Mastoid in Chronic Suppurative Otitis Media." A committee has been formed, the treasurer being Mr. A. E. Cumberbatch, 80 Portland Place, London, W.; and the honorable secretary, Mr. Cresswell Baber, 46 Brunswick Square, Brighton. The last congress met in Florence, under the presidency of Dr. Grazzi.

Western Surgical and Gynæcological Association.—The eighth annual meeting of this association will be held at Omaha, December 28 and 29, 1898. Titles of many papers are already in the hands of the secretary, and the coming meeting promises to be most interesting. The local committee of arrangements at Omaha is actively preparing for the entertainment and comfort of those who attend. Titles of papers should be sent to the secretary, Dr. George H. Simmons, Lincoln, Neb., as soon as possible, but not later than November 20th, to insure a place on the programme. Dr. D. S. Fairchild, of Clinton, Iowa, is president of the association.

The Red Cross and the Army Medical Department.—The vice-chairman of the Red Cross relief committee recently wrote to the President, asking why the intervention of the Red Cross relief committee should be longer needed, and why the government does not see to it that its own sick are provided for? To this Surgeon-General Sternberg has replied that there is now no further necessity for the Red Cross to provide for the sick soldiers, as the government has made ample provision for them, and he thinks "those patriotic and liberal citizens who have contributed so freely to aid in the care of our sick soldiers may now leave the matter in the hands of the government without any apprehension as to the result." Dr. Sternberg said that at first the emergencies of the war made the assistance of relief associations most valuable, notwithstanding the fact that it is the intention of the government to provide liberally for the care of sick soldiers. Supplies cannot always be provided at the proper place and time to meet an emergency, and, moreover, at the outset of the war the arrangements made for providing light diet for the sick were inadequate under the conditions which prevailed in the camps of instruction and among troops engaged in active operations. For this reason the presence of Red Cross agents, with their abundant supplies of delicacies for the sick, was of inestimable value. But now surgeons are entitled to draw sixty cents a day for each sick man in commutation of the regular ration, and this money can be used for the purchase of a proper diet, for which it is far more than sufficient. Furthermore, it is not at all probable that troops will again be sent so far away from their base of supplies.

Society Reports.

NEW YORK STATE MEDICAL ASSOCIATION.

Fifteenth Annual Meeting, Held in New York City, October 18, 19 and 20, 1898.

DOUGLAS AYRES, M.D., OF MONTGOMERY COUNTY, PRESIDENT.

First Day—Tuesday, October 18th.

THE meeting was called to order by the president, DR. DOUGLAS AYRES, of Montgomery County, at 10 A.M., in the Mott Memorial Hall.

Report of the Committee of Arrangements.—This report was presented by DR. FREDERICK HOLME WIGGIN, chairman of the committee, and showed that forty-nine scientific contributions had been offered, coming from eighteen counties in the State and from four other States.

Report of the Council.—This report was presented by the secretary, DR. FERGUSON. It stated that the library now contains nine thousand nine hundred and ninety-nine volumes, and that the financial condition of the association is very satisfactory, despite last year's donation of $2,000 to the Rush monument fund.

Report of the Committee on the Abuse of Medical Charity.—DR. FREDERICK HOLME WIGGIN, the chairman of the committee, presented this report. The main features of this work have already been quite fully presented to the readers of the MEDICAL RECORD. The committee, consisting of Drs. F. H. Wiggin, Parker Syms, and S. B. Wylie McLeod, of New York County, E. D. Ferguson, of Rensselaer County, and A. A. Hubbell, of Erie County, labored in season and out of season before the governor, before the committees of the senate and assembly, and in private; and in connection with the committees from the other medical societies these gentlemen did yeoman service against this great social evil. The report showed the chief differences between the last and the former dispensary bill, and asserted that the experience of all connected with charity organization had abundantly proved the necessity of empowering an impartial constitutional body, such as the State board of health, to make rules and regulations for the goverment of all institutions doing the semipublic service of relieving the sick poor.

DR. WICKES WASHBURN, of New York, one of the workers in this field, said that the arguments presented before the legislative committees by the opposition had been so flimsy that the senators did not hesitate to say that, if those opposing the dispensary bill had no better arguments to offer, they would better have remained at home. Another significant remark of an officer high in the councils of the State Homœopathic Medical Society was that he did not dare read before the home society the so-called arguments against the dispensary movement, lest they should lead the members to turn and indorse the bill.

Address by the President.—DR. DOUGLAS AYRES, of Montgomery County, in this address touched upon the great progress that had been made in medicine and surgery from the time of the introduction of the fever thermometer down to the present. He said that the use of the thermometer in clinical medicine had been first formally and comprehensively treated in 1835 by Becquerel, but this subject had received its first great impulse from Wunderlich in 1851. After observations in one hundred thousand cases this great physician felt justified in claiming that he had demonstrated that certain diseases, and especially typhoid fever, obey certain fixed laws, as evidenced by the range of temperature. The birth of that new and

wonderful science—bacteriology—was made possible by the development of the microscope. As long ago as the seventeenth century powerful magnifiers were wielded in a masterful way by such observers as Malpighius, Lieberkühn, and Van Leuwenhoek. In 1863 Pasteur had established the fact that certain diseases are due to micro-organisms, and after Koch's discovery of the bacillus of anthrax in 1875 Pasteur produced the identical disease by inoculcating animals with pure cultures of this bacillus. In 1882 Koch made the discovery of the specific cause of tuberculosis. The speaker then touched upon the discovery of the diphtheria bacillus by Loeffler, the Widal reaction of typhoid fever, and the wonderful triumphs of antiseptic and aseptic surgery growing out of the studies in microscopy and bacteriology. In view of these facts the speaker thought one was justified in saying that uncertainty in medicine was fast giving place to demonstration, and that the medicine of to-day is rich in those truths which go to make up the perfect science.

Conservative Surgery in Crushing-Injuries.—Dr. J. G. Hunt, of Oneida County, read a paper on this subject, based on a large factory experience of twenty-five years. He said that it was much more to a surgeon's credit to have saved one apparently hopelessly damaged limb than to have most skilfully performed a hundred amputations. In these days of antiseptic and aseptic surgery there seemed to be hardly any limit to the practice of conservative surgery in crushing-injuries. The paper contained a tabulated account of 887 injuries of this class, which may be summarized as follows: 566 were fingers, with 112 amputations; 38 were thumbs, with 14 amputations; 14 forearms, with 1 amputation; 42 arms, with 14 amputations; 14 shoulders, and no amputation; 30 injuries to the head and 5 trephinations; 24 injuries of the legs, with 12 amputations; 20 injuries of the feet, with 6 amputations; 42 injuries of the toes, with 10 amputations; 4 injuries to the spine and 5 injuries to the pelvis.

The Teaching of Physiology and Hygiene in the Public Schools.—Dr. Frank Overton, of Suffolk County, read this paper. He said that although for the past fifteen years New York and most other States had had a law compelling the study of physiology in our public schools, the instruction in this subject was more than a generation behind the times, and was anything but practical. It should be understood that physiology is a combination of mechanics and chemistry applied to the living body. If the subject was taught by a few demonstrations on small animals, etherized and treated tenderly, the children would not only obtain a far better idea of the true bearing of physiology on one's daily life, but it would give an effective quietus to the present antivivisection furor. Unfortunately, the evident intent of the compulsory law was to give a necessarily one-sided view of physiology, by dealing chiefly with the subject of the effects of alcohol on the human system.

Dr. Delancey Rochester, of Erie County, said that the teaching of physiology in the schools could be profitably extended to a consideration of the means of preventing epidemics of infectious diseases and the dangers of indiscriminate cohabitation. By reference to the lessons of botany, much could be taught the scholars about the relation of the sexes without bordering on the prurient, and the need for imparting such knowledge is only too well understood by physicians, who constantly hear one of the common diseases of women flippantly spoken of as "only a clap."

Dr. E. E. Holt, of Portland, Me., remarked that as physicians very frequently ignored the common teachings of physiology, as regards the care of the eyes and the direction in which the light should strike the book one is reading, it was obvious that such truths should be inculcated into the young and receptive minds of the pupils at our schools.

A New Method of Amputation at the Knee-Joint, Applicable to Cases of Senile Gangrene of the Foot.—Dr. Stephen Smith, of New York, described a method which he had successfully employed in a case of senile gangrene. The patient was a laborer, seventy-eight years of age, and of intemperate habits. For a month previous to coming under observation he had had gangrene of the great toe of the right foot. He was extremely emaciated and feeble. His arteries were everywhere calcified, and the pulsations of the heart were feeble and intermittent. The urine had a low specific gravity and contained a little albumin, but was free from sugar. The toe was black and dry, and there were some dusky spots on the dorsum of the foot and on the ankle. The capillary circulation was very imperfect. In this enfeebled state the only treatment possible was relief of pain and improvement of nutrition by proper attention to diet. For the first indication the man was given a pill of opium and soap, and, for the second, peptonized milk in large quantity and two ounces of whiskey every six hours. The local treatment consisted in the employment of antiseptic irrigations and moist antiseptic dressings. His general health improved decidedly under this treatment, but the gangrene steadily extended. He now desired more radical treatment. Amputation above the knee-joint for senile gangrene, the speaker said, had long been advocated and practised by such eminent surgeons as Valentine Mott and Jonathan Hutchinson. Recently Heidenhain and Kruger in Europe, and Powers, of Denver, had advocated this high operation. They allege, as a reason, that it is impossible to determine at what point the obstruction exists, and hence one is much more likely to secure healthy and well-nourished flaps by operating as high as the knee, or even through the thigh. Dr. Smith said that the structures about the knee are more largely supplied with blood than any of the tissues of the leg, and hence if an amputation could be performed in such a manner as to save all of the eight arterial branches in this region, it was evident that the flaps would be abundantly nourished. Bearing these anatomical facts in mind, Dr. Smith planned and performed the following operation: A straight incision was made from two inches above the upper border of the patella downward over the centre of that bone to the tuberosity of the tibia. From the lower extremity of this incision two curved incisions were made, having their convexities downward. One was made in the direction of the external border, and the other in the direction of the internal border of the limb. These two incisions were then joined posteriorly by a straight incision across the upper border of the calf. Next, the flaps were dissected up from the tibia and fibula, the patella was removed, and the knee-joint was disarticulated. It is important that the lateral incisions going from the lower extremity of the perpendicular incision should curve well downward, so as to conserve the desired blood supply. The patient was well stimulated for some hours before the operation, and required but little ether during the amputation. After it had been completed, his pulse was 96 and respirations 22. Primary union of the flaps took place. On removal of pressure from the artery in the groin, it was noticed that the flaps at once assumed a pink color, showing that the capillary circulation was fully and immediately secured. In due time the patient was supplied with an artificial limb, which enabled him to walk without a limp, using only a cane.

Dr. J. W. S. Gouley, of New York, said that the method just described was certainly an admirable one, yet he could not help thinking that the case was a most fortunate one, in that these arteries had all been

pervious. In his own experience he recalled having amputated under similar conditions and being surprised at the lack of hemorrhage. This was ascribed at the time to the very thorough application of the tourniquet, but a few days later the flaps sloughed and the patient died within a week. On dissecting the stump, not only was the popliteal artery found to be plugged, but the clot extended up to the upper third of the femoral artery. These cases of senile gangrene were very apt to present just such a condition. There were, of course, exceptions, as, for instance, the case just reported in the paper. The Esmarch bandage was surely contraindicated in cases of senile gangrene.

Dr. Smith remarked that, as the arteries in his case would not safely bear any considerable pressure, it was thought improper to apply the Esmarch bandage, and hence the artery had been controlled by placing a pad over it and making pressure on this with the finger.

Dr. M. C. O'Brien, of New York, cited a case in which he had performed amputation for gangrene. The operation had been done by him in 1882 on a man seventy-four years of age, and, following the custom of the Charity Hospital at that time, he had used the Esmarch bandage. The patient was found dead in bed twelve days after the operation. On post-mortem examination, it was found that from the point at which the Esmarch bandage had been applied to the extremity of the popliteal artery was one continuous clot, and also that all the other arteries contained plugs extending up from one inch to three inches. Only at the extremities of the flap, on the under side, had there been any effort at repair. Had the patient lived longer, gangrene would undoubtedly have recurred. The death of this patient, he thought, was very largely due to the use of the Esmarch bandage.

Subnormal Temperature.—Dr. Leroy J. Brooks, of Chenango County, read a paper on this topic. A distinction, he said, should be made between heat and fever, and the fact should not be lost sight of that a temperature that might be normal in health might be subnormal in disease. With the exception of temperature changes due to variations in the nerve centres, fever is due to specific infection. It was probable that the same toxins would produce opposite results in varying conditions of the system. In uræmia, for example, there is an elevation of temperature, but when decomposition takes place with the production of ammonæmia, the temperature becomes subnormal. A number of cases of carcinoma of the stomach and liver had been reported in which the temperature had been persistently subnormal, doubtless the result of infection and sepsis. The depressed temperature of cholera was doubtless the result of specific poisoning, the excessive drain, and the rapid and destructive nephritis and tissue changes. In some very malignant cases of diphtheria the temperature remains subnormal; and the same might be said of a type of pneumonia that had been quite prevalent during the past few years, in which death marked the patient as his own from the first. Cases of excessive venery had been placed on record, which had been associated with prolonged subnormal temperature and depression of the nervous system. Periodical alcoholics presented a subnormal temperature for several days preceding the outbreak, which was at once a sign of the lack of normal balance in the system and an indication for prompt treatment. Dr. Brooks cited several cases that had come under his own observation, in which a persistent subnormal temperature had been one of the earliest manifestations of an approaching nervous prostration as a result of prolonged strain. His conclusions were as follows: (1) Subnormal temperature is by no means uncommon; (2) it is a frequent prodrome of disease and an important indication for abortive treatment; (3) continued subnormal temperature is disastrous to the nerve centres; (4) subnormal temperature in diseases usually characterized by a high temperature is a grave symptom; and (5) it may result from primary disease or injury to the nerve centres, or from autotoxæmia.

Dr. Delancey Rochester laid stress on a deficient capillary circulation as a factor in these cases of subnormal temperature, and expressed the belief that, in the way of treatment, more could be accomplished by proper exercises and massage than by the administration of stimulants (such as strychnine) to the myocardium. There is usually a lack of perspiration or else a cold perspiration.

Dr. Overton remarked that he had observed a subnormal temperature and a condition commonly described by the older physicians as "biliousness" in many persons convalescing from acute diseases.

Dental Pathology in its Relationship to General Health.—Dr. Dwight L. Hubbard, of New York, read a paper with this title, having selected the subject, as he said, with the special object in view of directing the attention of the medical profession to a neglected field—a matter which once more proved the truth of the old saw, "What is everybody's business is nobody's business." He showed in a general way how many diseased conditions of the eye, nose, and throat are directly dependent upon abnormal states of the mouth, or rather of the teeth, and that pyorrhœa alveolaris, which physicians are prone to ascribe to reflex disturbances of the general system, is very commonly the result of caries of the enamel, acidity of the secretions, or syphilitic or other constitutional infections.

Dr. Rochester referred to two cases of most obstinate headache which had been finally cured through the good services of a competent dentist.

State Examinations of Milk for Tuberculosis.—Dr. Florence O. Donohue, of Onondaga County, presented this communication. He said that the opinion that tuberculosis was infectious was not a notion of yesterday, but had existed in more or less definite form for centuries. Most contagious diseases had a very definite period of incubation, but not so with tuberculosis, which might not make itself manifest for weeks, months, or even years after the introduction of the germs into the system. These germs entered the body either through the mucous membrane of the respiratory tract or that of the intestine. They might give rise to local tubercle, or pass on to the nearest lymphatic gland, developing a condition formerly described as "scrofula." It was always known that scrofula was the precursor of consumption, but the exact relation between the two was unknown. The human being found in the acid gastric juice a potent source of protection against this disease, for the tubercle bacillus throve in an alkaline medium, but was destroyed by acid fluids. The bovine race stood at the head of the list of animals which were susceptible to tuberculosis. The goat was not very susceptible, and the horse was rarely affected by it. For man, it was the tuberculous cow that was most to be dreaded, as cow's milk was consumed by invalids and infants whose gastric digestion was so disturbed as often to allow of the safe passage of the bacilli into the intestine. In milk from the tuberculous udder of the cow the bacilli were always found, and they had also been repeatedly found in the milk of cows whose udders were free from the disease. The statistics collected by the New York State board of health showed that for eight years previously every eighth death had been caused by tuberculosis. Tuberculosis cut off over twelve thousand inhabitants in the State of New York annually, no other disease approaching it as a cause of mortality in the human family. The State board of health was of the opinion that to tuberculous milk could be traced the tuberculosis of infants. There was at the outset of their labors

no legal precedent authorizing inspection of the cows throughout the State, but a large-hearted governor was instrumental in the passage of a bill with an appropriation of $5,000, to enable the first step to be taken. The "tuberculosis act" became a law in May, 1892, and authorized the board to inspect cattle within the boundaries of the State, and to cause those found to be afflicted with the disease to be killed. It had been estimated that about forty million dollars' worth of milk and its product were consumed every year in New York State, and, according to the census of 1892, there were nearly two million milch cows in the State. It had been abundantly proven that tuberculosis might be carried into the human system by tuberculous meat. A tuberculous cow might give tuberculous milk, and would do so if her udder was affected, and if she did not do so in a given case it was only a question of time when she would become a source of infection. The work of inspecting the herds was begun in Westchester County in 1892, and, at first, in the detection of the disease, the physical signs were alone relied upon. Later on, as a result largely of the experiments and observations of Prof. James Law, the tuberculin test was introduced, the board having convinced itself of the value of this test and of the innocuousness of the method. In the course of a year and a half twenty-two thousand cattle were inspected, and seven hundred ordered to be destroyed. Most of this work was done in the Hudson River district. This interference with the dairy business, and the pecuniary loss so entailed, caused the matter to be made the subject of a senatorial investigation. After careful consideration the committee decided that this important work of conserving the public health was not a matter to be taken up one season and dropped the next. The result was the establishment of a permanent tuberculosis commission on May 31, 1894, with all the powers of the State board of health. The small appropriation placed at its disposal only enabled the commission to establish the prevalence of bovine tuberculosis and its contagiousness. In most cases the disease could be traced from herd to herd. It was not found that any particular breed of cattle was immune. While New York took the initiative in this matter, it was not to-day by any means in advance of the other States. Sanitary science had long warned the public against the dangers of tuberculous milk, but ignorance, prejudice, and greed long held certain communities in what might truly be called a death grip. It was the duty of the medical profession constantly to preach the doctrine of the preventability of tuberculosis. The general belief was that infection most commonly took place by inhalation of the germs, as it was well known that the disease might be conveyed by dust. As milk was practically the only diet of artificially fed infants, this fact, together with the distribution of the tuberculous lesions in childhood, was sufficient to arouse the suspicion that tuberculous milk was the source of infection in such children. Tuberculosis in the cow was, as a rule, a chronic disease, and animals afflicted with it might yield a fair milk for a considerable time. The law was still in force in New York State, and the commissioners were still drawing their salaries, but for the past two years the work had been at a standstill.

Dr. Hiram A. Pooler, of New York, said that he had examined the milk of cows fed on brewer's feed and glucose grains, and had been able to establish a distinct difference between the milk from them and that from those fed on more healthful food. He had also observed that tuberculosis was more prevalent in districts in which this bad food was given to the cattle. In 1883 he had appeared before a legislative committee, and had presented the same arguments as had been brought forward by the reader of the paper. As a result a law had been passed that no unwholesome food should be given to cattle, and this law was still on the statute books, but it had led to endless argument and litigation because of the greater cheapness of the unwholesome food. Yet thousands of infants were to-day dying from disease conveyed to them through their foster mother, the cow.

Dr. H. O. Marcy, of Boston, said that one could hardly overestimate the good done by arousing public sentiment on this question. He had been deeply interested in the experiments recently made in Cattaraugus County, N. Y., on the refrigeration of milk. By agitating the milk while it is being frozen, and subjecting it to this process of ice crystallization for six or eight hours, it had been found possible on a commercial scale to eliminate almost entirely the pathogenic bacteria, and all but seven or eight per cent. of the water. This gave a product which was a good deal thicker than cream, and which had admirable keeping-qualities. The speaker said that he was disposed to share the view of some of the more enthusiastic advocates of this new method of treating milk, *i.e.*, that in the future it would be possible to eliminate even this small percentage of water, so that the milk might be distributed as a solid product like butter.

Dr. H. D. Didama remarked that if all the tuberculous cows in the State were destroyed, and all the others were kept under suitable supervision, there would be no occasion for refrigerating the milk.

Dr. A. T. Van Vranken asked if a relation had been established between bovine tuberculosis in certain localities and human tuberculosis in the same localities. This, it seemed to him, was an important link in the chain of evidence.

Dr. S. A. Knopf, of New York, said that he had given considerable attention to tuberculosis, and had formerly been of the opinion that in the majority of instances the tubercle bacilli entered the system through the respiratory passages; now, however, he was a convert to the view that the channel of infection was in the digestive tract. The frequency of tuberculosis in infants was explained by the fact that milk was almost their exclusive diet, and their general health was often feeble. The germs, having gained an entrance, found in the lungs of these feeble children the place of least resistance, and consequently they multiplied there.

Dr. Donohue said that the inspectors had found bovine tuberculosis to be exceedingly prevalent in the Hudson River district and eastern part of the State, while there was little or none in the western part. There was no doubt in his mind that much of the milk coming to New York City was infected with tuberculosis. The tracing of the disease directly to human beings must remain impracticable, but it was not at all necessary, as the so-called missing link was supplied by the analogy observed in experiments among animals.

The Cases of Pulmonary Tuberculosis that Cannot Go Away from Home.—Dr. Delancey Rochester, of Buffalo, read this paper. He said that it should ever be borne in mind that in the treatment of pulmonary tuberculosis the physician was called upon to treat individual cases. A most essential part of the treatment was to have the patient in the open air and sun as far as possible. The avenues of secretion should all be kept open, as the normal excretory function of the lung was seriously interfered with. Dr. Charles G. Stockton had first suggested to him the employment of induced sweating as a means of controlling the profuse night-sweats of phthisis. A full hot-water bath should be taken once or twice a week, and a tepid or cool sponge bath every morning, followed by vigorous rubbing. Very few general rules could be laid down regarding the diet of consumptives. Rare beef, eggs, baked potato, boiled rice, and boiled young beets were especially desirable articles of diet; milk should be taken freely, but not at the same meal

as meat; cocoa and chocolate were nutritious; coffee and weak tea might be allowed in moderation. If there was hectic fever or the physical signs indicated marked involvement of both lungs, exercise should be avoided or taken with extreme moderation. Too much exercise acted deleteriously, because of the deficient oxygenating area. When there was only a slight local bronchitis or a slight pulmonary infiltration, exercises were useful. The local treatment consisted in the local application of medicinal agents. Sprays and inhalations were our only means. Sprays rarely reached beyond the vocal bands or the first rings of the trachea, and the same was true of medicaments dissolved in the fixed oils; but inhalations of the essential oils reached much further. Of these, oil of peppermint was one of the best, and it was conveniently employed in the form of the essence. A cheap and efficient inhaler might be improvised from a cigar holder packed tightly with absorbent cotton. It was intended for constant use. Five or ten drops of the following mixture should be placed in the inhaler at a time, and should be renewed every two or three hours: Menthol, one part; spirits of chloroform, guaiacol, terebene, eucalyptol, and thymol, of each two parts. Guaiacol could be made into a perfect emulsion with milk of magnesia, and balsam of copaiba, which often acted beneficially, could be easily administered in an emulsion made with mucilage of acacia and syrup of tolu. For the emulsification of the guaiacol and the cigar-holder inhaler, Dr. Rochester said he was indebted to Dr. W. H. Woodbury. The copaiba could be conveniently prescribed in the following formula:

℞ Bals. copaibæ	6
Mucil. acaciæ	50
Morph. sulph.	0.10
Ol. menth. pip.	0.10
Ol. amygdalæ amar.	0.20
Syr. tolut	44

Four cubic centimetres to be taken every four hours.

A number of physicians had reported favorable results from the use of tuberculin and antituberculous serum early in the disease, but he had not been able personally to confirm these. He had, however, had some excellent results from the hypodermic use of nuclein. In the administration of creosote, care should be taken to have a pure article, to give it always after food, to increase the dose gradually, to watch the urine, and to be on the lookout for gastric disturbance. When it became necessary to reduce the dose, it should be done gradually; sudden stopping of a large dose often produced unpleasant effects. By proper attention to details, he had been able to give two cubic centimetres of creosote three times daily for three months at a time. When cod-liver oil did not produce gastric disturbance, it was still our sheet-anchor. An emulsion freshly made by a competent pharmacist was much to be preferred and would generally be well borne. In the treatment of the cough, if it was due to pleurisy, the chest should be stripped. When there was bronchial irritation, the cough was best treated by inhalations or by the administration of hydrocyanic acid and chloroform water. Stimulating expectorants rarely have any place in phthisis, and opium should be withheld, except in the last stages of the disease. Hæmoptysis was best treated by rest in bed and the hypodermic use of morphine or atropine. The use of antipyretics was to be deprecated. The sweats were best combated by general treatment, but among medicinal agents atropine had proved in his hands superior to all others. When there was excessive vomiting, drachm doses of oxalate of cerium were beneficial.

Dr. Knopf said that, while the climatic treatment was excellent, it was beyond the reach of the majority of tuberculous patients, who commonly lived near the great centres of population. He firmly believed that every State should have special sanatoria with accommodations for poor phthisical individuals, and that this was a worthy cause in which to enlist the services and influence of the members of the association. The plan had proved very successful in Germany. As to the matter of expense, it should be noted that, while the daily per capita cost in the general hospitals of New York City was $1.16, it was only $1 in the excellent special sanatorium of Dr. Trudeau, in the Adirondacks. In these special sanatoria, moreover, twenty-eight per cent. might be cured—by which was meant that the person was restored to a condition in which he was enabled to return to his occupation. In our general hospitals almost no tuberculous patients recovered, so that the money spent on phthisical patients in these institutions was virtually thrown away. He would treat the cough of phthisis very largely by discipline, as it was, for the most part, unnecessary and very injurious. In order to avoid undue shock in the use of baths, it was his custom to begin with a dry massage, then use use frictions with alcohol; next, alcohol and water; and, finally, to use douches. While sunlight was exceedingly beneficial to these individuals, they should not be exposed to it indiscriminately—indeed, the head should usually be well protected from the direct rays of the sun. When there was pleurisy, nothing acted so well as the old-fashioned dry-cups.

Dr. John M. Farrington, of Broome County, asked for information regarding the best treatment of very severe pulmonary hemorrhage. In one such case, when each act of coughing brought up a fresh gush of blood, he had given chloroform until the patient was insensible, and had then kept her under the influence of morphine for hours. In this particular case, on several occasions this plan of treatment had yielded very gratifying results.

Dr. Knopf said that a most excellent and tried method was the immediate temporary ligation of the four extremities. He had repeatedly seen it check severe hemorrhages very quickly.

Dr. Rochester, in closing, said that he would be almost afraid to administer chloroform in profuse pulmonary hemorrhage, but he would not hesitate to give one-fourth to one-half of a grain of morphine, and repeat it, if necessary, until the respirations had been brought down to 12 or even 8. The common error was to give too small a dose of morphine in such cases.

Genital Neuralgia and the Genito-Reflex Pains.—Dr. F. P. Hammond, of New York, treated this subject from the standpoint of the clinician, quoting freely from his clinical records to illustrate the many different types of nerve irritation met with. He said that there were eight genital crises in women, viz.: (1) The establishment of menstruation; (2) the menstrual period; (3) marriage; (4) pregnancy; (5) abortion; (6) parturition; (7) the puerperium; and (8) the menopause. It was small wonder, then, that women were so frequently the victims of genital neuralgias. In the treatment of perimetritis and adhesions he found pelvic massage extremely useful; it was, in fact, a series of nerve stretchings. Strychnine was often given to hysterical subjects, but it seemed to be a direct irritant to the nerves in these cases. Here he would give the preference to caffeine-sodium salicylate.

Memoranda.—Dr. H. D. Didama, of Syracuse, in a paper with this brief and rather vague title, described, in his humorous way, some of his clinical experiences, and made deductions therefrom.

Indolent Ulcers of the Leg.—Speaking of this very common condition, he advised painting with tincture of iodine, and filling up to a level with the surrounding skin with subnitrate of bismuth. The limb was next almost encircled by a series of strips of adhesive plaster, and over this absorbent cotton and an elastic

flannel bandage were applied. The bandage should reach from the ankle to the knee, and the dressing should be renewed daily after washing of the parts with soap and water. Under this treatment it would be found that granulations would soon spring up, and that the laboring man need not desist from his work. After the ulcer had healed, it might be of advantage for the patient to wear rubber-webbing bandages—not the black-rubber bandage.

Urethral Caruncle.—He advised injecting through a very fine hypodermic needle a four-per-cent. solution of cocaine into the growth. This would secure anæsthesia, not only of the sensitive neoplasm, but also of the surrounding parts, and then, with delicate scissors, the caruncle and a thin layer of the adjacent mucous membrane could be painlessly removed.

Epistaxis.—This, he said, could be frequently arrested, even when quite severe, by the administration of one grain or more of opium. He had used this treatment for the past thirty years, and it had proved successful even in cases in which astringent injections and plugging of the nares had not succeeded.

Bronchiectasis.—When the patient suffered from severe attacks of coughing several times daily, and expectorated or vomited up large quantities of fetid pus, he stated that improvement quickly followed if the patient would, from time to time, assume the recumbent position and allow the head to hang down over the side of the bed. In this position the pocket containing the fetid accumulation was inverted and its contents were discharged without much effort.

A Case of Fistulous Opening between the Ilium and Bladder.—Dr. H. O. Marcy, of Boston, reported an interesting case of this kind upon which he had operated. He also exhibited a vesical calculus and nine hundred and seventy-two gall stones which he had quite recently removed by operation.

Large Abdominal Tumors.—Dr. F. H. Wiggin, of New York, exhibited two large abdominal tumors which he had recently successfully removed by laparotomy.

Tuberculosis of the Middle Ear.—Dr. Seymour Oppenheimer, of New York, presented this paper. He stated that aural tuberculosis might occur at any age, but was most commonly met with in children between the ages of two and twelve years. Tubercle bacilli had been found in the purulent discharge from the middle ear in four out of twenty-five individuals, all of whom had finally succumbed to tuberculosis. In all but three of the cases in which tubercle bacilli were found there were marked evidences of tuberculosis elsewhere. A study of a large number of statistics showed that in 2.4 per cent. of tuberculous individuals the ear was involved. The first indication was the sudden appearance of pus in the external auditory canal, without previous evidence of disease there. The character of the affection was established by the discovery of the tubercle bacilli in the pus, or by the physical signs of tuberculosis in other parts of the body. The affection was characterized by an inflammation of low grade, with caries of the intratympanic bones. The perforation in the membrana tympani was circular, and its edges were thick. One distinctive feature was the bluish-white appearance of the membrane. More or less characteristic was the presence of two distinct perforations in the drum. An additional sign, which was of value when present, was enlargement of the peri-articular glands. The early diagnosis of tuberculosis of the tympanum was of great importance, as the early use of appropriate measures afforded a chance of getting rid of the local disease. The prognosis as regards hearing was unfavorable, and when the bone became involved the life of the individual was threatened. Chloride of zinc and lactic acid were probably the best local applications. The usual constitutional remedies for tuberculosis were important here.

Lantern-Slide Exhibition Relating to Prostatic Diseases.—Dr. Samuel Alexander, of New York, gave an address on this subject, and illustrated by numerous photographs the pathological anatomy of enlargement of the prostate. He said that there were probably few subjects about which there was such a diversity of opinion, and about which so little was actually known. This was because up to the present time all investigations had been imperfect, and had not taken a sufficiently broad view of the subject. It was important to decide what was the ultimate cause of the prostatic enlargement, the character of this enlargement, and the cause of the retention of the urine. Personally, he believed that in the vast majority of cases the growth was glandular, and that the obstruction to the outflow of urine was in the first instance mechanical, and afterward was the consequence of the vesical muscle being inserted into the prostate itself.

Anthropological Rambles in the Island of Java.—Dr. H. Ernst Schmid, of White Plains, gave an entertaining lecture on this topic, which was freely illustrated by lantern views.

Second Day—Wednesday, October 19th.

The president announced the appointment of the following committees:

Committee on Abuse of Medical Charity.—Dr. Wickes Washburn, of New York, chairman; Dr. E. D. Ferguson, of Troy; Dr. N. J. Hepburn, of New York; Dr. Delancey Rochester, of Buffalo; and Dr. Parker Syms, of New York.

Committee on Legislation.—Dr. E. Eliot Harris, of New York, chairman; Dr. L. J. Brooks, of Norwich; and Dr. E. D. Ferguson, of Troy.

Reception of Delegates.—Upward of twenty delegates, representing the State societies of Connecticut, New Jersey, Pennsylvania, Massachusetts, Maine, and Vermont, were in attendance and were formally received by the association.

Dr. Oliver T. Osborn, of New Haven, on behalf of the Connecticut Society, called attention to the action taken by that society in opposition to the now well-known senate bill, the object of which is to put a stop to vivisection in the District of Columbia.

On motion of Dr. E. D. Ferguson, the New York State Medical Association indorsed this action of the sister society.

Acute Frontal Sinusitis.—Dr. Henry L. Swain, of New Haven, read this paper. He stated that this affection had been more common since the prevalence of the grippe, and, as repeated attacks seemed to lower the powers of resistance, it was probable that it would be still more frequently encountered in the future. In some cases, especially those becoming subacute, the ocular symptoms were very prominent. The more stormy and violent attacks, as a rule, clear up much more rapidly than those characterized by less urgent symptoms. The reason for the occurrence of infection of the sinuses in one case, and of only an acute coryza in another, was probably to be found in the fact that in cases of the former class there was usually present some lesion, the effect of which was to narrow the outlet of the sinus. The secretion having once become damned up in the sinus, pressure resulted; and this, in turn, caused congestion, tumefaction, and hypertrophy. The retention of the secretion in the sinus offered favorable conditions for the lodgement and multiplication of micro-organisms. The secretion was actually more profuse at one time than at another, and the greater intensity of the pain of frontal sinusitis in the morning was probably explained by this fact. The prognosis, under appropriate treatment, was good, although not infrequently recovery took place without any treatment. Our effort should be to reduce the

trend of blood to the head, and to promote cleanliness by hot irrigations with saline solution and hot applications over the nose. If the nostrils were much obstructed, relief would be afforded by spraying with a solution of Seiter's tablets. Cocaine might be used by the physician for reducing the tumefaction, but should not be placed in the hands of the patient. It was safe, however, to permit him to use a solution of suprarenal extract; and a combination of cocaine and suprarenal extract, when used by the physician, afforded a speedy and effectual means of diminishing the obstruction. The object of the paper was to encourage the use of local treatment in this malady.

Dr. Rochester remarked that he had succeeded in reducing the tumefaction by combining a four-per-cent. solution of cocaine with a two or three per cent. solution of suprarenal extract.

True and False Medical and Other Charities.—Dr. Wickes Washburn, of New York, read this paper. He said that only now were we beginning to appreciate the fact that mendicancy was a disease. Mrs. Josephine Shaw Lowell, a life-long worker in charity, said that there were two fundamental axioms which every charity organization society established in the last twenty-nine years had taught and practised, viz.: (1) In order to help any person who was in chronic distress, one must find out the cause; and (2) having found the cause, one could not hope to cure a disease except by patient, intelligent, personal work. The initial cause of much of the pauperization of the present day, the speaker said, could be traced to the dispensaries and to the medical profession. He had obtained, through the United Hebrew Charities, the record of the following instructive case: A woman, named Esther, had been under treatment at four different dispensaries for "women's diseases," at six dispensaries for "internal medicine," in two for "nervous disease," in four for "nose and throat disease"—and all within a period of eighteen months. The recent efforts to secure legislation for the control of the dispensary evil had been met by opposition from sources which would have been hardly suspected, and the statement, on good authority, that $100,000 had been wrongfully taken from the treasury of the city of New York during the past year by three institutions, lent additional significance to this fact. The case of "Esther" conclusively proved the necessity for co-operation, if one would effectually apply the remedy for this social evil. Last year, by an unfortunate misunderstanding, the State Homœopathic Medical Society was arrayed against those who sought relief from the legislature; but this had been adjusted, and the prospect was that the entire medical profession of the State would make a united effort during the coming winter for the much-needed legislative restriction of the dispensary abuse. A dispensary could not now become incorporated without approval of the State board of charities, but, it having once become incorporated, this board practically had no control.

Dr. William Finder, of Troy, ascribed most of the present dispensary abuse to the medical profession, primarily and largely to the baneful custom of treating the clergy without remuneration.

Dr. Leroy J. Brooks, of Norwich, placed the blame for the existence of this evil upon the attitude of the larger cities, and especially New York.

Dr. A. Palmer Dudley, of New York, objected to this statement, and asserted that it was not the medical profession of New York City that was to blame, but rather the whilom students of the postgraduate schools, who, after returning home, sent patients to these institutions for free treatment.

Some Thoughts on the Rational Treatment of Disease.—Dr. Chauncy P. Biggs, of Ithaca, read this paper. He said that as the regular profession did not proclaim any adherence to exclusive dogmas, each physician was at liberty to use any remedy or method of treatment coming within the bounds of reason. Unfortunately, physicians often believed in and used remedies empirically without any good reason for the faith that is in them. If the efforts of the physician were directed toward assisting nature, the best results might be expected.

Medicine without Drugs.—Dr. Solomon Solis Cohen, of Philadelphia, delivered an address on this topic. He took the position, to use Bigelow's words, that "the function of the physician is to conduct his patient safely through the storm of disease into the haven of recovery." Habit and environment exerted a powerful influence on the human organism, both in health and disease. Just as mental emotion might at times give rise to disease, so the physician might occasionally use it to advantage in a therapeutic way in a few carefully selected cases. The speaker then directed attention to the influence of high altitudes in increasing the hæmoglobin and the number of red blood corpuscles. Regarding organo-therapy, the speaker said that such treatment truly supplemented the natural recuperative efforts of the organisms. He had found the suprarenal extract the most reliable remedy for raising the blood pressure, thyroid extract very useful in restoring the functional activity of the skin and kidneys, and thymus extract a valuable means of improving general nutrition.

Drugs versus Cardiac Insufficiency.—Dr. Oliver T. Osborn, of New Haven, read this paper. He advocated in urgent cardiac failure the hypodermic use of morphine and atropine with a small dose of nitroglycerin. When digitalis was indicated, $\frac{1}{10}$ to $\frac{1}{50}$ gr. of digitalin should be given subcutaneously, and the patient should be kept in the recumbent posture until the effect had passed off. After compensation had been restored, it was well to give the fluid extract of cactus, in doses of ten to twenty-five drops; its action was very much like, but superior to, that of strophanthus.

Treatment of Fractured Patella by Open Operation.—Dr. Charles Phelps, of New York, read this paper. He stated that at the present time the majority of surgeons favored some form of operative treatment. Of ninety surgeons recently addressed by Dr. Charles Powers, of Denver, nineteen did not express an opinion because of lack of experience; nine said they would operate in all cases in which there were no distinct contraindications; forty-one would operate under specified conditions; twenty-one would not operate in any case. His own experience with the operative treatment comprised one hundred and seventeen cases, and of this number it was exceptional not to find the capsular fibres intruded between the fragments. In none of his cases had there been reason to believe that the apparent osseous union was not real. The power of complete flexion was invariably restored after suture, and convalescence was much more rapid than under non-operative treatment.

Report of Nominating Committee.—The nominating committee made the following report regarding the officers for the ensuing year: *President*, Dr. Joseph D. Bryant, of New York; *Vice-Presidents*, first district, Dr. J. G. Hunt, of Utica; second district, Dr. D. C. Moriarta, of Saratoga Springs; third district, Dr. F. W. Ross, of Elmira; fourth district, Dr. W. M. Bemus, of Jamestown; *Secretary*, Dr. M. C. O'Brien, of New York; *Treasurer*, Dr. E. D. Ferguson, of Troy; *Members of Council*, Dr. John P. Sharer, of Little Falls; Dr. Charles H. Glidden, of Little Falls; Dr. C. E. Fritts, of Hudson; Dr. L. J. Brooks, of Norwich; Dr. Delancey Rochester, of Buffalo; Dr. C. Ellery Denison, of New York; Dr. Frederick Holme Wiggin, of New York.

(To be Continued.)

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, October 10, 1898.

W. W. Van Arsdale, M.D., Chairman.

A Case of Primary Infection of the Tongue by Mycosis Leptothriciæ.—Dr. James P. Tuttle, in presenting this case, said that leptothrix growth was supposed to be on the surface, and always present in the mouth, particularly in the tonsils and on the faucial region. Its development in the body of the tongue, however, seemed to be unique. The patient, a young man who had long been under his observation, consulted another physician, during Dr. Tuttle's temporary absence, for a sore on his tongue. This was about a year ago, and the physician in question diagnosticated it as specific disease, and treated it accordingly. He also introduced a hypodermic needle into one of the nodules which were present. On coming under the speaker's observation last February, the patient's general health was broken down, and there were extensive ulceration and nodulation on the tongue. At present, there was only one nodule remaining, on the tip of the tongue. There were previously about ten nodules. It being thought that the case was possibly one of actinomycosis, a microscopical examination was made by Dr. Heitzmann on June 10th. The report on this examination stated that the specimen consisted of greatly hypertrophied stratified epithelium, and greatly hypertrophied papillæ, showing that the growth was beneath the epithelium. Below the latter was seen myxomatous connective tissue, with numerous inflammatory corpuscles. Running throughout the specimen were numerous large and thick leptothrix threads. The blood-vessels were present in small numbers only. Dr. Tuttle said that after excision of the nodules healing was exceedingly slow. Incision and cauterization with nitric acid were also tried, but with no better result. Subsequently it was found that simple incision and cauterization with nitrate of silver accomplished far better results. This was contrary to the opinion of most observers who have treated cases of this kind. The nodules were very painful at times. No other portions of the buccal cavity were infected.

Dr. Lincoln said that he had seen the base of the tongue almost covered with the growth, but the tissue was not so hard as in the case just presented. Fraenkel had claimed that the growth penetrated through the submucous tissue, but, so far as he knew, there was only one such case on record.

Demonstration of Intestinal Anastomosis and Invagination by Means of a New Forceps.—Dr. Ernest La Place, of Philadelphia, presented an instrument that he had invented, and which was intended as a substitute for the Murphy button. The desirability of a substitute for the ingenious device of Murphy was evident from the danger of intestinal obstruction attendant upon its use. The great desideratum was to make intestinal suture easy and safe even in the hands of those of moderate experience. Dr. La Place said that the instrument consisted of a double hæmostatic forceps, each jaw of which was made in the form of an elliptical ring. This ring furnished the desired support for the suture. Having served this purpose, the rings were removed, and this was the distinctive feature of the method. The instrument was made in five different sizes, but for almost all purposes size No. 4 would answer admirably. In the performance of gastro-enterostomy with this instrument, the parts to be approximated were placed side by side, and an incision was made in both the stomach and gut sufficiently large to allow the introduction of the instrument. The forceps being closed and caught, very accurate approximation was secured, and the suturing was rendered very simple and almost mechanical. After suturing, the blades of the instrument were withdrawn separately, like the blades of an obstetric forceps, and one or two sutures then sufficed to close the openings through which the blades had been withdrawn. In an end-to-end anastomosis it was important that the mesenteric borders should be accurately approximated; consequently it was well to insert two stitches before the introduction of the forceps. If the gut did not fit the size of forceps at hand, it would be found more convenient to use four instead of two preliminary stitches. Where it was desired to invaginate the ends, Dr. La Place used a forceps having long and slender "alligator" jaws. The gut was seized and clamped in the jaws of this instrument, and then, the gut having been invaginated, the suture was inserted into it. The slender instrument was then withdrawn and an additional suture or two completed the invagination.

Dr. W. B. Coley said that he had become interested in the method when Dr. La Place demonstrated it on a dog last summer. There would always be a number of surgeons who would find it desirable to use some such mechanical device.

Mechanical Devices will Eventually be Abandoned.—Dr. J. P. Tuttle said that he was of the opinion that as experience in intestinal surgery increased all mechanical devices would be abandoned, and that sufficient support could be obtained by proper tension on the sutures. The dangerous part of the Murphy button was the spring which guarded against leakage during the first few days. Personally he never trusted the Murphy button alone, and Dr. Murphy had told him that when he had time he reinforced it with a Lembert suture. He had under observation five patients, in all of whom Murphy buttons had failed to be discharged, and it seemed to him that the danger of intestinal obstruction in these cases had been greatly exaggerated. One patient had been kept under strict surveillance for four months, and certainly during that time the button had not been passed.

Dr. C. N. Dowd said that he felt that the instrument had a place in intestinal surgery, for anything which facilitated the suturing of the intestine was useful, and in this particular instance the instrument had the additional advantage of making the approximation rapidly and firmly, and not leaving any mechanical device behind.

Dr. McGrau, of Detroit, said that it seemed to him better, if possible, to do away with all mechanical appliances. He had used the Murphy button because of the constant pressure which it exerted, and which guarded against leakage. In some cases, particularly those in which it was desired to make a lateral anastomosis, as in gangrenous hernia, he thought the surgeons might in time go back to a method of elastic suture. This method he had devised and advocated some years ago, and was again employing. In cases in which there was a fistula, and there was no occasion for an immediate passage, such a method seemed to him to present certain advantages.

Dr. H. Lilienthal said that any instrument which made intestinal suture easier was to be commended, and this particular instrument seemed well adapted for the purpose for which it was intended. He was of the opinion that it made a cleaner suture than even the Murphy button, because it did away with the necessity for handling the gut. Suturing in gastro-enterostomy was always difficult, and hence the Murphy button had been hailed with delight. The device exhibited this evening certainly made a quick suture, and left no foreign body to drop into the stomach. The speaker said that he had had considerable experience with the Murphy button, particularly in the large

intestine, and whenever he had been sure that the mucous membrane was inside he had omitted the Lembert suture, and had felt no anxiety on that account. In the use of the instrument of Dr. La Place for an end-to-end ileo-colostomy, a purse-string suture would be needed to pucker up the gut and make it fit the instrument, or else the invaginator should be used.

The Murphy Button Dangerous.—Dr. Coley said that he believed there was a distinct disadvantage in the button, because of its liability to remain behind. The only time he had used it in gastro-enterostomy the button had fallen into the stomach and had been removed later on by another surgeon. The instrument under discussion seemed to him to have its chief sphere of usefulness in gastro-enterostomy. The constant spring pressure of the Murphy button might prove in itself to be a source of danger by causing rapid necrosis of the tissues pressed upon.

Dr. La Place said that his reason for devising the instrument was that he believed that all intestinal suturing was better done when a circular support was used. Dr. Murphy had told him that he had always thought his button would be useful in cases in which rapid operating was imperative, but he believed that when more deliberation was proper it was preferable to perform intestinal suture. He had used his new forceps on the human subject in only two cases—both gastro-enterostomies—and they had proved entirely successful.

Resection of the Liver.—Dr. H. Lilienthal presented a specimen of resected liver, which had been removed by him from a man, forty-four years of age. The patient had been admitted to the medical side of the Mount Sinai Hospital early last August. He had had a certain amount of diarrhœa, was very cachectic, and appeared to be about sixty years of age. There was a hard and not very sensitive tumor above the umbilicus, which was very movable. The surgeons were undecided as to the nature of the tumor, but on abdominal section it proved to be the edge of the left lobe of the liver containing a growth. The abdomen was carefully explored with an entirely negative result. A double temporary ligature of catgut was put around the portion of liver to be resected. Then, while strong traction was made, a tentative cut was made in the liver, and, to his surprise, he found that the vessels were drawn out so that they could be easily ligated as the resection proceeded. This was done, and a large piece of the liver resected without any hemorrhage. A large piece of sterilized rubber tissue was placed on the intestines and a piece of gauze against the raw surface of the liver. These were removed in a few days. The patient's general condition improved markedly, and he returned to his home. Dr. Lilienthal said that he had just heard, however, that the diarrhœa had returned. The pathologist of the hospital reported that the tumor resembled a perithelioma—a tumor such as was found in the suprarenal bodies. The pathologist stated that almost microscopical tumors of the suprarenal body of this nature might cause large metastatic tumors of the liver.

Old Spa in London.—London at one time contained many mineral wells and spas, but all have been drained away into the sewers and have disappeared, with the exception of the Streatham Spa, which still exists on a dairy farm in a village to the east of Streatham High Road. This little known Spa has been in existence for over two hundred years and in the eighteenth century was a fashionable resort. For many years afterward the water was supplied to the London hospitals. A trade is still done in the water, which, as the chemical analysis shows, contains valuable medicinal qualities, but no effort is made to make the spa well known. —*London.*

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, October 4, 1898.

Frederick Peterson, M.D., President.

Double Athetosis from Infantile Cerebral Palsy.—Dr. L. Stieglitz presented a boy, sixteen years of age, the youngest of several children. All the others had been well at birth, but he had been born asphyxiated, although the labor was normal. He did not walk until five years old. At the age of seven years he had scarlatina. The speaker said that after that time the peculiar movements which the boy now exhibited became worse. Soon after birth it was noticed that he moved his arms, legs, and head in an unusual way. After a few years the movements remained at a standstill until the attack of scarlatina. On voluntary motion, the movements were aggravated. His face showed a constant succession of grimaces. The peculiar movements affected the trunk, as well as the upper and lower extremities. The tongue and the eyeballs were free from these movements. The deep reflexes of the arms were lively, as were also the knee jerks, but not more so than in many healthy children. His mental development was very good, but his physical development was rather deficient. Close study of the movements had led the speaker to the opinion that the case was one of double athetosis, due to infantile cerebral palsy, the result of a lesion occurring at the time the child was born asphyxiated. These cases rarely showed any defective mental development. In cases of athetosis the lesion was probably usually in the lenticular nucleus or in the corpus striatum, and it was not surprising that there was no epilepsy or disturbance of the mental development.

Dr. B. Sachs said that, as he recalled similar cases he had seen, he was forced to the conclusion that the one just presented was a most excellent illustration of the combination of the choreiform and the athetoid movements. The probability that they were not cortical was, of course, very great. That there was a direct relation between the typical spastic cases of infantile cerebral palsy and the choreic and choreiform athetoid cases, he verily believed. In a number of cases he had found that peripheral restraint on these unruly members, kept up for months, had had a remarkably good effect.

Dr. Edward D. Fisher said that he now had under observation a boy of the same age, who presented almost exactly the same symptoms, except that they were not quite so severe. It seemed to him that the lesion was very apt to be subcortical. The absence of epileptic conditions did not mean necessarily that the lesion was not a cortical one. The lesion was certainly not an extensive one in the motor tract.

Dr. Joseph Collins said that he agreed entirely in the diagnosis made by Dr. Stieglitz, and he was glad to see such a typical illustration of this group of cases. He did not favor the name "athetosis," nor would he apply it to this case. Taking the case in its entirety, he would look upon it as an example of the choreic form of infantile cerebral palsy. He was inclined to think that the involvement was primarily of the corpus striatum and quite as much so of the optic thalamus, and he based this opinion on the study of the patient's motions, coupled with his spastic gait. The question of the existence of epilepsy in such a case did not seem to him of much importance, for the opinion was growing yearly that idiopathic epilepsy was a cortical disease. He had tried peripheral restraint for months at a time in a case of his own, without observing the slightest benefit, even temporarily.

Dr. Peterson thought the case was undoubtedly one of post-paralytic morbid motion, and he agreed with Dr. Collins that athetosis was not a proper name.

The position was athetoid, but the movement was rather a paramyoclonus. The term "athetosis" should be applied to a slow, vermicular movement.

Dr. C. A. Herter remarked that he thought the term was applied to much more rapid movements, and it did not seem to him that there was a proper pathological basis for such a distinction as that made by the last speaker.

Dr. Collins thought the term "athetosis" should be limited to rhythmical movements, and "choreic" to non-purposive, dancing movements.

Dr. Stieglitz, in closing the discussion, said that in cases of infantile cerebral palsy all the different varieties of movements mentioned were often combined, so that perhaps it would be better to select a name which would cover all of them. When the boy was less excited, the movements were usually less rapid and more vermicular in character. Under ordinary conditions he did not present a spastic facies. The restraint treatment had been advocated by Dr. Hammond when he had first described these cases.

Disseminated Insular Sclerosis.—Dr. Joseph Collins presented a case and spoke as follows:

"The patient who is before you has the symptoms of two rather obscure diseases of the nervous system, and I bring him here that you may assist me in determining the one from which he suffers. He is forty-one years old, married, and by occupation a silk weaver. His personal history is that he has been a user of stimulants and tobacco, the latter rather intemperately. Physically he has led a very active life, and in many directions, particularly fencing and boxing, he has been an amateur athlete. The only point of interest in his family history is, according to his own statement, that a brother younger than he by two years complains of the same trouble in walking that he does. When this patient was thirty-three years old he had a sore on the penis, for which he was treated by Dr. George H. Fox. The latter assured him that this sore was of the nature of a chancroid, and gave him only local treatment. Aside from bubo, which complicated it, this terminated uneventfully in a few weeks, during which time he was treated in private practice by Dr. Fox. Aside from an attack of the grippe, which he had in 1892, he has been quite well. His present illness dates back nearly three years, the initial symptom having been, he thinks, dizziness which was sufficiently great to interfere with his locomotion. Apparently this vertigo was not continuous, because, he says, when it would come he would have to hold something to prevent him from falling. About this time he must have had some trouble with his sight, for it appears that he went to the New York Eye and Ear Infirmary, where he was told that he had locomotor ataxia. The symptoms that next appeared after the dizziness seem to have been what he describes as piercing pains in the calves and the sensation of heavy weights in the thighs. So far as I am able to infer, this constitutes the major part of the patient's complaint until the beginning of the present summer, although it should be said that he has been sexually impotent for two years. The fact that he has been unable to work has, according to his own statement, preyed very much upon his mind and made his symptoms worse. About six months ago his bowels and bladder became functionally derelict, and sometimes the one or the other would discharge its contents without his being aware of it. At this time likewise his speech and handwriting became affected, both in very much the same way as they are now. That is, the enunciation is measured and scanning, the intonation rather high and uniform, while the handwriting is very irregular and ataxic. The patient avers that at about the same time he became uncommonly emotional. He would burst into tears at one time, and at another would grin or smile senselessly. The patient also underwent a psychical as well as physical alteration. He says that he became very forgetful, that he was unable to read understandingly, even the newspapers. This state persists in a very much slighter degree today. For instance, it is quite impossible to elicit the symptoms of his disease except by asking him leading questions, and he forgets easily. At present he is able to concentrate the attention sufficiently to read a newspaper or magazine understandingly.

"His complaint at the present time is of difficulty in locomotion and impaired dextrality. The abnormalities of articulation and the slight psychical aberrations do not concern him sufficiently to lead him to complain of them. The functions of the bladder and bowels are now moderately normal, although occasionally there is some incontinence, especially of urine. He does not complain of pain or of a tight-band sensation about the waist, and the feeling as if there were heavy weights in the thighs has disappeared.

"Examination shows a man of medium height and good muscular development, whose body is the seat of a marked deformity due to a cervico-dorsal scoliosis, which he believes to have been caused by carrying heavy loads in the right hand or on the right shoulder during boyhood. As to the plausibility of such an explanation, each one must determine individually. Both feet show the deformity which is known as pes cavus, 'pied bot' of the French writers. The plantar surface of each foot is very much hollowed beneath the arch, while all the toes are forcibly extended save the first phalanx, which tends to claw the floor. When the patient stands, titubation of the whole body is the most striking phenomenon, and this persists, though to a lesser degree, when he sits. The gait is ataxic and reeling; unlike the ordinary taboid patient, he does not watch his feet while walking. He is rather more inclined to fix some point at or near his objective, and keep his vision on it until he reaches it. Station is extremely uncertain when the feet are approximated, and when he closes the eyes under such circumstances he is pretty sure to fall. The superficial or cutaneous reflexes are present. The tendon jerks of the lower extremity are all absent, while of the upper extremity they are all present. The right palpebral fissure is somewhat larger than the left, and to explain this the patient says that it followed an attack of sore eyes. The pupils are of medium size, slightly asymmetrical, and do not respond to light. When the backgrounds of the eyes are viewed with the ophthalmoscope, the left optic discs appear rather pale—a state of pink atrophy. The right optic nerve is normal. Tactile and thermal sensibilities seem to be normal. There is well-marked analgesia over both legs. The patient has been examined four times only with great care, but the analgesia seemed to be present on each occasion, although varying somewhat in intensity. There is no perversion of sensibility in any other part of the body. Color sense is normal, and the visual fields are unchanged. Senses of smell, taste, and hearing are intact. The trouble with speech and writing has been already sufficiently referred to above.

"Now the question arises: Has this patient Friedreich's disease or has he multiple sclerosis? Perhaps, indeed, this question is not sufficiently comprehensive. Some may be inclined to ask, and legitimately, I think: Can disease of the cerebellum be eliminated on the one hand, and genuine tabes on the other? Personally I am inclined to the opinion that the case is one of disseminated insular sclerosis, although perhaps the evidence pointing to such a diagnosis is not so direct or so convincing as some might wish. If a brief analysis of the symptoms be made, it will at once be seen that there exists a certain number of condi-

tions which are usually considered inimical to the diagnosis of Friedreich's disease. These are, first, the patient's age; second, the sensory disturbances; third, the perversion of function of the uro-genital sphere; and, fourth, loss of the pupillary light reflex and paleness of the temporal side of the optic nerves. On the other hand, all of these, and the other symptoms and physical accompaniments which the patient presents, including the deformities of the trunk and feet, can be explained by the existence of islets of sclerosis in the posterior columns, in the oblongata, and possibly in the cerebellum. If my diagnosis be the correct one, you will agree with me, I think, that the case is one of the most atypical thus far reported."

Dr. Sachs said he was of the opinion that the case was probably a somewhat atypical example of multiple sclerosis. There was, after all, not so much difference between this case of multiple sclerosis and the cases of combined sclerosis that one sees, for he had observed cases of combined sclerosis which at one stage had presented all the symptoms of a spastic paralysis, and subsequently the appearance of typical cases of tabes.

Dr. Fisher said he would agree with the diagnosis of disseminated sclerosis, basing it largely on the mental condition and the character of the speech, particularly the former.

Remarks on the Kidneys in Cases of Cerebral Hemorrhage and Cerebral Softening.—Dr. Christian A. Herter read a paper with this title, in which he gave some of the results of his observations in four hundred and sixty-four autopsies on adults at the Presbyterian Hospital. There were twenty-three cases of cerebral hemorrhage, eleven of cerebral softening, and one of softening and hemorrhage. The three cases of hemorrhage in patients with large kidneys showed the lesions of chronic diffuse nephritis. Six of the patients with small kidneys were males, while all those with large kidneys were females. Of the patients with large kidneys, four had cerebral softening, two thrombosis, and two embolism. The great majority of the medium kidneys were granular. In the cases of cerebral softening the kidneys presented a granular surface and freely stripping capsules. According to this series of observations, cerebral hemorrhage was most frequent among persons with small granular kidneys, and least frequent in those having large kidneys. None of the cases of hemorrhage had smooth kidneys; on the other hand, the majority of the cases of cerebral softening were associated with smooth kidneys and freely stripping capsules. The speaker said that in these cases, when there was a high arterial tension and the urine was of low specific gravity and contained very little albumin and few if any casts, it might be inferred that the kidneys were small and granular, and this condition, in cerebral cases, pointed strongly to hemorrhage.

Dr. Mary Putnam Jacobi said that she had recently seen a case which bore on the relation of uræmia and hemorrhage. The patient was a woman of about forty-five, who had been previously in excellent health. She awoke one morning to find that her vision was extremely dim. The next day she complained of double vision, and a paresis of the abducens appeared, and increased until the muscle became completely paralyzed. The urine on several examinations was found entirely free from albumin, and granular casts were found without the use of the centrifuge. The urine contained a large quantity of urea. The dimness of vision was probably uræmic and the paresis of the abducens due to a very minute hemorrhage in the sixth nerve.

Dr. Herter said it seemed to him probable that in Dr. Jacobi's case the symptoms were due to hemorrhage rather than to œdema, although the latter should always be borne in mind. It was a common thing to find considerable urea during the uræmic state. This was probably to be explained by a gradual accumulation of the urea in the blood, owing to the defective action of the kidneys, and this accounted for the fact that these patients often passed a normal quantity of urea in the urine at the time that the symptoms of acute uræmia were present.

Traumatic Hæmatomyelia, with Reports of Cases, with and without Autopsy.—Drs. Pearce Bailey and P. R. Bolton presented a paper on this subject, from which extracts were read by Dr. Bailey. Speaking of that class of cases in which the hæmatomyelia was consequent upon injury to the spinal column, the authors said that in a large proportion the general destruction of nerve tissue was so severe that hemorrhage could have had but little influence. The blood was poured out first and most profusely into the gray matter, and this central limitation was often very sharply defined. The columnar extension of the blood was usually in the gray matter of the anterior or posterior horns, and the column extended farther upward than downward. Occasionally it might extend into the white matter just behind the middle commissure. These hemorrhages were most commonly found at autopsy between the fifth cervical and the third dorsal segments. The lower dorsal or lumbar cases either did not come to autopsy or did so only after so long a time that it was difficult to draw definite conclusions regarding the pathological findings. The evolution of the lesion in spinal hemorrhage was somewhat obscure. The natural tendency was to absorption of the blood, so that cavity formation was an early consequence of hæmatomyelia. In primary hæmatomyelia, bleeding into the substance of the cord constituted the primary lesion. There were two forms, viz.: (1) the localized; and (2) the disseminated. A force sufficient to rupture the blood-vessels of the spinal cord must affect the nerve elements; hence when bleeding was prominent it was reasonable to expect to find lesions of the nerve cells. In the majority of cases, however, the hemorrhage was the most important factor. The focal form of primary hæmatomyelia was always found in the lower cervical or upper dorsal region. Most of the cases resulted from falls. One form of injury which was especially fertile in producing this lesion was a sudden bending of the neck, such as occurred in the falling of heavy weights on the neck, diving in shallow water, etc. The symptoms differed from those of crushing of the cord, in which the white and gray matters were both implicated. The paralysis was at first flaccid everywhere, and the reflexes were generally either diminished or lost. An injury to any part of the spinal cord above the upper lumbar region, severe enough to cause paraplegia, would usually inhibit or abolish the knee jerk for a time. This was eventually followed by an exaggeration. In the muscles of the lower extremities the paralysis usually changed within three weeks from the flaccid to the spastic type. Immediately after the accident, the paralysis of motion was usually widespread and severe. Sensibility to touch was little, or not at all, modified in primary focal hæmatomyelia; there was, however, analgesia or thermo-anæsthesia, or both. In the cases reported the power to distinguish between heat and cold was lost, while sensibility to pain was unaffected. Compared to the prognosis of secondary cases of injury, the outlook in primary focal hæmatomyelia was favorable. Primary disseminated hæmatomyelia occurred after severe general traumatism. In these cases capillary hemorrhages were found throughout the cerebro-spinal axis. Microscopic examination showed small masses of red blood cells, lying, for the most part, in the gray matter, but also in the white matter. They were not accompanied by other evidence of destruction, and were not artefacts.

Dr. Sachs said there seemed to be every reason to suppose that in many cases which were classified as of secondary origin there must have been effusion, not only into the cord, but around the cord. On this account the question arose as to whether many of the symptoms might not be due to compression of the root fibres. He had seen dissociation of sensation as one of the earliest symptoms of Pott's disease and Pott's paralysis. It need not, therefore, be a symptom of destruction of the gray matter. He recalled a series of cases that were not traumatic in origin, were rather slow of onset, and occurred in adults, and yet presented all the typical symptoms described under the head of hæmatomyelia. The question arose as to whether in the non-traumatic cases the peculiar arrangement of the blood-vessels in the spinal cord might not account for some of the cases in his series. A case now under observation was instructive for the reason that the lower extremities alone were affected, and there was an association of the spastic symptoms with a dissociation of sensation.

Dr. Onuff said that he had seen the case just referred to by the last speaker. The patient stated that soon after a tiresome bicycle ride he noticed that he could not urinate easily. The next morning there was a tingling sensation in the legs, but it was not until five days that a partial paraplegia appeared. At this time incontinence of fæces was also noticed. There was atrophy of the leg, affecting chiefly the adductors of the right thigh. The sensation of pain was exaggerated, so that there was a marked drawing up of the limb when it was pricked. The difficulty of urination was followed by incontinence. The atrophy in the thigh would seem to indicate a higher lesion, while, on the other hand, the initial bladder and rectal symptoms would point to a lower lesion.

Dr. Fraenkel said that he thought the abolition of the reflexes in such cases as those described in the paper was of much diagnostic importance. Enough cases had been reported to show that even in the face of the absence of the reflexes it was possible for a communication to exist between the upper and lower portions of the cord. He regretted that the condition of the deep sensibility had not been recorded in the cases quoted.

Dr. Bailey remarked that in one case in which the reflexes were absent the muscular sensation had returned.

The Red Cross Society and the Nile Campaign.—The *Mayflower*, a stern-paddle steamer one hundred and forty feet long, has been chartered by the National Society for Aid to Sick and Wounded in War (the British Red Cross Society) to convey sick and wounded soldiers from the Soudan between Assouan and Cairo. She carries two medical officers and eight men of the royal army medical corps lent by the government, and two nurses sent out by the society. Reconstructed from a pleasure vessel into a hospital ship, to hold fifty-two sick and wounded and on an emergency seventy-two patients, she is fitted out with the most modern medical and surgical appliances and medical comforts of every description. The sick and wounded will thus enjoy the luxury of being conveyed by river, and will be saved the heat-choking dust and the severe discomforts of the railway journey of about six hundred miles between Assouan and Cairo, which a high authority has described as the worst part of the transit between Khartoum and Cairo. The ship was inspected by the general officer commanding, and she started on September 6th on her first voyage of mercy, leaving Assouan for Cairo on September 15th, with twenty-eight wounded and twenty-four sick.

Correspondence.

OUR LONDON LETTER.

(From our Regular Correspondent.)

SANITARY CONGRESS—SIR J. FAYRER, K.C.S.I., ON VACCINATION—RELATION OF PROFESSION TO THE STATE—TENEMENT DWELLINGS—FOOD PRESERVATIVES—THE BIRTH-RATE—POLLUTION OF STREAMS—INEBRIATE HOMES—TYPHOID—DEATHS—OPENING OF THE SESSION—VIRCHOW'S LECTURE—DINNER TO VIRCHOW—INTRODUCTORY LECTURES—ERRORS IN DIAGNOSIS—THE PRINCE'S SURGEONS HONORED.

London, September 30, 1898.

The seventeenth congress of the Sanitary Institute opened at Birmingham on Tuesday, and the proceedings occupy the week. Some eight hundred members attended. The presidential address of Sir Joseph Fayrer has attracted attention outside the circles interested in sanitation and medicine, as it was anticipated that he would deal with the subject of vaccination in view of the recent act. Sir Joseph is held in honor not only by the profession, but by the public, his long and distinguished services having often brought his name forward in the most favorable manner. He spoke of the immense value of preventive medicine and sanitary measures, and pointed out how well the public health is cared for in the present day compared with the past. Nevertheless, he added the warning that diligence could never be relaxed. Sudden invasions of cholera and other epidemics were a sufficient proof of that. The reduction in the prevalence of small-pox he found was greater than had been attained in any other disease, and those theories which ignored the effects of vaccination as a preventive must necessarily be rejected until a better explanation of the cause of the diminished incidence and mortality could be offered. Since the passing of the first vaccination act in 1841, the death rate had fallen from five hundred and seventy-six to twenty per million in 1891–95. All the evidence that is forthcoming, he said, shows there is no doubt of the value of vaccination. As to the methods of securing that every one should submit to it, that is for the State to determine. That the acts passed up to the present time are inadequate is shown by the large numbers who are unvaccinated. It was to be remembered, he added, that the Royal College of Physicians had recently repeated their unaltered conviction that the only known preventive of small-pox is vaccination; and that conclusion is endorsed by the whole medical profession.

The question of relations of the profession to the State was brought before the congress by Dr. McVail, who said he had been mainly moved to take up this topic by recent criticisms and incidents. Thus it had been said that medical men were sulking because their collective views as to legislation had been pushed aside. Not so. Medical men advise the State regarding the prevention of disease and the preservation and improvement of the public health. As to vaccination, the object is and should be to vaccinate—not to punish, not to fine, not to display temper. Medical men have done their duty, and there must leave the matter. The responsibility is with the legislators. Isolation hospitals for the treatment of small-pox cases should be recommended to be established in every district.

The subject of tenement dwellings was brought before the congress by Dr. Sykes, who remarked that in St. Luke's, a poor and crowded London district, twenty-one per cent. of the population were living in one room; while in Lewisham (a suburb), only five per cent. were so living. The weight of skilled advice is decidedly against permitting one-room tenements to

form part of any improvement scheme, though it is also against retaining the present rule-of-thumb calculation as to the amount of air a bedroom must contain. On the other hand, open-air staircases are strongly recommended for collective dwellings, as infection among children has so often been traced to the use of a common staircase in such buildings.

Yesterday Dr. Alfred Hill, M.O.H. for Birmingham, presided over the section of sanitary science and preventive medicine, and in his address dealt with the question of food preservatives, which, he held, has hitherto received less attention than it deserves. He would prohibit the use of all chemical preservatives, as they enable foods to be sold as fresh which are stale and have often undergone changes making them harmful or even poisonous. Whatever the minor differences of physiological experimenters, they admit that, though small doses may exert no perceptible influence on the health, we cannot say the same of large doses. He moved that the council of the institute be recommended to represent to the proper authorities that scientific investigations be forthwith set on foot on this matter and that a court of reference be established. This motion was seconded by Mr. Vincent Jackson, and carried.

Dr. Dawson Williams then gave an address on "The Decline in the Birth Rate." He said that at the census in 1891 it was found that the increase of the population of England and Wales only amounted to a little over 3,000,000, which was less by 750,000 than had been estimated. The births were 290,000 below expectation, while emigration was 412,000 above. The death rate was lower, so that the natural increase ought to have been larger. Both urban and rural populations had increased, but not in the ratio estimated. The increase had been much less in the latter than the former. There were more children born in towns than in the country in proportion to population, but the urban infant mortality was so much higher that the town excess did not maintain a corresponding excess in proportion to the total population.

Dr. Sims Woodhead presided in the section of physics, chemistry, and biology. In his address he reviewed some of the most important advances in sanitary science in recent years, and pointed out the importance of what had gone before our own time and on which we have builded. Had there been no Jenner, he said there could have been no Pasteur, no Lister, no Koch. We should have been in a sorry way had it not been for our predecessors.

Mr. Christopher Childs contributed an interesting paper on the "Prevention of Pollution of our Streams and Rivers"—an evil which the act of 1876 has failed to remove. He urged the regular and constant inspection and supervision of all parts of the water supply from source to distribution. He was astonished that this was not included in the proposals made last session. Chemical and bacteriological examinations could be of great service, for they could give indication of pollution that inspection failed to detect. But if relied upon alone, they gave a sense of false security; for they could detect pollution only after it had taken place. It was of the greatest importance that inspection should be enforced, and early legislation should include this as the most urgent requirement.

The report of the government inspection of retreats for inebriates for 1897–98 looks rather out of date, as last session the act for compulsory detention of drunkards was passed. The report dwells upon the need for compulsion, and so far is forestalled by the legislature. Among the voluntary institutions that at Rickmansworth is the chief, and 475 cases have been treated there. Of these patients, 241 were between thirty and forty years old, and 249 were married. Over 400 were well educated, 112 were gentlemen of no occupation, and 363 belonged to the professional and mercantile classes. The after-history of 400 has been traced, and 161 are reported as "doing well," but 176 "not improved." The periods for which these patients agreed to enter were three, six, and twelve months. The shorter periods are not to be recommended. Indeed, the opinion of those who have watched the various homes seems to be that twelve months should be the minimum.

Typhoid has broken out in some villages near Plymouth. In one there are twenty-three cases, in another fourteen, and others are becoming infected. They are all in the district from which Plymouth draws much of its supply of dairy produce. Defective drainage, or rather want of drainage, is supposed to be the cause, with the consequent pollution of the wells and streams from which the inhabitants draw their water. Five years ago the district council was informed of the insanitary state of the area, but nothing seems to have been done. The M.O.H. describes the water as "grossly polluted," and it is said to have a disgusting smell. Accumulations of offensive matter abound round the villages.

Typhoid was prevalent at Rowley Regis in Staffordshire in the first half of the year—the M. O. H. reporting ninety-eight cases. Defective drainage and ashpits with pollution of water were found. No less than twenty-two wells, supplying sixty-two houses, have been condemned as supplying water unfit for domestic purposes: but I have not heard that the government local board has moved in the matter.

In the London school board's industrial school at Brentwood fifty-six boys out of one hundred suffered from heat stroke in the late hot weather, and there were two deaths. The medical officer considers the ventilation and overcrowding of the building to blame. There were also three cases of typhoid and one of diphtheria. A report has been sent to the board.

The Belfast outbreak persists. There were fewer cases in the last week, indeed, but the outlook is discouraging. The general death rate has gone up to 30.6, and the mortality from zymotic diseases to 12.2.

Dr. G. Hart, of Bolton, died on Tuesday, apparently from the effects of an insect bite or sting near the eye. Cellulitis, septicæmia, and pneumonia developed. His medical neighbors did all they could, and streptococcic serum was tried, but he succumbed. He was only thirty-eight.

Dr. William Clarke, when acting as a *locum tenens*, died on the 15th from the effects of strychnine accidentally included in a tonic draught he took as a "pick-me-up."

Surg.-Maj. J. McDermott committed suicide with prussic acid "while temporarily insane," as the jury found.

LONDON, October 7, 1898.

The winter session was opened in due course, and we are now settling down to work at our several schools after attending and discussing the merits of our introductory lectures or other ceremonies. The most remarkable of these, as I mentioned must be the case, was that of Charing Cross Hospital, Professor Virchow having undertaken to deliver the address there in memory of the late Professor Huxley. Lord Lister presided on this occasion, and a crowded audience received the lecturer with the greatest enthusiasm. Huxley was once a pupil at Charing Cross, and this school has established the "Huxley lecture"—the present being the second of the series and serving for "the introductory."

Professor Virchow opened his address by an expression of his admiration for the illustrious man commemorated and a compliment to English biologists. He went on to say that an initial difficulty had been

caused by the tendency to set the search after the unity of life in the forefront of biologists' inquiries, whence arose the discarded doctrine of vital force. No progress, he said, could be made until the idea of highly organized living things as units had been set aside, and it was recognized that they were organisms, each constituent part of which had its special life. Analysis of animals and plants alike brings us to the cells—the factors of existence. The discovery of the development of complete beings from the ova of animals and the germ cells of plants bridged the gap between isolated living cells and complete organisms, and enabled the study of the former to elucidate the life of the latter. In a medical school, where teaching is concerned almost entirely with human beings, this sentence should be writ large: "The organism is not an individual, but a social mechanism." To these he added as corollaries: (*a*) that every living organism, like every organ and tissue, contains cells; (*b*) that the cells are composed of organic chemical substances, which are not themselves alive.

The notion of free cell formation, which really implied spontaneous generation, when driven out of the domain of zoölogy, found a temporary refuge in that of pathology. Virchow said he was himself taught the discontinuity of pathological growths—a view which would lead back to the origin of living from non-living matter—and then he related how enlightenment came to him in this matter. When clinical assistant in the eye department of the Berlin Hospital, he was impressed by the fact that keratitis and corneal wounds healed without plastic exudation. This led him to study inflammation in other non-vascular structures, such as articular cartilage and the intima of the larger vessels, and in none was plastic exudation found, but in all changes of tissue cells. Turning then to vascular organs, he proved that the presence of cells in inflammatory exudates was not the result of exudation, but of multiplication of pre-existing cells. He next extended this to the growth in thickness of long bones. Eventually the biological doctrine of *omnis cellula e cellula* was extended to pathological processes; every new formation presupposes a matrix or tissue from which its cells arise and the stamp of which they bear.

Herein is the key to the mystery of heredity. The cells are the factors of inherited properties, being the sources of the germs of new tissues. But as to the hereditariness of any given disease, the most elaborate doctrines may at once break down before the discovery of the real cause, as happened in regard to leprosy, favus, and scabies.

In heterotopia fragments of tissues or organs are found in positions not normal to them—it is a kind of transplantation. The misplaced tissues do not develop new properties, but merely continue their normal powers of growth. But to attribute all tumor formation to this cause would carry the idea beyond its scientific limits.

Turning to parasitism, the illustrious lecturer remarked that the old notion, that disease in general was a parasite, pushed to a logical conclusion, implied that each independent part of an organism might act as a parasite toward the others. The true conception of a parasite implies harmfulness to the host. The larger have been longest known, but the minutest produce the principal infectious diseases. But here three points must be considered: (1) The necessity for distinguishing between the cause and the nature of these diseases, the latter being determined by the reaction of the tissues and organs to the microbes. (2) The relation between the smaller parasites and the diseases they excite. This may be summed up by the term infection; but to assume that all infections are due to bacteria would be to go beyond our present knowledge and would probably retard further progress. (3) The mode of action. It is only the larger parasites whose chief effect is devouring parts of their hosts; the smaller act mainly by secreting virulent poisons.

The cellular pathology further entails the principle of destroying or removing the focus of disease. Again, the cells, like bacteria, secrete juices which influence the rest of the organism. Hence arises the therapeutic use of extracts of organs.

In conclusion, Professor Virchow mentioned the qualifications of a physician and a naturalist, and wished success to the school he addressed.

On Wednesday Professor Virchow was entertained at a dinner given in his honor, at which some two hundred and fifty enthusiastic admirers and disciples were present. Lord Lister presided, and, after the usual toasts had been honored, proposed that of the evening, "Our honored and beloved master, Professor Virchow." His lordship said many of those present had had the advantage of the professor's personal instruction, and all were his disciples. Only a few in the company could remember the effect produced when the professor established his fertile doctrine, and no part of the great discourse they heard on Monday had a deeper interest than that in which the lecturer noticed in too few words the observations which led him into the true path of cellular pathology. In this science Virchow reigned supreme, and probably no living man was better versed in the history of medicine. He was also an acknowledged authority on anthropology and a distinguished antiquary. From early life he had been interested in politics, and his voice was always heard in defence of liberty, truth, and righteousness. Rare as it is for a man to excel in so many departments, it was rarer still and seemed almost miraculous that any one should retain his intellectual and physical powers as Virchow had done. The whole medical profession joined in wishing that his wonderful powers, activity, and usefulness may long be preserved.

Professor Virchow, on rising to acknowledge the toast, was received with enthusiastic cheering. He spoke in English, with the same exactitude as in his lecture, and of course with the same slight German accent. He said he felt no stranger among them. Long before he had the privilege of friendly relations with many of the best sons of England, he had admired the country and people who amid political storms had preserved and developed the principles of civil and religious liberty—a glorious example for all mankind. He then praised Huxley for his work in anthropology and ethnology, so great in the eyes of German savants as to immortalize his name among them, and they will not cease to follow in his footsteps. May this, he said, further consolidate the union of German and British science. He proposed, in conclusion, the medical corporations of Great Britain and Ireland—a toast responded to by Sir S. Wilkes, Sir W. MacCormack, and Professor Chiene.

The other introductories were by no means devoid of general interest, although none of them could pretend to compete with Virchow's. Some were of special value to their particular audiences, and all had points worth considering, did your space permit. There was again an interchange between some schools. Thus Professor Foster went to Birmingham and discoursed on the nature and function of a university—a very timely topic, now the Midland City is proposing to establish one for itself. Dr. Saundby went to Cardiff and spoke on the allied subject of modern universities. Dr. Cullingworth went to Leeds, of which he is a native, and urged on his audience the great importance of personal character in the medical profession. Here in London the lecturers also chose subjects for the most part which appeal to the practitioner

as well as the student. At St. George's Mr. Turner showed the value of medical work to the community and denounced its inadequate pecuniary rewards. At University College Mr. Spokes, the dental surgeon, broached similar views in an address on the present status of the profession. At St. Mary's Dr. Caley struck what some call a higher note in dilating on prevention in medicine and urging the need for a forward movement, and showing that the community ought to appreciate this need. At the Middlesex Dr. Voelcker, while not ignoring the outside world, gave more direct advice to the freshmen—good advice, too, in which he warned them to be careful of their conversation in lay circles, avoiding all random talk which might cause them to be accused of callousness or behavior unworthy of a gentleman. This they owed in loyalty to their hospital and the high aims of their chosen profession. At the Women's Medical School Dr. Walter Carr took for his subject "Fashion in Medicine"—very appropriate to his audience, say some.

The other schools dispensed with the lecture, but not with the festival dinners—details of which would be of little interest to you, although most of those present express satisfaction with their entertainment.

From time to time some error in diagnosis affords the newspapers an opportunity for a sensational paragraph. They seem to expect infallibility from doctors, but from others the plea of human fallibility is readily accepted. A little time ago mistakes at two of our hospitals afforded the text of much declamation. The errors were regrettable, and it is well that the officers of these institutions should feel their responsibilities. This week a case has occurred which is unusual, from the fact that two doctors made the same mistake of thinking a man who had fallen from a tramcar was only drunk, whereas he had sustained a fracture of the skull. At the inquest he was proved to have been perfectly sober, and the history of the accident should surely have suggested the possibility of serious head injury.

The notification act is responsible for many errors, as it requires a positive diagnosis of the kind of infectious disease at a stage when the most careful man cannot be sure. A doctor lately certified a case as scarlet fever. The medical officer of health declared it was influenza. It was referred to the district council, which holds the purse strings. It refused the fee, and left the doctor to settle the dispute with the medical officer of health.

The Queen has given distinctions in the Royal Victorian Order to the surgeons who have been attending the Prince of Wales: Sir W. MacCormack and Sir F. Laking, to be knights commander; Mr. Fripp and Fleet-Surgeon Delmege, to be members of the fourth class.

TYPHOID FEVER AND FLIES.

To the Editor of the Medical Record.

Sir: In your issue of October 8th, "A. H. S.," on page 537, delivers himself of his amazement at the stupidity of old army men (surgeons) in regard to the use of lime. Let me reply by first saying that the United States government does not issue chloride of lime in large quantities, or in wooden casks, in which it soon loses its chlorine; second, that when a solution of chloride of lime is put into a sink five feet wide, twelve feet long, and from eight to twelve feet deep, which four hundred men are using every day and night, much is required, and chlorine escapes rapidly, and the flies are not kept away all the time from the sink or its neighborhood with any ordinary quantity. The government furnished a great deal of lime in barrels, and it was in use. The sink problem and the country-privy problem are the same. I would respectfully ask "A. H. S." to refer to my remarks on this subject in the issue for October 8th of the *Journal of the American Medical Association*.

R. S. Sutton, M.D.

516 Market Street, Pittsburg, Pa.,
October 10, 1898.

THE MIDWIFE OR THE WOMAN DOCTOR.

To the Editor of the Medical Record.

Sir: The article in the Medical Record of October 1st, entitled "Some Remarks on the Midwifery Question," has been read, marked, and inwardly digested, with much interest and not a little quiet chuckling and amusement, by some of those to whom the author refers as "none other than the woman doctor or what polite usage calls the lady physician."

In spite of the author's repeated statements that the female physician is neither wanted nor tolerated by the great mass of women, and that the medical profession at large is not only not opposed to her, but (worst rub of all) mildly indifferent to her and to her success or lack of it, he cannot, in fact he does not, attempt to hide his great fear that there is a place where the ubiquitous woman doctor can fill a long-felt need, and that is at the bedside of her parturient sister. Not only among the lowly and ignorant, but in the higher classes of society to-day the feeling is strong and growing yet stronger that this sphere of work belongs pre-eminently to women—not to the often ignorant, unskilful, dirty midwife, whose sole claim to ability lies in the fact that she has seen half a dozen or more confinements; but to her cleanly, thoughtful, well-educated, and possibly really skilful sister, the woman doctor.

Curiously enough, as I wrote the above, a Swede, a cable conductor, came in to engage me to attend his wife, who had a difficult time with her last labor. I quote his words. "She has always had a midwife before, but the midwives here are not as at home in Sweden. They have not studied and they are dirty. Of course I could have my own club physician, but you know how it is, doctor—they want a woman at such times."

The author's openly expressed fear, that should the midwife come to be no more the woman doctor would take her place, is certainly not without foundation. Indeed, the care which the city has taken to protect its poor, by paying a proper fee to such institutions as will guarantee to send a reputable physician to attend poor women in their confinements, has already done much to oust the midwife. Rarely, indeed, does it happen that a woman once attended by a lady, who is also a physician, returns to her midwife or to a male physician. Women, even the most ignorant, are quick to recognize the woman doctor's superiority to a midwife and even to a man.

No, the woman doctor is not quite so quick to take fright as is her inexperienced "stepsister," and when she is alarmed she does, indeed, send for a sister-practitioner; and, strange to say, kindly nature helps these twain as freely and as impartially as she would the stronger sex, and all the hitherto unenlightened neighborhood stand and wonder, and, "wondering, say, can such things be?" Two women, or even one, doing versions, applying instruments, repairing perineums, and all as deftly, as neatly, as skilfully as could a man—a man doctor! And all the female constituency of that district forthwith register a vow that "next time" (if there be a next) they will have a woman doctor, in place of young Dr. Hurryall, who was in such haste that he wouldn't give their pains time (and beside left such a mess), or old Dr. Slowcome, who made them suffer two days and three nights because he

had had fifteen hundred cases and had never had occasion to use instruments.

Yet is the worst to come. Who knows the baby better than the doctor who brought it into the world? Who can best minister to that baby's special form of colic or diarrhœa or what not, if not the doctor who "knows her constitution"? The husband may indeed put in a plea for his own doctor, but agrees with his good wife that the baby is hers, not his, and he leaves it to her; so we become that baby's doctor. And when the mother begins to feel the results of some previous labor, who so likely to help her as her lady doctor? And when, some day, John, her goodman, worries her to death with his cough, for which he refuses to consult a doctor, it is barely within the limits of possibility that the lady doctor may be asked to leave something for John, and lo! John is healed and half converted.

"Of course," says our author, "we shall be found on the side of right and justice;" but if right and justice be on the side of the woman doctor, who, even as he, has given the best years of her life to preparing for her work, we must make an exception—we must first look after her poor, downtrodden, "stepsister," the midwife, whose lack of training, of ordinary skill, and even of cleanliness puts patients into our hands and money into our pockets. Let us be just, but, first of all, let us be just to ourselves. "The neighboring doctor and the midwife have a perfect understanding." True! The woman doctor and the midwife have nothing in common.

"By thus suppressing the midwife, we open wide the gate to our professional sisters, and flood the whole country with female doctors." Pardon! However gladly women in the past might have been to have these gates thrown open wide by chivalrously inclined gentlemen, the women of the present hold the key and can open for themselves. That key is knowledge, and knowledge is power.

I cannot trace the mental connection, but something in the article led me to look up again Edward Sill's satire on our narrow little human lives. You will remember that of the "five mites of monads who dwelt in a round drop"—

> "One was a barren-minded monad, called
> A Positivist; and he knew positively."

And again of the five—

> "The last was a strong-minded monadess,
> Who dashed amid the infusoria,
> Danced high and low, and wildly spun and dove,
> 'Till the dizzy others held their breath to see.
>
> "But while they led their wondrous little lives
> Æonian moments had gone wheeling by;
> The burning drop had shrunk with fearful speed:
> A glistening film—'twas gone; the leaf was dry."

ELIZABETH JARRETT, M.D.

159 WEST FORTY-EIGHTH STREET.

Crepitant Râles are caused by agitation of fluid in the air cells or in the finest extremities of the bronchial tubes; or, to adopt a view now held by many, by the forcing open during inspiration of the air cells agglutinated together by exuded lymph.—DACOSTA.

There are several views as to the production of these sounds; that they are due to the bubbling of air through a liquid in the pulmonary vesicles and terminal bronchioles; that at the end of expiration, a viscid secretion glues the walls of the vesicles together, and their separation on inspiration gives rise to the crackling noise; and that they are produced in the pleura independently of the pulmonary parenchyma.—LOOMIS.

Whether this is a fine pleural crepitus or is produced in the air cells and finer bronchi is an open question.—OSLER.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 15, 1898:

	Cases.	Deaths.
Tuberculosis	177	133
Typhoid fever	117	25
Scarlet fever	65	4
Measles	42	0
Diphtheria	118	18
Cerebro-spinal meningitis	0	6
Laryngeal diphtheria (croup)	8	2
Chicken-pox	13	0

Etiology of Epilepsy.—The general causes assigned for epilepsy are much the same as those for idiocy. That the malady is frequently transmitted by heredity is clearly proved by Dr. Féré. He observes that when the marriages of epileptics have an average fecundity, scarcely one-fifth of the children are healthy. Epilepsy seems to be propagated more directly than are other neuropathic diseases. This is what is called similar heredity. Eccheverria found that out of a total of five hundred and seventy-two epileptics, thirty-nine per cent. had an hereditary taint received directly from the parents. In many cases epilepsy appears in the collateral lines, and sometimes passes over the son or daughter to affect the grandchild. Sometimes, on the other hand, the neurosis takes another form, such as idiocy, insanity, hysteria, hemicrania; or the epilepsy is combined with these affections. Perhaps as many as one-fourth of all idiots are epileptics, or have fits now and then. Drunkenness in the parents is found to be a common cause. Eccheverria found it in seventeen per cent. of his cases, but Wildermuth in less than two per cent. Excess in alcohol may originate epilepsy or bring it back after the disease seems to be cured. The craving for intoxicants may itself be an inherited disease, apt to propagate its like or some other form of neuropathy. Epilepsy is occasionally caused by injuries to the head or by cerebral tumors. Brown-Séquard has proved by experiment that guinea-pigs may be rendered epileptic by lesions of the sciatic nerve or of the spinal cord, and that this epileptic proclivity was transmitted to their descendants, and Luciani has observed the hereditary transmission of epilepsy in animals in which the disease was provoked by irritative lesions of the brain.—IRELAND, "Mental Affections of Children."

Sunstroke.—The State board of health of Pennsylvania has issued for distribution a long circular on "Precautions Against Sunstroke," in which it sets forth the cause, symptoms, and treatment (emergency), and the necessary precautions against sunstroke.

Diabetic Foods.—Some years ago Dr. Charles Harrington, of the Harvard school, analyzed all the so-called diabetic foods to be purchased. They were advertised to be practically free from starch. The examination showed that they contained from twenty-one up to seventy-one per cent. of starch, and that it would be far safer to use ordinary bread.

A New Safety Match.—A match which contains no trace of yellow phosphorus and in no way affects the health of the workers, yet is capable of being ignited by friction on any ordinary surface. The *Daily Chronicle*, London, of a recent date, was the first to report the good news of this important discovery. The inventors are two Germans, Mr. S. A. Kohlmann-Ro-

senthal and Dr. S. J. von Romoch. These chemists and experts have been strenuously working for the past three years, partly in Berlin but more continuously in London. The doctor, indeed, has almost lived in his laboratory, and every known explosive has been tested in search for the right thing. Success has been achieved in England, and the match is being brought out there. The assayers of the Bank of England and the mint have given a certificate, testifying that the matches will ignite freely by friction and contain no trace of yellow phosphorus. The invention which promises to abolish the deadly necrosis so prevalent in match factories is said to be likely to bring economical advantages.

Drunkenness in the Navy.—With reference to certain statements recently made in a temperance journal called *The Voice*, I have questioned a number of army officers as to the use and abuse of alcohol in the service and they, without exception, affirm the "good habits" of officers and men. The Rev. Mr. Robinson, the chaplain of this ship (United States hospital ship *Relief*) tells me that in twenty-two years of service he can recall but one case of an officer being intoxicated on duty, and says it is a pleasure to be able to attest the self-restraint exhibited by our officers in all such matters both on and off duty.—*Special Correspondent, London Lancet.*

In Ireland they put up signal boards for the benefit of cyclists, "This hill is dangerous," at the bottom of the hill.

Sterility.—Dr. Vedder, of Christiania, Sweden, reports the results of examination of three hundred and ten married women who had never been pregnant though married at least one year. In fifty of these cases he was able to examine the husband also. He draws the conclusion that in seventy per cent. of these cases the husband is to blame for the sterility, either through impotence or through infecting his wife with gonorrhœa.—*Norsk Magazin for Lägevidenskaben.*

Health Reports.—The following statistics concerning yellow fever and small-pox have been received in the office of the supervising surgeon-general of the Marine Hospital service during the week ending October 15, 1898:

SOME OBSERVATIONS ON THE CHEMICAL REACTION OF HUMAN URINE.

BY HEINRICH STERN, PH.D., M.D.,

NEW YORK.

Acidimetry and Alkalimetry of the Urine.—Clinical medicine does not sufficiently take into account the degree of urinary acidity or alkalinity. Physicians and chemists, in the vast majority of instances, merely ascertain the chemical reaction of the urine without attempting to estimate or determine the same. This habitual omission I ascribe to two reasons:

(*a*) The lack of a recognized general standard, the empirical unit of acidity or alkalinity.

(*b*) The incomplete knowledge as to the significance of the variations of urinary acidity or alkalinity.

Oxalic acid has been made use of as a standard of comparison for urinary acidity. Generally the acidity of the twenty-four hours' urine has been thus calculated. This acidimetric procedure, though, not only is impracticable to some extent, but does not seem to serve any specific clinical purposes. An acidity of the twenty-four hours' urine equivalent to, say, 1.5 gm. of oxalic acid, does not tell me anything. What I wish to ascertain are the more minute variations in the chemical reaction of the urine at each time it is voided. To accomplish a more rational study of urinary acidity, this should not be expressed to be equivalent to so many grams of oxalic acid, but to so many degrees of an empirical scale. Then the chemical reaction of urine becomes at once the subject of a more general consideration. Furthermore, we should have a standard and scale for the determination of urinary alkalinity.

I keenly felt the want of such standards when I first engaged in experimental work upon the chemical reaction of urine. I found it impossible to accomplish anything of practical value without the assistance of empirical units of acidity and alkalinity and the respective scales.

To facilitate acidimetry I employ a decinormal solution of potassium hydrate. The $\frac{n}{10}$ KHO solution is a most convenient agent to effect a more exact neutralization of normal urine; I prefer it to the NaHO solution of equal strength, on account of its lesser foaming. A $\frac{n}{10}$ solution of one of these alkalies, in a given volume, comes nearer to neutralizing an equal volume of normal urine than any other standard solution.

The neutralization of 1 c.c. of urine by 1 c.c. $\frac{n}{10}$ KHO sol. is my acidimetric unit. I always employ 10 c.c. of urine when determining its degree of acidity. If this amount is neutralized by 10 c.c. of the $\frac{n}{10}$ KHO sol., then the degree of acidity is 1. If the urine (10 c.c.) loses its acid reaction after the addition of 5.2 c.c. of the alkali solution, its degree of acidity amounted to 0.52; if 1 c.c. of the latter agent is sufficient to neutralize it, its acidity was 0.1; and if 12.3 c.c. of the KHO sol. is necessary to effect the urine's neutralization, its acidity amounted to 1.23 degree.

For urinary alkalimetry I employ a decinormal solution of oxalic acid. The same may be said of the $\frac{n}{10}$ $C_2H_2O_4$ sol. as of the $\frac{n}{10}$ KHO sol.—it is a standard reagent of convenient strength. If 10 c.c. of alkaline urine becomes neutralized after 10 c.c. of $\frac{n}{10}$ $C_2H_2O_4$ has been added, its degree of alkalinity was 1. If 2.8 c.c. of the acid solution brings about the neutralization of the 10 c.c. of urine, its degree of alkalinity was 0.28. If 0.2 c.c. renders 10 c.c. of the urine neutral, its alkalinity amounted to 0.02 degree.

Preparation of Normal and Decinormal Potassium-Hydrate Volumetric Solution.—

KOH = 55.99.

$\frac{n}{1}$ sol. = 55.99 gm. in 1 litre.

$\frac{n}{10}$ sol. = 5.599 gm. in 1 litre.

Potassium hydrate, 75 gm., is dissolved in enough water, at or near 15° C., to make about 1,050 c.c., and a burette is filled with part of this solution.

Into a flask capable of containing 100 c.c., 0.63 gm. of pure oxalic acid is placed, which is dissolved with about 10 c.c. of water. After two or three drops of phenolphthalein test solution for indicating-purposes have been added, the potassium-hydrate solution is allowed to flow from a burette slowly into a flask, which should be gently but constantly shaken. This agitation should be continued until the red color does not disappear any longer and distributes itself uniformly through the fluid, causing a light pinkish discoloration. Observe the volume of KHO solution utilized, and dilute the remaining part of the solution so that exactly 10 c.c. of the dilution is necessary to effect neutralization of 0.63 gm. of $C_2H_2O_4$. After diluting, the KHO solution should be subjected to another trial in the aforesaid manner, whereby 10 c.c. of the dilution should cause exact neutralization of 0.63 gm. of $C_2H_2O_4$.

The decinormal potassium-hydrate solution is prepared by adding to 10 c.c. of normal potassium-hydrate solution enough distilled water to make 100 c.c.

Only small amounts of these potassium-hydrate solutions should be made at a time, and they ought to be kept in bottles tightly closed with pure rubber stoppers. Such solutions, even if exposed only in the smallest possible manner, will readily absorb carbon dioxide contained in the surrounding atmosphere, and may thus cause errors when applied together with phenolphthalein or litmus solutions.

Ten cubic centimetres of $\frac{n}{10}$ potassium-hydrate V.S. is the equivalent of 0.063 gm. of oxalic acid. According to the older mode of expressing the degree of urinary acidity as equivalent to a certain amount of $C_2H_2O_4$, 10 c.c. of a urine requiring 5 c.c. $\frac{n}{10}$ KHO V.S. corresponds to 0.0315 gm. For a twenty-four hours' urine of 1,200 c.c., 10 c.c. of which is neutralized by 5 c.c. $\frac{n}{10}$ KHO V.S., the acidity, compared to $C_2H_2O_4$, would be $0.0315 \times 120 = 3.78$ gm.

Preparation of Decinormal Oxalic-Acid Volumetric Solution.—

$C_2H_2O_4 + 2H_2O = 125.7$.

6.285 gm.[1] in 1 litre.

Pure oxalic acid, 6.285 gm. (rounded off, 6.3 gm.), is

[1] May be rounded off to 6.3 gm. for all practical purposes.

dissolved in enough water to make exactly 1,000 c.c., at or near 15° C. One cubic centimetre of $\frac{n}{10}$ oxalic-acid V.S. is the equivalent of 0.005599 gm. of potassium hydrate.

Indicators for Urinary Acidimetry and Alkalimetry.—I have tried cochineal, methyl-orange (tropæolin D, Poirrier's orange, helianthin), litmus, and phenolphthalein test solutions.

Tincture of cochineal turns yellow with acids and purple with alkalies. The dihydric phosphates react with it like acids, the two other phosphates like alkali hydrates.

Methyl orange test solution is colored red by acids, yellow by alkali hydrates. Monohydric and normal phosphates turn it also yellow; dihydric phosphates change it to brownish-yellow. This solution is a delicate indicator, but not suited for use with a fluid in which organic acids are contained.

Litmus will indicate acidity when brought in contact with dihydric phosphate, and alkalinity when it reacts with the other phosphates.

Phenolphthalein test solution turns to a Bordeaux red in the presence of alkali hydrates or carbonates; in acid fluids it remains colorless. Monohydric phosphates change it to pale red. Dihydric phosphates show no coloration, and the change from colorless through pinkish and afterward deep red is more gradual. In alkaline fluids a deep red color will appear from the beginning.

The degree of delicacy of these indicators is not the same; the results obtained are therefore not alike. These are approximate only, more or less, on account of the phosphate reaction. Exact and more definite results can be obtained if the phosphoric acid contained in the monohydric and dihydric phosphates is first determined.

The Writer's Method for the Determination of Urinary Acidity and Alkalinity.—Apparatus necessary: One burette of 50 c.c. capacity for the $\frac{n}{10}$ KHO V.S.; another burette of 25 c.c. capacity for the $\frac{n}{10}$ $C_2H_2O_4$ V.S., both mounted on a burette stand. Half a dozen beaker or smooth whiskey glasses, each holding about 75 c.c.; one 5 c.c. pipette graduated to 0.1 c.c.

Mode of Procedure.—Measure off exactly 10 c.c. of the previously boiled urine by means of the graduated pipette, and put it into a beaker or whiskey glass. Examine with litmus paper as to its reaction. Then add two or three drops of the phenolphthalein solution, and note carefully if the two indicators show the same reaction. If this be acid, as it is in the great majority of cases, place the container underneath the burette holding the KHO solution, read off the amount of it contained in the burette, and run it slowly into the urine. The phenolphthalein will at once turn deep red, but the discoloration disappears when the urine is agitated. Continue to titrate the urine mixture with the $\frac{n}{10}$ KHO V.S., constantly shaking and proceeding slowly with occasional interruptions to effect the disappearance of the red coloration. Soon, however, the red color ceases to disappear, and the moment the color of the mixture of urine, phenolphthalein, and potassium hydrate shows a permanent and uniform pale pink the end of the reaction is indicated. If more of the KHO is added to the mixture, then the latter becomes decidedly alkaline. The uniform pale pink indicates exact neutralization to a greater or lesser degree; this may be proven to some extent by litmus paper, though the latter, in point of delicacy, differs somewhat from phenolphthalein, and the readings taken by means of one of the indicators always differ from those in which the other was utilized. Finally, note how many cubic centimetres of $\frac{n}{10}$ KHO V.S. were necessary to effect neutralization, and calculate the acidity as per standard unit.

If the urine be alkaline, according to the litmus test, and the phenolphthalein indicates the same reaction, place the container under the burette holding the $\frac{n}{10}$ $C_2H_2O_4$ V.S., noting the number of cubic centimetres of the latter, and titrate the urine mixture slowly (in a similar manner as with the alkali solution) until the reddish coloration of the mixture has completely disappeared. Read off the amount of the acid solution utilized in producing neutralization, and calculate the alkalinity according to the standard unit.

Further to facilitate urinary acidimetry and alkalimetry and a rational study of the cases under observation, the writer has designed a chart with a scale based upon the standard units previously defined. This chart, when properly used, will give a graphic description of the urine's degree of acidity and alkalinity; it will record the variations in the acidity and alkalinity in a manner similar to that in which the rise and fall of the temperature are illustrated on the fever charts. Apart from the columns devoted to the date and hour, the quantity of urine voided, the medicines and nourishment taken, which occupy only a small portion of the chart, the greater part of the latter is divided into two equal sections—the one on the left, the ruling of which is printed entirely in red for recording the acidity; the other on the right, ruled in blue throughout, to show the alkalinity. In the centre, at the junction of the red and blue ruling, lies the zero point, indicating the chemic neutrality of the urine. Toward the right from the zero line ascend the degrees of alkalinity; to the left, those of acidity. The ruling in both sections is so arranged that even the one-hundredth part of the standard unit (0.01 degree) can be conveniently recorded. Each tenth of the unit (0.1, 0.2, etc., degree) is marked by a bolder line, while both units are made more distinct by double lines. Each chart can record twenty-nine examinations.

My observations on urinary acidity and alkalinity have been recorded, to the greater part, on these charts; a graphic illustration of some of the observations will be found in the following, but it must be remembered that the chart in print appears in only one color and in greatly reduced size.

On Some of the Causes and Variations of the Urinary Reaction. — The reaction of the normal twenty-four hours' urine, under the prevailing influences of environment and under a mixed diet, is always acid. The greater part of this acidity is due to the dihydric phosphates, NaH_2PO_4 and KH_2PO_4, which has been already demonstrated by Liebig.[1] The amount of acid sodium phosphate occurring in a urine is the greater, the less the phosphoric acid has been saturated by the base sodium. Phosphoric acid, besides forming dihydric phosphates, may occur in an acid urine in different other combinations, principally as monohydric phosphate, Na_2HPO_4, giving an alkaline reaction. If the dibasic and monobasic phosphates are present in a certain and definite proportion to each other, the reaction of the urine will be amphoteric—*i.e.*, red litmus paper is colored blue, and blue litmus colored red at the same time. Normal urine is never indifferent toward litmus; it will always react with it, indicating either acidity or alkalinity, or both when under the condition just mentioned.

A relatively small proportion of urinary acidity is due to the presence of acid urates. Uric acid, which when excreted normally hardly ever exceeds 0.75 gm. per diem, is a dibasic acid giving rise to the formation of neutral and acid salts. Although generally regarded as contributing to the conversion of some of the neutral into acid phosphates, the small amount normally produced, the neutral salts it furnishes at the side of acid urates, and its weak degree of acidity, do not let

[1] Liebig's Annalen, Bd. i., S. 173–184.

it appear as an important factor in the causation of urinary acidity.

The assumption that the acidity of the urine may be in part due to the presence of free carbonic, uric, and hippuric acids is apparently an erroneous one. Ingested acids, as well as those originating in the system, combine with bases to form salts. In case the elements and radicals should not occur in sufficient quantity to form salts, the acids—provided they were not introduced in lethal quantities—would become fixed by carbamid, which is always produced amply in the healthy organism.

Even if one or the other acid exists in a free state and in minute quantities in the urine, it would not materially affect the latter's acidity. Carbon dioxide, the weakest of all acids, is undoubtedly present as a gas at the moment and for some time after normal urine is voided; but I doubt very much that it is previously liberated in the system. It is my opinion that all the carbonic acid excreted with the urine originally occurs therein, loosely combined with a chemic body. The unstable compound becomes detached when the urine in the bladder is agitated; an agitation of the urine, sufficient to cause the liberation of this carbonic acid, is the very act of micturition. A portion of the carbonic acid continues to remain in its loose combination after the urine has been passed. The combined carbonic acid, however, will also soon be liberated and will escape completely when the urine is subjected to boiling. We may assume that the gaseous carbonic acid hardly contributes to the acidity of the urine.

The same may be said of lactic and acetic acids, whose very presence in normal freshly voided urine seems dubious. Hippuric acid, which is daily excreted to the amount of 0.35 gm., half as much as of uric acid, never occurs in human urine in the free state and only in combination with one of the alkalies, principally as hippurate of sodium, $NaC_9H_8NO_3$.

Uric acid is nearly insoluble in water, as 14,000–15,000 parts of water at 20° C., and 1,800–1,900 parts of it at 100° C., are necessary to effect this acid's solution. For this reason the urine's acidity is hardly ever increased by free uric acid, though the latter may be found uncombined—under certain conditions—as a crystalline precipitate soon after the urine is voided. This, however, does not indicate that it was kept in solution while the urine was still in the organism; it may have become detached from one or the other of its looser combinations.

As no precipitate is formed by sodium hyposulphite, indicating the presence of any free acid, we may conclude that all the acidity of normal freshly voided urine is practically derived from its acid salts. Aside from the dihydric phosphates, the other acid salts are of only secondary importance as factors in the production of urinary acidity, both as to quantity and as to the degree of acidity.

With the exception of some of the acid urates, whose uric acid is of probable plasmolytic nucleinar origin, the occurrence in the urine of other acid salts appears to be merely accidental—accidental in the sense that they are seemingly not the equivalents of any plasmolytic processes. The greatly reduced quantity of acid urates excreted during fasting represents quite exactly that amount of uric acid which is the consequence of plasmolysis. A portion of the acid urates derives its uric acid from proteolysis. Their occurrence, as well as that of other acid salts, though unfailingly and normally present in the urine of man, is still an accidental one, depending upon the amount and quality of the ingesta and the digestive processes in general.

Acid sodium phosphate, the principal dihydric urinary phosphate, seems to derive its phosphoric acid, to the greater extent at least, by plasmolysis. The phosphoric acid, combined to form a dihydric phosphate, appears to be a product of cell disintegration, occurring independently of the phosphoric acid yielded as such or in the form of phosphates by the food ingesta.

The monobasic phosphate may be considered as the derivation of the dibasic alkaline phosphate, Na_2HPO_4, of the blood. Whether or to what extent the uric acid of plasmolytic origin is effecting this conversion cannot be definitely stated, though it is possible that it combines with part of the sodium of the dibasic phosphate to form a sodium urate, leaving a monobasic, that is, the dihydric phosphate. One or the other acid salt not mentioned here may slightly contribute toward urinary acidity; for all practical purposes, though, the amount of phosphoric acid as eliminated by the acid sodium phosphate may well serve as a general indicator of the urine's total acidity.

If it is desired to ascertain the degree of acidity of a urine, it should be examined soon after it is passed, as it may occasionally attain some additional acidity upon standing. This so-called acid fermentation, to which Liebig and Scherer have already drawn attention, soon takes place at a moderate temperature, producing only a temporary increase in urinary acidity, which continues for about two or three days. Liebig isolated thus from the decomposing urine acetic and benzoic acids, while Scherer demonstrated the occurrence of lactic acid. The urinary mucus has been considered an active agent in effecting acid fermentation—an assumption to which I cannot agree, however. Disintegration of the urates and throwing down of acid urates and uric-acid crystals often take place during this type and stage of urinary decomposition.

The acids separated during acid fermentation of the urine are undoubtedly yielded by certain substances present—as for instance, alcohol, sodium hippurate, and sugar. While I have not been able to identify acetic acid during the acid fermentation of urine, I have succeeded in demonstrating the presence of benzoic acid in two or three, and that of lactic acid in a greater number of instances. I am of the opinion that many fermentative processes occur without the interference of a special ferment, and that they are the result of very simple chemic alterations of a complex substance.

Hippuric acid or a hippurate in solution, for instance, in the presence of sodic phosphate at a suitable temperature, will yield benzoic acid after the lapse of a certain time. I have repeatedly observed in the urine of diabetics a lactic-acid fermentation, generally occurring about sixty or seventy-two hours after micturition. Glucose, in the presence of decomposing albuminous bodies and alkaline carbonates, may be readily converted into lactic acid, as the first stage of a further fermentation:

$$C_6H_{12}O_6 = 2C_3H_6O_3.$$

The degree of urinary acidity varies at different periods during the twenty-four hours, and the reaction under physiologic conditions may even become temporarily alkaline. The appended Tables I. and II. will illustrate the rise and fall of urinary acidity. Table I. gives the mean reaction of eight hundred and seventy examinations of the urine of healthy males, while Table II. demonstrates the fluctuations in the reaction according to six hundred and six examined specimens of urine of healthy women. This table shows a distinct alkaline reaction at about six o'clock in the evening, while Table I. records a greatly diminished degree of acidity for the same period of the day.

The lesser degree of acidity and the temporary alkalescence of normal urine apparently stand in some relationship to the digestion of food, but this is not its sole causative factor. There will occur, independently of the ingestion of certain foodstuffs, a decrease of the urinary acidity during certain periods of the

twenty-four hours, and the reaction may even become alkaline occasionally.

Table III. illustrates the mean reaction of the urine of five healthy fasting males for the twenty-four hours, the observations being all made on one and the same day, the Jewish Day of Atonement. In one specimen of the urine examined I found an actual alkaline reaction, while the mean degree of acidity for some time during the afternoon had distinctly decreased.

The direct influence of certain foodstuffs in effecting a lesser degree of acidity of the urine or the latter's alkalescence depends in part on some of their constituents, which are excreted by the urine in the form of alkaline carbonates. When these occur in excess—that is, in greater quantities than necessary to saturate the acids present—the urinary reaction will be but slightly acid and more often distinctly alkaline.

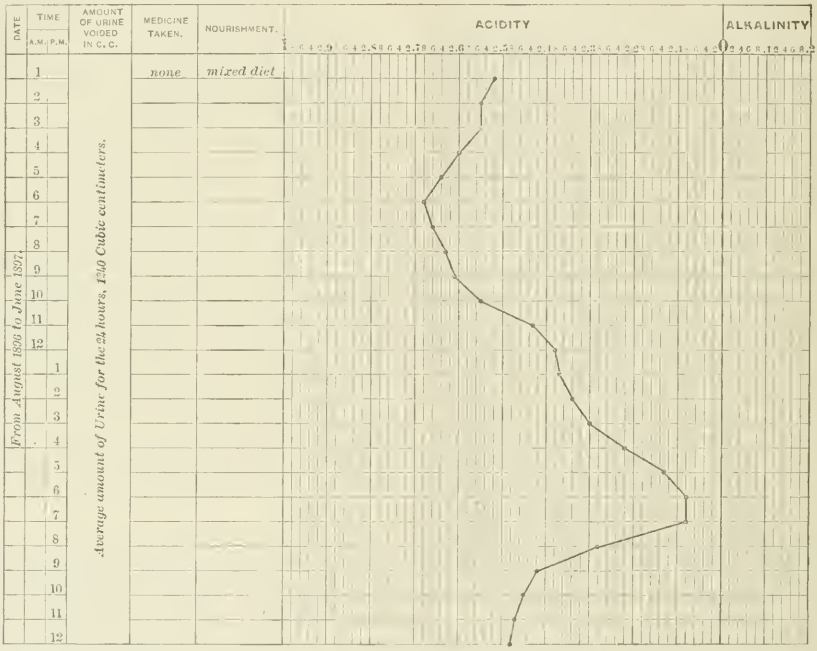

TABLE I.—Showing the Alterations in the Chemic Reaction of Normal Urine for the Twenty-Four Hours. Based upon 870 examinations of the urine of healthy males.

It is generally believed that this variation in the reaction takes place by the medium of the blood, and that the alkalescence of the latter is also increased.

If the alkalinity of the blood increases at all under these circumstances, it cannot be to such an extent as the increased excretion of alkaline salts by the urine would indicate. Moreover, the relative rapidity with which the salts of the organic acids—as the acetates, tartrates, malates, etc.—are converted into carbonates, in which form they appear in the urine, excludes in my opinion the direct participation of the blood.

In other words, if the urine is a filtrate of the blood it cannot contain a constituent in larger quantities than the former, and certainly not at a time when resorption has hardly begun. We must conclude, therefore, that the lesser acidity of normal urine or its alkalescence occurs independently of the condition of the blood, and that the urine derives its additional alkaline carbonates in another form or aggregate and in a more direct manner.

I have stated before that the alterations in the reaction of normal urine are not exclusively due to the ingestion of certain nutritive substances. The foodstuffs even act as accidental modifiers only; they influence the acidity according to their composition, their digestibility, their quantity, etc. Other accidental causes affecting more or less the degree of urinary acidity may set in during the twenty-four hours, but, fearing it would lead me too far, I have to refrain from detailing all these accidental and possible factors.

The accidental modifiers, in my opinion, only participate in the production of a lesser acidity or in that of the physiologic alkalinity of the urine; they do not effect it. These conditions will occur whether the accidental factors are contributing to it or not; some time during the twenty-four hours, most frequently in the afternoon, independently of the ingesta and other accidental causes, the urine becomes less acid and even alkaline. This phenomenon—for it is virtually but one—seems to be indicative of certain systemic processes, and it is met with in a more or less pronounced form in every human urine, in normal as well as in pathologic specimens. I am not prepared to offer any explanation at this day as to the nature of the underlying vital processes.

Table III., giving the mean reaction of the urine of healthy fasting males for twenty-four hours, though based on but five observations, will sufficiently demonstrate that a decrease in the acidity may occur independently of ingested substances. I have not carried on observations in fasting people beyond the twenty-four hours, and cannot state therefore whether the temporary decline in the urinary acidity is equally pronounced if the fasting is continued for some days longer; if the deprivation of liquid and solid ingesta is kept up for a longer period, the acidity will increase again and may even become excessive; this, however, is of pathologic significance.

Table IV. shows the urinary reaction of two pregnant women for twenty-four hours under a similar

mixed diet as was taken prior to conception. The tracing will at once illustrate the lessened acidity and the increased alkalinity so frequently met with during gestation. The variations in their persistent recurrence cannot be explained by the ingested foodstuffs, as the latter hardly differed in quality and quantity from the nourishment partaken of before pregnancy had occurred. A part of the lessened acidity or of the alkalinity may have been occasionally caused by the ingestion of certain foods, as of diluted organic acids in the form of fruit, etc., of which pregnant women are at times extremely fond.

I have alluded to the lessened urinary acidity of pregnancy, as I think it stands in causative relationship to certain vital processes taking place during the time of gestation. Though the urinary secretion in this state presents, as a unit, a lowered degree of acidity, it exhibits during the twenty-four hours modifications similar to those of the urine of non-pregnant women; that is, notwithstanding its general lack of acid principles, the urine of pregnancy still further loses temporarily some of its acidity at one or more periods during the twenty-four hours. The urine during the period of gestation is more deficient in carbamid and salts and more abundant in water than is generally that of non-pregnant women. Urine rich in water turns more readily alkaline than the urine of a higher specific gravity with an abundance of salts; consequently the urine of pregnancy will readily subject itself to the alkaline fermentation. The lesser acidity of the urine of pregnant women and its often occurring alkalinity might be ascribed to the facts last referred to. The manifold processes which we group together as alkaline fermentation invariably bring about the urine's decomposition; thus alkaline fermentation can take place only in decomposing or decomposed urine, and it is practically synonymous with a well-defined stage of the latter's decomposition. One of the chief processes of the alkaline fermentation is the splitting up of some of the carbamid into ammonium carbonate, thus:

$$CO(NH_2)_2 + 2H_2O = (NH_4)_2CO_3.$$

A part of the ammonium carbonate enters into the formation of urate of ammonium, $C_5H_3(NH_4)_2N_4O_3$, part of it into that of ammonio-magnesium phosphate, $MgNH_4PO_4 + 6H_2O$. This ammoniacal decomposition will in the course of time occur in every healthy urine upon standing; it is of pathologic significance if it takes place within the organism or immediately after the urine is voided.

The low degree of acidity and the alkalinity of the urine of pregnancy, however, are not caused by any auto-fermentative processes, and are not dependent upon the presence of volatile alkali. The peculiar character of the urine of this condition is due to salts of the fixed alkali, and reflects certain vital processes and not merely some auto-fermentative alterations.

True, the composition of the urine of pregnant women favors rapid ammoniacal fermentation, which may even take place before it is voided; still the urine of this condition possesses a "permanent" alkalescence, which is due to its non-volatile alkaline salts.[1]

The inherent characteristic of healthy urine—its lesser acidity or its eventual alkalescence during one or more periods in the twenty-four hours: I mean that condition which occurs independently of accidental causes—is to be met with, more or less pronounced, during all the different periods of life. Accidental causes will still further decrease the declined acidity, and their influence might vary according to the age and the constitution of an individual. It is in most

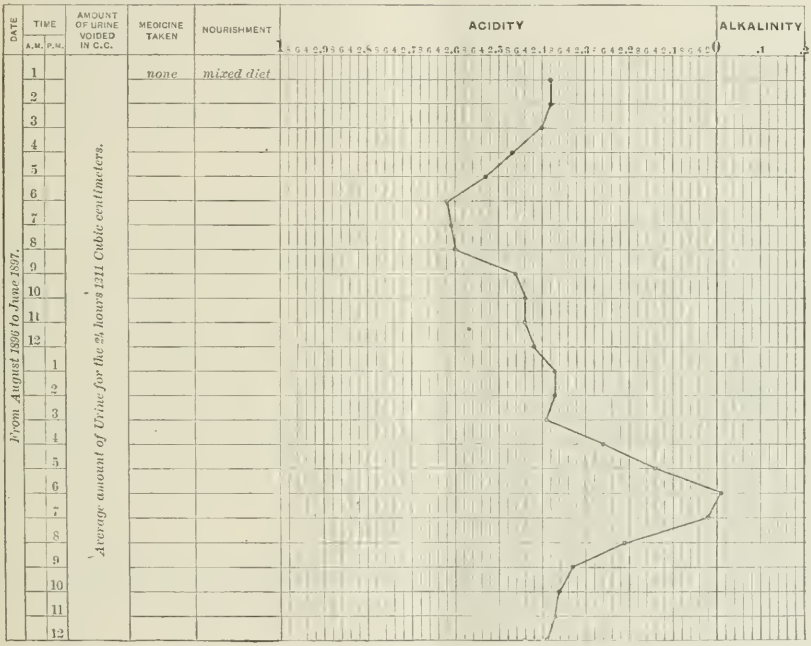

TABLE II.—Demonstrating the Alterations in the Chemic Reaction of Normal Urine for the Twenty-Four Hours. Based upon 606 examinations of the urine of healthy women.

[1] The alkaline reaction of the urine in general depends mainly upon the products consequent to the disintegration of carbamid, or upon the carbonates of the alkalies. If the latter are present in sufficient quantity they will soon effect a decomposition of the urea. Hence the urine should be subjected to an immediate examination to obtain exact results as to its kind and degree of alkalinity.

cases nearly impossible to differentiate between the variations in the urinary reaction due to inherent and those due to accidental causes, as both factors in the production of these alterations may be coincident. Complete deprivation of foodstuffs even may not demonstrate the exact rôle which the inherent causes play therein, as during a fast of any length of time the excretion of phosphoric acid becomes greater, which will influence the reaction of the urine. The yielding of greater quantities of phosphoric acid is mainly due to the decomposition of the osseous tissues, and it will be eliminated, combined possibly with sodium, in the form of an acid sodium phosphate.

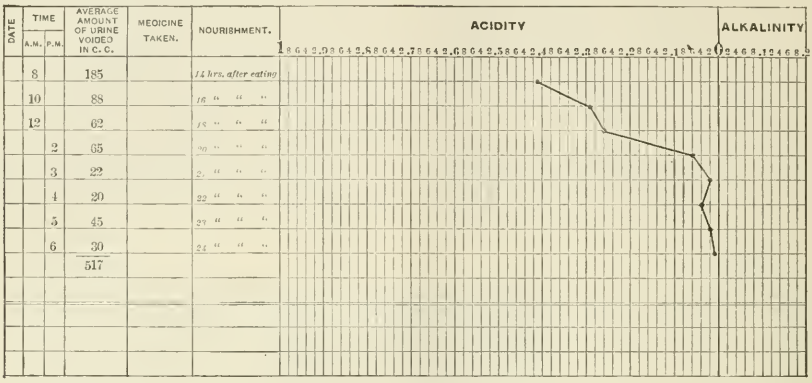

TABLE III.—Illustrating Alterations in the Chemic Reaction of Urine while Fasting. The mean reaction of the urine of five healthy fasting males.

Table V. records the urinary acidity for three days of a patient afflicted with prolonged hydruria. It will be noticed that the mean degree of acidity is an unusually small one. However, if the large amounts of urine voided are taken into consideration, we will find that the absolute amount of acid principles excreted is far in excess of that occurring under normal conditions. The reaction curve, though very large amounts of urine were voided, clearly shows the variations during the twenty-four hours and the still further decline of the acidity during certain periods. One would suppose that the enormous amount of fluid ingesta, principally of plain water, would bring about a rather uniform degree of urinary acidity; instead of this, we meet with a diminished degree of acidity, especially in the afternoon hours, much in the same manner, though somewhat less pronounced, as it occurs in the urine of healthy individuals.

Tables VI., VII., and VIII. still further illustrate the inherent tendency to a lesser urinary acidity during certain hours of the day. Each drawing represents the mean curve of acidity, for the different hours of the day, of fourteen cases of diabetes mellitus under the influence of certain nutritive substances. Table VI. records the urinary acidity under the exclusive ingestion of meats and fats, Table VII. that under an exclusive milk regimen, and Table VIII. that under a mixed diet with carbohydrates in abundance.

The acidity is the greatest under the exclusive meat-and-fat ingestion, the smallest under that of a mixed diet. The curve obtained while the patients were under the influence of mixed food does not materially differ from that of healthy persons under the same regimen. The graphic illustration of the acid degree of the urine of the same patients while they were subsisting on meats and fats shows an excessive amount of acidity. This we may *a priori* ascribe to the effect of the specific nutriment. Either the excessive quantities of acid salts are due to proteolysis directly, or they are caused by plasmolysis—the ingested foodstuffs being not sufficient to continue normal metabolism, or they may be produced by both these factors together.

The same patients under a strict milk diet, as recorded in Table VII., excreted an amount of acid salts less than when under a meat-and-fat regimen and more than when subsisting on mixed food. This is especially noticeable if a comparison of the degree of acidity and the amount of urine voided is made. Under the meat-and-fat diet the average quantity of the twenty-four hours' urine amounted to 3,205 c.c., under the milk regimen to 2,705 c.c., and under the mixed nutriment to 1,975 c.c. Naturally the fourteen cases under observation did not always remain in the same condition, and an improvement more or less pro-

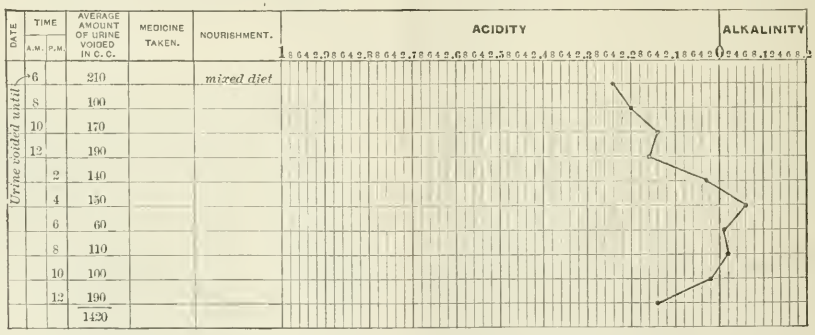

TABLE IV.—Showing the Mean Urinary Reaction of Two Pregnant Women (Sisters) for the Twenty-Four Hours.

nounced ensued, at least for the time being. The fourteen patients were in a precarious condition when first seen—that is, when the meat-and-fat diet was ordered; they were somewhat improved when the milk regimen was started, and most of them were free of dextrose or nearly so when the mixed diet, including sufficient amounts of carbohydrates, was prescribed. The diminished amount of urine voided under the milk and mixed diets seems to be due both to the nutriment and to the improved condition.

Apart from all secondary considerations, the reaction records in Tables VI., VII., and VIII. prove beyond doubt that there occur variations in urinary acidity independently of food decomposition and fermentation, which seem to be of an inherent nature.

Table V.—Urinary Acidity of a Case of Hydruria for Three Days.

The Normal Degree of Urinary Acidity.—Hyperacidity, as well as hypoacidity or hyperalkalescence, of the urine is the indicator of some disturbance of the systemic equilibrium. It matters not for our considerations of what precise nature are the factors which interfere with the normal course of certain vital processes.

These factors may produce a transitory disturbance only, in which instance the abnormality in the urinary reaction may be readily pointed out; or they may exert a persistent and continuous influence, directly or more indirectly, when, on account of their chronicity and that of the abnormal urinary reaction resulting therefrom, the latter may be often deemed normal and a pathologic state may be frequently overlooked.

Moreover, there are individuals, apparently healthy and not losing in body weight, who excrete habitually either larger or lesser amounts of acid urinary substances; that is, if compared with the degree of urinary acidity usually found in persons living under similar conditions. In these cases we have to assume that the metabolic processes, though being normal, are either accelerated or retarded. Another explanation for these phenomena cannot be attempted.

The Mean Degree of Acidity of the twenty-four hours' urine of healthy adult males (Table I.) I found to be 0.434. The average quantity of urine voided per diem in the cases under observation amounted to 1,240 c.c.

Expressed as oxalic acid, the total urinary acidity for the twenty-four hours would correspond to 3.390408 gm.

The individuals weighed in the mean 74 kgm.; the urinary acidity amounts therefore to 0.045817 gm. of oxalic acid to 1 kgm. of body weight.

In healthy adult women the mean urinary acidity for the twenty-four hours (Table II.) amounts to 0.373 degree. The quantity of urine excreted during this time I found to average 1,211 c.c. Expressed as oxalic acid, the total acidity of the urine per diem would be the equivalent of 2.843379 gm.

For each kilogram of a mean body weight of 66.5 kgm. we would have, therefore, an amount of acidity corresponding to 0.042756 gm. of oxalic acid.

The urine of men contains a larger amount of acid salts than that of women, which may be due to:

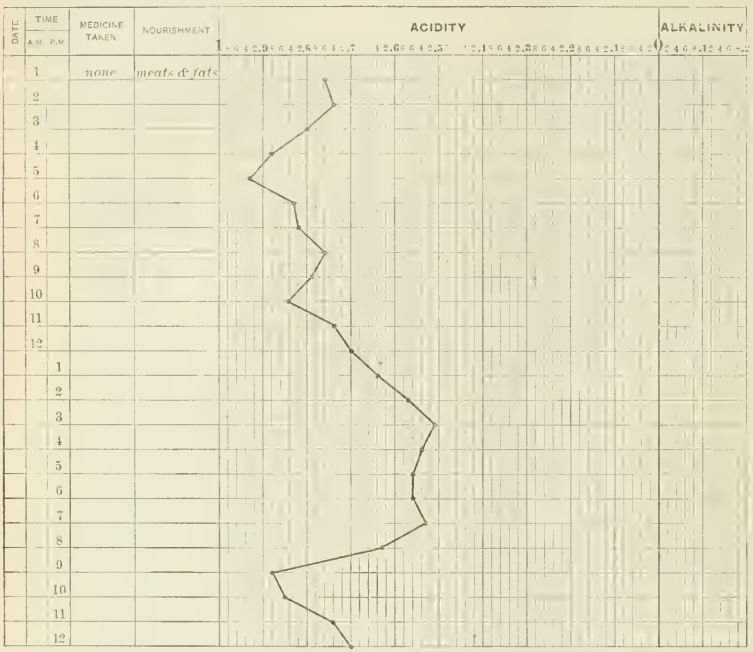

TABLE VI.—The Mean Curve of Urinary Acidity for the Twenty-Four Hours of Fourteen Cases of Diabetes Mellitus. *A*, under a rigid meat and fat diet.

(*a*) A relative greater ingestion of foodstuffs for each kilogram of body weight.

(*b*) Some other accidental influences.

(*c*) A greater general activity.

(*d*) A higher intensity or an acceleration of certain vital processes.

It is an easy matter to calculate the total acidity of a twenty-four hours' urine and express it as oxalic acid, if its relative acidity and its quantity voided for that time be known. I alluded to this point in the first part of this communication, where I have brought forth an example to make clear the calculation.

The amount of urine excreted and the weight of the individual should always be taken into consideration. Though we may take it for granted that the normal degree of acidity of a twenty-four hours' urine be 0.434 in the male and 0.373 in the female, the urines of certain pathologic states may be abnormally concentrated and scanty in amount, or they may be of a low specific gravity coincident with a diminished or excessive flow.

I have found in my observations that during the twenty-four hours and under normal conditions, 16.756 c.c. of urine are excreted for each kilogram of man, and 18.210, c.c. for each kilogram of woman.

If a man weighs 95 kgm., he should therefore normally void 95 × 16.756 c.c.; that is, 1,591.820 c.c. of urine per diem.

Assuming the mean normal degree of urinary acidity for the twenty-four hours to be 0.434, the total daily acidity of this man's urine expressed as oxalic acid would amount to 4.3523542 gm. If the urinary acidity of one kilogram of man is represented by 0.045817 gm. of oxalic acid, and if for each kilogram of body weight 16.756 c.c. of urine is discharged, then it may be inferred that 16.756 c.c. of urine possesses a total acidity equivalent to 0.045817 gm. of oxalic acid. A urine to the amount of 1,591.820 c.c. should therefore possess an acidity equal to 4.352615 gm. of oxalic acid.

I have in the calculations presented carried out the fractions to their full extent, to demonstrate that the results obtained are practically identical. While one calculation starts from the degree of urinary acidity and gives the total acidity expressed as oxalic acid, the other calculation, expressing the result by the same medium, starts from the kilogram of body weight and its accordant amount of urinary secretion and acidity.

It will be noticed that the results of both calculations are absolutely identical to the fourth decimal; beyond that is shown an infinitesimal difference, which is due to the modes of calculation. For all practical and clinical purposes we may round off the different figures thus:

The urine of the male: Mean degree of acidity, 0.43; total acidity per diem corresponding to 3.39 gm. of oxalic acid; acidity for each kilogram of body weight corresponding to 0.046 gm. of oxalic acid; urine excreted for each kilogram of body weight, 17 c.c. per diem.

The urine of women: Mean degree of acidity, 0.37; total acidity per diem corresponding to 2.84 gm. of oxalic acid; acidity for each kilogram of body weight corresponding to 0.043 gm. of oxalic acid; urine excreted for each kilogram of body weight, 18 c.c. per diem.

The figures laid down in the foregoing are derived from investigations carried on in the city of New York during all the seasons of the year. No doubt the average acidity of the urine in other localities of this country or in other parts of the world may differ more or less from that I have met with. Even if the degree of an inherent urinary acidity were the same in all sections of the globe, the ultimate degree of urinary acidity would be a diverse one on account of the varying accidental modifiers in the different localities.

We may conclude that the acidity of the urine of males is abnormal or pathologic if it is in the mean for the twenty-four hours decidedly less or more than 0.43 degree, and that the acidity of the urine of women showing a pronouncedly lesser or greater degree than 0.37 must be considered abnormal.

The Urinary Reaction as Affected by Certain Medicinal Agencies.—In considering the influence of certain drugs on the urinary reaction, I abstain from

referring to their effect upon urine of a normal or less degree of acidity or upon alkaline urine, and shall confine myself solely to such observations as relate to the influence of some therapeutic substances upon urine of an excessive degree of acidity.

Incidentally to some experiments on my own person on the behavior of certain types of nutritives toward the reduction of body weight, I had occasion to observe and study closely a hyperacid urine and the effect of some therapeutic modifiers upon its degree of acidity. The increased amount of the acid urinary salts in this instance was caused either directly or indirectly by the almost exclusive ingestion of proteid substances, and the drugs were primarily employed to overcome a vesical uneasiness, the consequence of the hyperacidity of the urine.

A perusal of Table IX. will show that under a mixed diet on March 3, 1898, the amount of the twenty-four hours' urine and its degree of acidity were almost normal. The proportion of the excreted uric acid to the urinary carbamid was found to be somewhat small, if the ratio of 1 to 45 is accepted as a standard. On March 4th, under an almost exclusive proteid nourishment, the amount of urine voided during the twenty-four hours became considerably diminished, while the acidity, as expected, was raised to 0.71 degree. The proportion of uric acid to carbamid became not materially altered, though the absolute amounts of both substances were largely increased. The following day, under a larger quantity of a similar nourishment, the amount of urine again became almost normal, while the acid degree was slightly lessened; the proportion of uric acid to carbamid was 1 to 47—both substances occurring in larger absolute amounts. On March 6th the amount of urine voided was about normal, while the degree of acidity was raised to 0.77, the proportion of uric acid to carbamid remaining about the same—1 to 48. The following day, on account of some vesical and urethral uneasiness, citrate of lithium was taken, the dose amounting to 0.75 gm. three times daily. The quantity of urine for that day became markedly increased, while the acidity fell to 0.61 degree. The proportion of uric acid to carbamid became only slightly altered. On March 8th, while still under a food greatly abundant in albuminous matter, and under the influence of 3 gm. of the lithium citrate, the urine became about normal in quantity, the degree of acidity increased somewhat, and the proportion of uric acid to carbamid was reduced to 1 to 43. The following day the degree of acidity was still more heightened, and I concluded to substitute thereafter piperazin for the citrate of lithium.

On March 10th, under a nourishment a little increased in its caloric value, piperazin in aerated water was taken, amounting in all to 1 gm. The quantity of urine decreased, as did its degree of acidity. The discharge of uric acid was in the ratio of 1 to 41 of carbamid. Under larger doses of piperazin, 1.5 gm. to 1.75 gm. per diem, the degree of acidity of the urine remained nearly stationary and the output of uric acid never amounted to more than 1 part in 40 parts of eliminated urinary carbamid.

On March 14th, under an almost exclusive proteid nourishment, 1 gm. of lysidin was taken in broken doses. The quantity of urine voided was little changed. The acid degree amounted to 0.66, and the uric acid-carbamid ratio was 1 to 43.

Two grams of lysidin effected little change from these figures. Three grams of the drug caused a slight increase in the quantity of the urine, but bore very little influence upon its general degree of acidity. For the five days during which the quantity of lysidin taken amounted to 3 gm. for the twenty-four hours, the amount of the carbamid excretion became noticeably diminished, while the uric-acid elimination remained about the same. The latter's proportion to the urea present was therefore increased, amounting on one day to 1 to 35.

On March 21st, still under a diet abundant in albuminous material, 1 gm. of uricedin was taken. The degree of acidity fell at once to 0.58. The following day, when 2 gm. of that drug was used, the acidity became lowered to 0.53 degree, while the amount of urine voided was raised to 1,660 c.c. Uricedin, in doses of 3 gm. per diem, effected a still lower degree of acidity, which averaged only 0.12 degree on March 26th. The daily dose of 3 gm., though considered a small one for this mild-acting preparation, brought about pronounced alkalescence of an otherwise hyperacid urine on more than one occasion during the twenty-four hours. The excretion of uric acid became

TABLE VII.—The Mean Curve of Urinary Acidity for the Twenty-Four Hours of Fourteen Cases of Diabetes Mellitus. *B*, under an exclusive milk regimen.

also proportionally enlarged, being as high as in the ratio of 1 part to 27 parts of carbamid on March 25th.

From March 28th to April 1st it was necessary to turn again to a more pronounced mixed diet. No medicine was taken during that period and the acidity resumed its normal degree. The absolute quantities of both carbamid and uric acid became markedly diminished, and the latter occurred on one occasion in the proportion of 1 to 68 of carbamid.

Subsequently the proteid nutriment was again tried for another four days, with the ultimate result of reducing the body weight to 91 kgm. The urinary acidity for the first of these four days was excessive, but it fell at once after uricedin in small doses was taken again.

Having found it inopportune to make regular daily examinations of the fæces, I could not calculate the nitrogen balance. This, however, is not essential for our considerations.

Inasmuch as the degree of urinary acidity is the indicator of certain vital processes, the above-cited data will interest us, though they do not reflect a urine of a pathologic state. The increased acidity of the urine in this instance was caused by a known factor, which was introduced purposely.

Whether this factor—the proteid nutriment—acts as a direct intensifier of the urinary acidity, or whether it modifies the degree of the latter in a more remote and indirect manner, I shall not dwell upon any further.

The proportion of uric acid to carbamid in the related case was and is normally very small, about 1 to 55 or 1 to 60.[1] The exclusive proteid nutriment altered this ratio, augmenting the formation and the subsequent excretion of uric acid. The latter was still further increased after the administration of certain medicinal substances.

Furthermore, the degree of general urinary acidity was immediately raised after the albuminous diet was instituted, and the carbamid secretion was doubled in amount. On the other hand, the behavior of the drugs employed was a different one toward the general acidity than it was toward the uric-acid elimination. While citrate of lithium, piperazin, and lysidin effected a decrease—though minute—of the general urinary acidity, they invariably caused an increased output of uric acid.

The action of uricedin on the degree of general acidity of the urine was very decided and more pronounced than that of either of the drugs just mentioned. It successfully lowered the acidity and turned the reaction alkaline on many occasions; this, however, cannot be seen from the table, as it only records the average degree of acidity for the twenty-four hours, and not the reaction of each specimen of urine voided during that time.

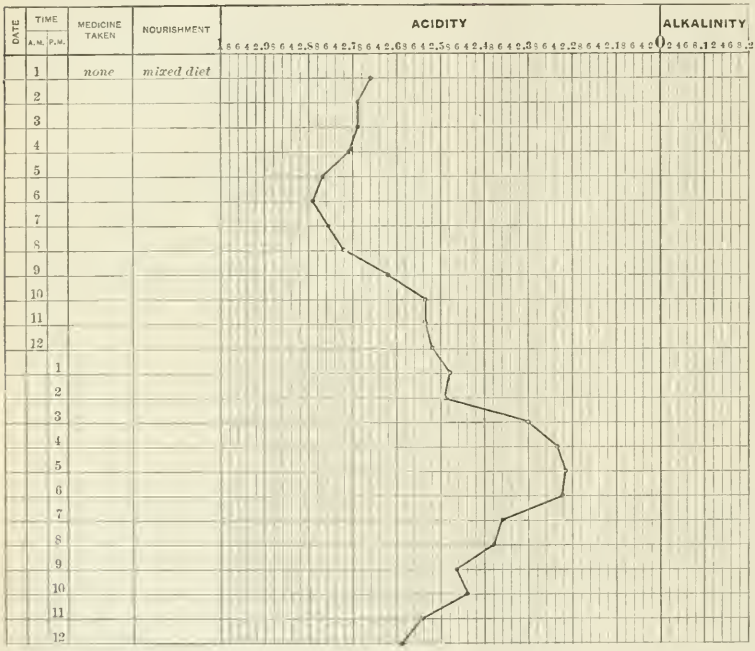

TABLE VIII.—The Mean Curve of Urinary Acidity for the Twenty-Four Hours of Fourteen Cases of Diabetes Mellitus. (, under a mixed diet.

Some medicinal agencies tend to demonstrate that we may have an apparently increased output of uric acid without a proportional augmentation of the general urinary acidity. When uricedin was taken, the degree of the general acidity became subnormal, while there occurred an enlarged excretion of uric acid simultaneously—the latter, as a matter of course, having been eliminated in the form of a urate.

Medicines diminishing the general urinary acidity act either as accidental modifiers by retarding or preventing the formation of acid salts or by influencing directly the anabolic and catabolic processes. Some remedial agents, however, possibly effect the reduction of urinary acidity by both, acting as accidental modifiers as well as influencers of the systemic activity.

Moreover, it is an easier task from the clinical standpoint to render the urinary reaction alkaline or to reduce the acidity and to keep it for some time at a lesser degree, than to increase it. It seems that the human organism is more readily accessible to the influence of drugs diminishing the acidity of the urine or effecting its alkalescence than it is to that of innocuous medicinal agencies given for the purpose of raising the acidity. I have found no drug of a mild nature equalling the proteid nutriment in effecting the latter.

The influence of certain drugs on the urinary hyperacidity of some pathologic conditions was studied by me in a number of patients. I will relate some of the cases in the following:

CASE I.—Mrs. I. S——, aged thirty-two, American, consulted me in June, 1897, on account of a general

[1] Haig's ratio of 1 part of uric acid to 33 parts of urea, I find too large for the average urine of Americans; the proportion of 1 to 45 or 1 to 48 appears to be about the norm.

feeling of malaise, associated with depression, irritability, and insomnia.

The examination did not reveal any organic disease. The urine was scanty; its specific gravity, 1.028; and came greatly enlarged, rising to more than 1,800 c.c. —about twice the amount previously voided. The degree of urinary acidity became reduced to 0.7; but this, on account of the increased amount of urine, is

TABLE IX.

its degree of acidity, 1.12. No abnormal constituents were present.

I diagnosed the affection as one of latent gout, and treated the same accordingly.[1] Gram doses of sodium salicylate and dimethyl-xanthin (theobromine) were ordered to be taken in hot water three times daily.

The quantity of urine secerned for the first twenty-four hours while influenced by this combination be-

[1] I did not search for uric acid or the urates; their absence from the urine does not always indicate their retention in the organism.

no indication that the absolute amount of acid salts became lowered.

On the fourth day 1,500 c.c. of urine, of a specific gravity of 1.017 and of an acidity of 0.66 degree, was secreted, and the patient felt greatly relieved.

The medication was continued for a fortnight, during which period and for some time after the urinary acidity was kept down to 0.5 degree. The lessened acidity of the urine was coincident with a marked improvement of the systemic condition.

In December, 1897, there was a recurrence of the

condition of malaise and the concomitant phenomena. The secretion of the urine became again scanty, the specific gravity was raised to 1.028, and the acidity to 0.85 degree.

Taking the excessive acidity again as an indicator of the systemic condition, I administered the sodium salicylate and dimethyl-xanthin—this time, however, with very little success, as the drugs made only a slight impression upon the urinary acidity and did not alter the general status.

In the beginning of January, 1898, the patient was started on piperazin water. Subsequently the quantity of urine became larger, and the specific gravity, the degree of acidity, and the absolute acidity were somewhat lowered. The patient improved to some extent, when, on March 24th, she had a well-defined acute attack of gout, including pyrexia and pains in the toes and particularly in the lumbar region. I immediately put the patient on uricedin, 2 gm., three times daily. The amount of urine voided became nearly trebled during the first twenty-four hours; the specific gravity fell to 1.0135 and the acidity to 0.32 degree. On the third day the average acidity amounted to 0.2 degree and the acute condition had almost disappeared. In a week the patient had completely recovered from the attack. Diminished doses of the drug were continued, and the urinary acidity was kept below normal for some time thereafter.

The patient has had no recurrence since, and feels very well at the present day.

Case II.—Mr. A. H——, aged fifty-six, German, is afflicted with a general gouty diathesis and is subject to occasional goutyform attacks of the diaphragmatic type. The paroxysms are, as a rule, not of a very severe character; still they cause the patient a good deal of anxiety and restlessness.

The urine, on November 16, 1897, just prior to a paroxysm, was scanty in amount, of a high specific gravity, 1.036, and of an acidity of 0.78 degree. Soon after the attack a comparatively large quantity of urine, of a density of 1.028 and an acidity of 0.92 degree, was excreted. A urate deposit composed of acid urates was precipitated almost immediately after the secernment of the urine.

Potassium iodide and vinum colchici seminis, in doses of 0.5 gm. and 1 c.c. respectively, every four hours, were subsequently prescribed.

The pain was soon allayed by this combination, and after twelve hours the diuretic property of the colchicum seed demonstrated itself.

After a week's administration of these drugs the quantity of urine per diem amounted to 1,750 c.c., its average density to 1.022, and its mean acidity to 0.65 degree. Medication was discontinued toward the middle of December.

On February 2, 1898, the patient experienced a very painful attack, resembling almost in every detail one of angina pectoris. The first urine excreted after the paroxysm had a specific gravity of 1.030 and an acid degree of 0.8.

To keep down the urinary acidity the patient was put on potassium citrate, in doses of 0.35 gm. three times daily. The acidity soon became subnormal and the patient felt comfortable. Potassium citrate, however, like all similar remedies, possesses a great drawback, inasmuch as it produces no lasting effects. It will readily reduce the urine's acidity or bring about its alkalescence as long as it is taken; as soon, however, as its administration is discontinued, the urine will attain again its former degree of acidity. This fact demonstrates that potassium citrate and the drugs belonging to its class—in therapeutic doses at least—are non-influencers of metabolism.

A more permanent effect is produced by uricedin, a double salt, into the combination of which enter, besides a citrate, the sulphate and chloride of sodium. A patient, especially one afflicted with a so-called diathesis, is only too apt to become tired of and satiated with incessant medication. To prevent exacerbations, it is essential to keep the urine of gouty individuals in a state of low acidity for long periods. The last-mentioned drug, in doses from 1.5 to 2.5 gm., taken even only twice or three times during a week, will often effect a comparative permanency of a lesser urinary acidity.

On March 5th the patient was ordered to take the drug in doses of 2 gm. every third day. With occasional interruptions of a week or two, he has taken it ever since. The urinary secretion is about normal in quantity, its specific gravity varies between 1.017 and 1.028, and its degree of acidity between 0.2 and 0.4. The patient feels comfortable and at the present moment shows occasionally only slight symptoms of a gouty dyscrasia.

Case III.—Mr. E. S. G——, aged thirty-one, American, consulted me first on March 12, 1898. The patient was greatly emaciated and showed marked metabolic disturbances, and was afflicted with an irritability of the bladder. He ascribed his condition to his irregular mode of living and long-continued nightwork.

The quantity of the urine of the following twenty-four hours was estimated to be 1,200 c.c.; its specific gravity amounted to 1.031, and its degree of acidity to 0.99. Carbamid and uric acid were present in about the normal ratio. Albumin and dextrose were not detected.

The patient was put on an exclusive milk regimen, starting with 4 litres per diem. Medicinally sodium bicarbonate combined with sodium acetate, 0.5 gm. of the former and 0.75 gm. of the latter *pro dosi*, was ordered to be taken four times daily.

On March 19th the patient had gained 1.5 kgm. in body weight; the urinary secretion amounted to 1,620 c.c., with a specific gravity of 1.024 and an acidity of 0.68 degree. (It must not be inferred, however, that the fall in the acid degree corresponds with the absolute decrease of acid salts.)

Incidentally the irritability of the bladder, principally due probably to the excessive urinary acidity, was relieved to some extent.

The prescribed diet and medication were continued for a fortnight longer, when the patient was attacked with a well-defined case of rubeola.

During the course of the acute affection, which lasted for three weeks,[1] the alkaline therapy was dispensed with. At the onset of the pyretic state the flow of urine became greatly diminished, the density rose to 1.033, the acidity to 0.95 degree. The nitrogenous urinary constituents, principally carbamid and uric acid, occurred in excess; on the third day nucleoalbumins in considerable quantity were detected, and on the fifth day serum albumin appeared in the urinary secretion. The latter abnormal constituent, even at the present day, is still to be found in traces in the patient's urine.

The urine's acidity was greatly diminished, but remained still above normal soon after recovery from the attack of rubeola had taken place.

On April 28th the patient was in a state of marked adynamia and mental depression, complained of dull lumbar pains and of vesical irritability. Still the secretion of urine had materially lessened, but its degree of acidity had meanwhile risen again to 0.83. Besides medication for the general asthenic condition, urotropin in 0.5 gm. tablets, each dissolved in 50 c.c. of water, was ordered to be taken every three or four hours. This was done in order to overcome the irritability of the bladder as well as to effect incidentally a reduc-

[1] The patient was treated by his family physician during that time; I merely made the examination of his urine.

tion of the urinary acidity. While the vesical condition was ameliorated after 10 gm. of the drug had been taken, the latter failed to exert any influence whatsoever upon the acid degree of the urine. Prolonged administration of this remedial agent, though benefiting the patient's local affection, definitely demonstrated its inefficiency in the reduction of urinary acidity.

Case IV.—Mrs. L. G——, aged thirty-four, Cuban, is afflicted with a general lithæmic condition. On the evening of February 19, 1898, she experienced violent exacerbations of pain in the gluteal and inguinal regions. Oliguria set in the following day. The urine's density amounted to 1.032, and its acidity to 0.79 degree.

Taking the excessive acidity of the urine as an indicator of a perversion of certain systemic processes, which in turn are the precursors of the lithæmic state, I prescribed an alkaline antidote in the form of potassium bitartrate, 2 gm. of which was ordered to be taken three times per diem.

The appended table will illustrate the action of the potassium bitartrate on the secretion, specific gravity, and degree of acidity of this patient's urine.

Date.	Medicine Taken.	Amount of 24 hours' Urine in c.c.	Mean Density.	Mean Degree of Acidity.	Plus and Minus Acidity in Degrees.
February 19.	Morphine	....	1.026	0.52	.....
" 20.	"	860	1.032	0.79	+ 0.27

March 1....	"	1,510	1.017	0.46	— 0.06
" 2....	"	1,550	1.015	0.47	+ 0.01

The acute symptoms subsided as the degree of acidity fell.

Case V.—Mrs. H. B——, aged twenty-three, American, began to suffer from a severe case of pleurodynia on May 9, 1898. Micturition occurred quite frequently, though the amount of urine voided for the twenty-four hours was rather small. The specific gravity of the excretion was 1.023, and the acid degree 1.05; abnormal constituents were not present. Apart from repeated hypodermatic injections of morphine and atropine for the relief of the acute pain, I endeavored to reduce the urinary acidity. Sodium salicylate in gram doses, three times daily, was consequently ordered to be taken. The degree of acidity and the absolute quantity of acid salts became diminished on the second day, though not sufficiently so to mark it an improvement. On the third day the acid degree of the urine had again fallen somewhat, it being then 0.9. The following day 0.86 degree, and on the fifth day 0.7 degree of acidity, were recorded. The drug was employed for two days longer, without effecting any further reduction of the urine's acidity.

As the myalgic symptom had almost disappeared by this time, no further medication was ventured then. On the ninth day the urinary acidity declined to 0.45 degree, spontaneously to all appearances.

Apart from the report on the action of various drugs upon urinary hyperacidity, the last section was added to demonstrate the clinical value of determining the urinary acidity.

True, the degree of acidity is only one indicator of the systemic condition, but I deem it of greater and more unfailing significance in the recognition of a number of diseases than any other single symptom.

The causes underlying the changes of the acidity of urine are little understood as yet, and until we shall learn more about them our treatment of urinary hyperacidity will naturally remain a more or less empiric one.

NEURASTHENIA AND AUTO-INFECTION.

By A. M. DAVIS, M D.,
PHILADELPHIA, PA.,
PATHOLOGIST TO THE GERMANTOWN HOSPITAL.

In attempting a study of the clinical manifestations of neurasthenia, one cannot fail to note the large and widely diversified chain of symptoms which present themselves, and the endeavor to explain those symptoms brings us in contact with the physiology of the whole economy; *i.e.*, cerebro-spinal, gastro-intestinal, genito-urinary, and circulatory systems; for no one symptom or group of symptoms referable to a single organ exists in a given case, but all proceed in a manner *pari passu* with each other, the preponderance of one class giving rise to the type of the disease—cerebral, cardiac, spinal, sexual, gastric, etc. Although the etiology of this so-called functional disorder has been dwelt upon at length ever since its recognition as a distinct entity by Beard, yet it would seem, at least in many cases of profound type, that some underlying condition predisposing to nerve devitalization was present; some product or group of products formed and circulated in the economy to cause such general disturbance as exists in a well-marked case.

Whether the disease originates primarily from exhaustion of the nerve centres or is the direct result of the action of animal alkaloids and their products on these centres, remains as yet to be demonstrated.

Physiologically the "cell receives by assimilation from the medium which surrounds it certain materials which it converts into its own proper substance or which it may utilize in various ways. There appear to be two phases of the assimilative process: (*a*) one in which the cell transforms the matter which it receives; (*b*) the other, in which the substance transformed becomes an integral part of the cell. The first phase is well marked in the life of a vegetable cell, but is not so distinct in an animal; the second phase, on the contrary, exists to an equal extent in both the animal and the vegetable cell. The assimilating process in the living portion of the cell has received the name of metabolism, while the chemical change by which matters taken up by the cell may be converted into other matters is called metastasis. Thus a cell may by metabolic processes convert dead matter into living matter like itself, or it may by metastatic processes convert dead matter into another form. The dissimilative processes occurring in the living cell consist of chemical changes in the substance of the cell itself or of materials in contact with the cell. Certain materials are separated from cells by a process which may be termed 'cellular excretion,' and other cells may store up certain materials in their interior—a process called 'cellular secretion.'"[1]

Aside from this purely physiological mechanism at work in cells of our bodies, Gautier has shown that they possess fermentative properties independently of oxygen derived externally, which give rise to the formation of alkaloids and other waste products in the tissues. That these toxins exist in normal tissues, and that they are present in the normal fluids of the body —*i.e.*, blood, saliva, and urine—have been abundantly demonstrated.

Thus Bouchard produced, by injections of normal urine into rabbits, slow respirations, contracted pupils, muscular weakness, lowered temperature, abolition of

[1] McKendrick: "Text-Book on Physiology."

reflexes, and death from respiratory paralysis. Gautier extracted an alkaloid from normal urine, which, when injected into rabbits, arrested the heart in systole, paralysis and death following. In Bouchard's experiment, the salts present in the urine (urea, uric-acid and potassium salts) were not in sufficient amount to produce the symptoms noted.

Coppela found experimentally that the healthy blood of a dog, without having undergone putrefactive changes outside of the body, exhibited highly poisonous properties; and, further, that from normal saliva a toxic substance is obtained which is strongly reducing in its action.

In physiological conditions, then, toxins are constantly being formed and eliminated through the various paths of exit of our bodies; when from some retarded or suspended action occurring in pathological states (intestinal torpor with fæcal impaction, altered skin secretion, fevers, or anuria from acute renal congestion) an accumulation of these deleterious products takes place, inevitable symptoms of the condition known as "toxæmia" appear.

Farquharson writes: "No better example of a self-propagated disease can be found than gout, and the same relation which nitrogenous waste products bear to this affection may be assumed by alkaloids developed in the tissues to other diseases." Lépine and Guérin have shown that various acute diseases, notably typhoid fever and pneumonia, are attended with an increased urinary discharge of alkaloids; Villiers found a peculiar alkaloid in the alimentary canals of children who died of broncho-pneumonia. Spica detected the presence of ptomains[1] in the serum of patients suffering from peritonitis; while Selmi, Brieger, Charrin, and Bourget noted either an increased toxicity of the urine or the presence of ptomains in the blood in cases of progressive muscular atrophy, tetanus, uræmia, and puerperal fever. (It will be noted that two of the diseases just mentioned are non-microorganismal.)

While these facts in connection with the diseases just mentioned have been demonstrated, the exact rôle which auto-infection and consequent ptomain poisoning play in the etiology of neurasthenia has not, within the writer's knowledge, been well established. Certain clinical facts, however, are constantly occurring in these cases which tend to lead to one conclusion, namely, that neurasthenia, if not directly produced through the medium of auto-intoxication, is prolonged and its symptoms are greatly aggravated by this concurrent condition.

In every instance, perhaps, the onset (although it may occur suddenly from some exciting cause) is preceded by some evidence of impaired health, of general atony, gastro-intestinal disturbance, sexual excess, or the like. This in itself would tend to alter cell metabolism and prevent normal tissue change, giving rise to the formation of effete products. As the disease advances, the symptoms have been noted in many cases to vary according to the condition of the alimentary tract, prominent among these being the psychical manifestations.

In the ordinary form of neurasthenia dyspeptic symptoms appear early, the gastric contents showing in many cases hyperacidity following the test meal of Leube, the exhibition of even predigested foods giving rise to rapid formation of flatus with distressing abdominal distention. Constipation is the rule, with offensive stools. The reflex nervous phenomena which are present at the onset now become intensified: the flushes of heat are more profuse, palpitation increases, areas of hyperæsthesia or of anæsthesia make their appearance, and exhaustion becomes extreme. Often a complete rest, with change of environment, accompanied by vigorous tonic treatment, are sufficient to relieve this distressing condition; but as often the symptoms become aggravated. The tongue, which was at first highly coated, now becomes dry and brown, sordes appearing on the teeth. Anorexia is complete, and forced feeding gives rise to increased hyperacidity with abdominal distention. The stools are undigested and often clay colored, while the surface of the body may present a sallow, jaundiced appearance.

Coincident with these phenomena symptoms referable to psychic disturbance appear, and added to lack of concentration, irritability of temper, imperfect memory, etc., mental torpor with various visual and auditory delusions develop. These vary in different cases, consisting mainly of confusion of surrounding objects, gloomy forebodings founded on imaginary facts, or apprehensions of fear of impending danger. In the case of a patient under the writer's care, robbers were secreted about the house; the sounds of passing carriage wheels interpreted themselves into warnings, and strange forms of birds and figures filled the sick-room. In the case of another, who had convalesced so far as to be able to sit up and look out of her window, each horse as it passed seemed to nod especially to her, and passers by spat apparently in anger on observing her, while her children acted in (to her) an absurd and nonsensical manner.

In both of these cases, which were characterized by the profoundest symptoms described under neurasthenia, the theory of autoinfection suggested itself strongly, for the reason that both patients had, during this hallucinatory period and, in fact, throughout the entire course of their illnesses, marked evidences of gastro-intestinal derangement, and, concurrently with the improvement of their dyspepsias (as evinced by absence of flatus, clean tongues, and normal stools), the mental pathological state cleared up simultaneously and remained normal throughout their convalescence. In both the pupillary reactions and reflexes were always normal; the kidneys remained active as in health, repeated urinalyses giving negative results. The psychic symptoms present were therefore not due to uræmia, were not those of hysteria, and could not have been produced by cerebral anæmia, as in both cases they disappeared entirely with the establishment of free catharsis and diaphoresis and did not return.

The effect of the elimination of intestinal poisons in causing an amelioration of the psycho-pathological symptoms is plainly demonstrated in the cases just mentioned and also in many other instances. Who among practitioners has not noticed mental torpidity disappear by correction of a disordered liver, and in children delirium abolished upon the relief of constipation? In those whose mental faculties are perverted —among the insane—this is true also.

In a reprint from the "Philadelphia Hospital Reports" for 1892, "Concerning Some of the Alimentary Affections of the Insane," the resident physician, Dr. Amelia Gilmore, writes: "I observe the victims of mental disease on admission to the hospital in restless mania, chattering like magpies, trying to escape from those who have brought them; or in the other extreme of deepest gloom and despondency, where the mental degradation has been so extreme as to induce even the attempt at self-destruction. I observe them daily, taking note of all the changes, the progress, the relapse, the stationary condition, the slow or rapid improvement; and again I meet them going out, possessed of all their faculties, useful to their kind, and happy in the love of their friends. As these conditions and results come before me daily in my hospital practice, I ask the question, 'What has been the influence which has brought them from the state of mental unsoundness to soundness — from insanity to sanity?'

[1] Farquharson: "Alkaloids and their Toxicity."

. . . I answer that it is chiefly the care of the alimentary tract which has brought about this metamorphosis."

In the "Bruntwood Asylum Medical Reports" a number of cases are cited, chiefly those of acute mania or melancholia, in which the mental functions have been entirely restored by producing free elimination and promoting normal alimentary secretion.

If, then, these toxic substances resulting from intestinal putrefaction are sufficiently virulent to pervert the functions of the great psychical centre, the brain, would they not be entirely capable of producing depression of nerve centres?

Ziegler, in his "General Pathological Anatomy," writes: "The detection of microbes is but the first step toward the discovery of the cause of the disease and the mode of its operation." Until the pathogenic microbes giving rise to these toxins have been isolated, it will be impossible to derive "proteins" similar in properties to those described by Nencki with which to produce leucocytosis and thus to eradicate the offending bacteria.

THE EVOLUTION OF SURGICAL PROCEDURE.[1]

By G. K. DICKINSON, M.D.,

SURGEON TO CITY AND CHRIST HOSPITALS, JERSEY CITY; CONSULTING SURGEON TO BAYONNE CITY HOSPITAL.

To have studied and worked during the three important periods of surgical procedure has been the fortune of but few of us. To be trained to a routine that has brought a certain degree of success and to have that routine questioned are at least disquieting. When some one questions an old-time procedure, even with facts and logic, he is not immediately heralded into fame. He, though a strong man, is often ignored; but a point well taken soon makes for itself, and gradually progress is made.

In science, as in art, it has frequently happened that method has reached its limit on account of imperfect knowledge of facts and illogical deductions from the same; or perhaps a pre-Raphaelite attention to unimportant detail may have diverted the mind from the essential to the non-essential. But the laws of evolution are irresistible, and even though for time—and time may mean generations—little advance is perceptible, yet sooner or later some discovery is made or some hypothesis exploded, and then will come a period of rapid progress in insight, in knowledge, and in application of the same.

Such has been the history of surgery. For centuries it relied solely on a knowledge of anatomy—it was simply essential to be a good anatomist to rank also as a competent surgeon. Any system that is dependent on but one other, and that other little subject to advance, can hardly become perfect. So it was for all those years the two sister studies went hand in hand, waiting for some potent germ to give renewed growth.

For centuries surgery was but a mechanical trade practised largely by doctors, monks, or even men of low degree, as well as by the surgeon proper. As intelligence increased and the sway of bigotry decreased this art was practised by those more specially trained. This specialization resulted naturally in improved methods.

The barber Paré in 1552 courageously substituted the ligature for the cautery, the bleeding of all operative wounds previous to this being controlled by the hot iron. Insignificant as this incident may seem to be, it nevertheless marked an epoch. From the time of Ambrose Paré until 1846—three hundred years—little advance was made. Full skill had been attained in reading indications and in the manipulative work, but unfortunately the same horrors surrounded the operating-room, the same complications persisted in keeping up the death rate, so that the inscription to the inferno, "All hope abandon ye who enter here," might well have been placed over every surgical ward.

It has been reserved for the latter half of the nineteenth century to see a positive and continuous advance in all departments of applied science—an epoch of research, nothing being accepted unless substantiated by proven fact. In 1846 Morton demonstrated the value of ether in overcoming pain; in 1847 Simpson added chloroform. The use of these anæsthetics materially enlarged the sphere of surgery, allowing the surgeon to deliberate, to give attention in an operation to many details heretofore slighted, on account of extreme haste made necessary by pain. Pain annulled, shock wonderfully diminished, and time given to precision were factors in favor of the patient.

The first training-school for nursing was established in 1840. Previous to this time a nurse was a common domestic, her points of merit being that she must not be Irish or a drunkard. Miss Florence Nightingale became interested and entered a school for deaconesses in 1815, and from that time wrote many elaborate and practical articles and works on nursing and hospital management, constructed from the unique side—that of the best interests of the patient.

These several notable advancements, though material, were largely the result of chance. There were yet to be made several even more important discoveries, the practical application of which have revolutionized all surgical method. The fact remained that with all care in after-treatment, with the full knowledge that ventilation, cleanliness, and segregation were important factors in hospital mortality, the death rate from amputation was twenty-seven to sixty per cent., so that eminent surgeons claimed no better results than the tyro. The death rate for ovariotomy was fifty-eight per cent.; for childbed two and one-half per cent.

The conscientious man of the day must have contemplated this with agony of mind, knowing his duty but fearing the result. The question must often have been asked, Why does this awful mortality continue? Why should operations so certainly terminate in inflammation, erysipelas, septicæmia, pyæmia, tetanus, or gangrene? These questions burned deeply into the mind of many an operator, and each was alive to any discovery that might aid in solving the problem.

The one factor noted as most constant was putrefaction, whether excessively as in gangrene or to a less degree as in ordinary inflammation. Some connection was suspected to exist between this putrefaction and the unfortunate results. It was noted that when little fermentation existed a better healing resulted, while an excess meant pus, inflammation, etc.

An effort was made to imitate nature, which allowed a subcutaneous fracture to repair with little disturbance, and to operate subcutaneously if possible.

In 1800 Bichat, the father of pathology, and since then many industrious surgeons have endeavored to discover the cause or causes of post-operative lesions. The microscope had been utilized in the study of the pus and fluids that bathe wounds, and many low forms of life were found. In 1850 the anthrax bacillus was discovered. Pasteur in 1857 proved that fermentation could occur only as a result of the presence of certain organisms. This accomplished the downfall of the hypothesis of spontaneous generation, so ardently defended by Bastien and others. Tyndall showed in 1870 that in the air were always floating minute particles of dust. These wonderful and frequent discoveries were but the result of years of laborious thought and research.

[1] Read before the Practitioners' Club of Jersey City, October 11, 1898.

Lister, operating in Edinburgh, dissatisfied with the poor results of the day, death and distress, had come to his mind the use of carbolic as a disinfectant in public places, and thought it might be of similar service on wounds, and so applied it, with a most marvellous result; pus diminished, inflammation decreased, and the frightful mortality lessened. As a result an attempt was made to apply the same more scientifically; and thus in 1867 he gave to the world his antiseptic theory of wound treatment, that created another epoch. This was styled by Lister the antiseptic method. Recognizing the various avenues of ingress of germs, not then specialized, as the science of bacteriology was in its infancy, he built around a wound a wall of protection that was intricate in detail, logical in reason, and very successful in practice, but clumsy in method. Its early application was naturally upon accidental wounds, compound fractures, etc.

Let me describe his method, now obsolete but yet suggestive. Not having a full knowledge of the different disease-producing germs, their life history, habitat, conditions necessary for growth and effect on the economy, as well as the local process incident to their presence, Lister had the site of operation washed with soap and water, then scrubbed with 1–20 carbolic acid. The operator's hands after cleansing were scrubbed in 1–20, and then anointed with carbolized oil, 1–20; ligatures of silk were dropped in 1–20. During the operation a spray of 1–40 was thrown over the wound, and frequent irrigation of 1–40 to the wound. The dressing was a carbolized gauze made stiff and impervious by resin; eight layers were applied, and pieces of rubber tissue placed between the sixth and seventh and seventh and eighth layers: a strip of protective, colored green, was laid on the wound to prevent adhesion of the dressing to the same, as well as to keep any air from it. In this protective was a salt of lead, which became blackened by the changes which are incident to decomposition, or suppuration, as we now term it.

Thus you see he suspected the hands of the operator and sterilized them, the ligatures and instruments, and particularly the air, which he most feared. So great was his confidence in carbolic that to this day he relies on it alone to sterilize his material.

As a result of this logical but elaborate process the frightful mortality greatly decreased, and the disease complications so common to wounds nearly disappeared. Pus remained, but it was not so abundant nor was it accompanied by marked cellulitis.

The Listerian method and its arguments were championed or derided for years by many a strong advocate or opponent. The literature of the day teemed with articles pro and con. Strangely enough, some of the opponents of this method, for instance Gamgee, could present a series of cases showing excellent results. He covered the limb subject to the compound fracture with an abundance of cotton, and between the splint giving rest and the cotton excluding the air the secretion from a wound became inspissated and consequently practically germless, as pathogenic germs need a certain per cent. of water to thrive. Gamgee would leave his cotton dressing on a month, and on removal obtain very fair results.

There were two points in the method of Lister on which he laid much importance—the presence of germs in the air and the use of carbolic. Gamgee, having a different idea, gained an approximate result, not knowing that he was carrying out the essential principle of Listerism—protection from air by his cotton and inhibition of present germs by inspissation.

The improved methods of research instituted by Robert Koch enabled the bacteriologist to isolate from a fluid or particle the several germs contained, and to make cultures from them on appropriate media, to see the effect of inoculation by these pure cultures, and thus to know accurately each germ and to differentiate one from the other.

In time a fund of information was obtained as to the natural habitat of each germ and the conditions necessary for its existence; what promoted its virulence, and what deprived it of the same. It was found that lesions were not always due to a single germ, but that several acting together might induce disease. Thus pus was shown to be the result of the infection of more than one germ. Several pyogenic germs were discovered, some, as the staphylococci and streptococci, being the most common. It was shown that the staphylococci preponderated on the skin and the streptococci in extraneous dirt: then, again, that the more acute inflammation, such as erysipelas, was a streptococcus disease, while in ordinary suppuration a staphylococcus was generally more abundant. More than this, of the air-germs the saprophytes predominated. If a cubic foot of glass be allowed to remain exposed an hour in an operating-theatre, not less than one hundred organisms will settle on it, and they will have very little potential value as to inducing disease on account of exposure to sunlight and absence of moisture; whereas the germs of the skin, hidden from sun, are more pathogenic, and are, from their larger numbers, constant presence, and greater virulence, more of a menace to the success of an operation.

So, gradually, and with enlarged and more exact information, this elaborate technique of wound treatment was simplified. First with many misgivings the spray in the room before the operation was discontinued; then the spray on the wound—irrigation of wound—the complex and heavy antiseptic dressing—in fact, all the antiseptic treatment of the raw surface was stopped, for the reasons above given.

The air, being proven to be a minor source of infection, was not considered during an operation, and a filtering sterile gauze was found a better dressing than were the resinous, weighty, impervious gauzes of Lister. As all chemicals which are in sufficiently strong solution to kill microbes act as irritants, it became manifest that carbolic and all other antiseptic substitutes for it produced superficial necrosis of the tissues and retarded healing and often produced pus. In fact, it was found better to allow no liquid to touch the surface, relying on the serum to bathe it and the leucocytes to act their normal part.

Thus was evolved the third stage of wound technique, the aseptic or German method, thanks to Robert Koch.

With this much simplified process we cleanse and treat the neighborhood of the wound, not the wound itself, in contrast to the antiseptic method, which treated the wound, however innocent. The steps of this process are so familiar it is hardly necessary to detail it.

It being known that the microbes of the skin reside mostly in the glands, it is washed and scrubbed thoroughly with hot water and an alkali soap, which being rinsed off, ether or alcohol is applied to remove yet further the fat, after which a strong solution of carbolic and, lastly, of bichloride is rubbed over the skin.

Hands are cleansed in about the same process, much care being given to the nails. Instruments are boiled in a one-per-cent. soda solution, and all that touches the wound during and after operation, as gauzes and dressings, are rendered sterile by exposure to steam. All non-absorbent ligatures are discarded and catgut is used entirely (1869).

As a result, the wound is irritated as little as possible by chemicals or foreign bodies, and catgut, being soon absorbed, can be used plentifully to stanch bleeding and the wound closed without drainage.

Thus is seen how the purely mechanical art evolved

into a simple yet elaborate method—simple as to reason, elaborate as to application; how, instead of much attention as to instrumentation, speed and accuracy being desirable, there is now a comparative indifference as to the time necessary for an operation. Instead of acknowledging defeat and sacrificing a part, now an attempt may be made to preserve the same.

The rust of bigotry which interfered with research was removed in the sixteenth century, when the monks lost their control. But it takes time to raise a generation of thinkers, and the reaction from monastic repression was slow to develop. Much more slowly were facts ascertained and proven, and even as late as 1857 it was believed by savants that life could develop *de novo*.

As is often the case, a great discovery is made in a simple way, and yet its true gist is not recognized, and it is elaborated with scientific precision, with the result of producing a chaotic mass of details; then by gradual gain first one fact is disproven and another is found not relevant, and so on, until we may reach the sure truth in the most direct manner.

In this we have the three periods of operative surgery—the simple instrumental; the elaborate antiseptic; the again simple aseptic, when we have but to know how to wash and be clean.

AN EMULSION AND A METHOD FOR THE TREATMENT OF PURULENT OPHTHALMIA AND OPHTHALMIA NEONATORUM.

By NORBURNE B. JENKINS, M.D.,

KNOXVILLE, TENN.

The treatment laid down in the text-books for the above-mentioned diseases often results disastrously to the patient. The various potent solutions and crayon applications of nitrate of silver, alum, sulphate of copper, etc., in many instances work more injury to the eye and its appendages than the diseases which such agents are recommended to relieve. Sloughing, perforation, discoloration, and many other permanent injuries to the tissues of the eye and lids may follow the continuous use of the mild solutions of nitrate of silver, or may result from a single application of the more powerful caustics.

Probably the least injurious and most efficacious remedy in the treatment of all forms of purulent diseases of the eye is an emulsion, the formula and directions for the use of which are herewith given:

℞ Argenti nitratis ..... gr. v.–x.
Acaciæ ..... ʒi. (or q.s.)
Aquæ destillatæ ..... ʒss.
Petrolati liquidi ..... ʒss.
M. Make emulsion and put it into a wide-mouth two-ounce bottle. Shake well before using.

When properly prepared, this emulsion is of the consistence of thick cream and is milky white in color. After it has stood for a few hours there takes place a partial separation of the ingredients, which immediately and perfectly re-emulsify if the mixture is violently shaken. Since the nitrate of silver in any combination has a tendency to oxidize, the emulsion, a few days after being made, will probably lose some of its strength.

In the initial stage of blennorrhœa, the customary treatment—*i.e.*, iced compresses, Leiter's tubes, leeches, frequent cleansing with mild solutions of corrosive sublimate and of potassium permanganate, etc.—is to be followed.

When suppuration is established, the emulsion may be used in the following manner: The patient is placed on his back, the lids are everted, and the eye is thoroughly cleansed with a sterilized 1 to 5,000 solution of corrosive sublimate or permanganate of potassium. The wash should be used as hot as can be borne by the patient. While the lids are still everted, an assistant drops two or more minims of the emulsion into the eye. The surgeon then manipulates, for about thirty seconds, the everted lids in such a manner that the emulsion may penetrate to the utmost recesses of the folds of transition of the conjunctiva. In this manipulation consist to a great extent the proper application and efficacy of this remedy, inasmuch as the fornix conjunctivæ cannot otherwise with safety be medicated. Another method is an application with a camel's-hair pencil, to be introduced under the everted lid into the fornix conjunctivæ. This is a hazardous procedure when practised by any but the deftest fingers. Extreme care is to be observed that the conjunctiva of the cornea, lids, and sclerotic be not wounded, as such injuries are shortly followed by an exaggerated focus of infection.

The emulsion at first should be used every twelve or twenty-four hours, according to the severity of the disease. Afterward it may be applied once in twenty-four, forty-eight, or sixty hours, this being continued until the discharge entirely ceases. In the interim of the applications of the emulsion, as often as any purulent secretion shows itself the eye is to be washed with the above-mentioned solution of corrosive sublimate or permanganate of potassium.

For a few hours following the use of the emulsion, the resultant discharge, altered by the presence of this preparation, should not be confounded with pus. The nurse is to be given instructions as to the difference in character of a purulent discharge and that occasioned by the emulsion, since the eye should not be washed until a purulent secretion appears, for fear that, with unnecessary interference, the eye may become reinfected.

For about half an hour after the application of the emulsion a slight pain is experienced, which is not so intense as that produced by the use of much weaker aqueous solutions of nitrate of silver.

This emulsion is offered as a substitute for the aqueous solution in the "method of Credé" in the prophylactic treatment of the eyes of the newborn.

The formula given below is also of value. The chief objection to this is its eye-destroying qualities when improperly compounded, something which too often happens, and therefore it is not recommended.

℞ Argenti nitratis ..... gr. v.–xv.
Aquæ destillatæ ..... q.s. ad saturandum.
Petrolati ..... ʒi.
Misce bene, fiat unguentum et signetur: Keep in a cool place.

Discovery of the Smegma Bacillus in the Sputum.—Dr. O. Poppenheim, in the *Berliner klinische Wochenschrift*, reports the following case: A woman, thirty-five years of age, suffering from chronic diarrhœa, died with the symptoms of pneumonia and œdema of the lungs. Microscopical examination of the sputum stained with Gabbot's solution revealed the presence of numerous red-stained particles. As these were considered tubercle bacilli, the positive diagnosis of tuberculosis of the lung and intestine was made. The post-mortem examination, however, did not show a trace of tuberculosis. From careful examination of numerous cover-glass preparations with the use of a variety of staining processes, it was concluded that these were in reality smegma bacilli. It was especially noted that this deeply stained bacillus offered very slight resistance to the decolorizing action of alcohol. In conclusion, the author dilated upon the staining processes which serve to differentiate this bacillus from that of tuberculosis.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, October 29, 1898.

EPILEPSY AND OPERATION.

DURING the past few years it has become generally recognized that epilepsy from traumatism, though apparently a condition that could be favorably influenced by operation, is not often really so. Many patiens have been operated upon and a compression relieved, a "cicatrix" excised, a cyst evacuated, a spicule removed, or nothing macroscopic found, and have been discharged cured, but many such patients have after various periods relapsed and have returned to the same or sought other surgeons. The reason is not far to seek, and it is that the cicatricial formation and adhesions developing at the site of operation, no matter what the original condition, very soon form a focus of irritation which reproduces the condition existing before operation, or one very much like it. When this fact came to be recognized, surgeons began to look about for some means to prevent the formation of adhesions between the cortex and the dura, for it was to such adhesions that most of the trouble was referred, and the introduction of various foreign substances was attempted for this purpose. Naturally thin, smooth substances suggested themselves, and gold foil, tin foil, and rubber tissue were among them.

In some cases these bodies have been induced to remain in place for a time, and certainly while they are in place no adhesions can form under them. But does this not merely move the site of the adhesions irom the centre of the foreign substance to its edge? Foreign bodies certainly have remained harmlessly in all parts of the body for long periods, but is there any record of one which has not sooner or later been surrounded by connective tissue, which is practically cicatricial tissue? In most parts of the human organism this tissue serves a useful purpose, but on the surface of the brain it is just what we want to avoid.

It is very probable that between the healthy dura and a cortex which had never been the starting-point of any epileptic manifestations adhesions might occur which would not necessarily cause epilepsy, but, in a cortical area which has been the focal point of a Jacksonian epilepsy, it seems certain that the circulatory conditions in the neighborhood are such that a very little irritation would serve to start new or maintain the old conditions. We must remember that when we speak of cicatricial tissue we do not mean tissue in mass, but rather a microscopic diffusion of connective tissue through a more or less definite region.

Recently it has been suggested, evidently with the general idea that an animal membrane would be better than one of an inorganic material, that the sterilized lining membrane of the shell of a fresh egg be used, and the substance certainly has all the advantages of any of the materials previously suggested, and is, furthermore, easy to obtain. It is also almost certain that its fate in the body would be the same as that of a sterile catgut suture,—that is, it would be very promptly absorbed and replaced by new tissue. But are we any better off than we were before? The only kind of tissue which can permeate and absorb such a membrane is connective or cicatricial tissue, and there is apparently no reason for any other result than is seen with the other substances. It may be that the use of such an absorbable substance will make the process of new tissue formation so smooth and non-irritating that the adhesion between cortex and dura will be insignificant, but even then there may still be cicatricial tissue in the cortex itself, which will keep up the irritation. It is the latter which is probably the most active element in starting the convulsion, and its removal seems to present an almost hopeless surgical problem. We may diminish the irritability of such a damaged cortical area with drugs, but to attempt to eradicate the cause by surgical means simply substitutes a new connective-tissue formation for an old one. However, it is, on general principles, an advance if we can secure for our purpose an absorbable and non-irritating substance to interpose between the cortex and dura, and if we can thus prevent the formation of extensive adhesions we shall eliminate one important element in the problem. The removal of scar or connective tissue from the cortex itself is quite another problem, and, as the occurrence of convulsions is to a large extent undoubtedly dependent upon its presence, it is a very important aspect of the case. When there is adhesion between the cortex and dura, there is very apt to be more or less cicatricial tissue in the cortex, and of course the removal or prevention of surface adhesions would have no effect on such tissue. Excision of the offending part of the motor tract has been tried a number of times, but such an operation is not apt to be undertaken without very serious consideration.

A NEW DISEASE VIRUS (MYXOMATOUS VIRUS).

SANARELLI, of yellow-fever-bacillus fame, has recently described a new form of disease-producing virus which, if his discovery is verified, may throw a new light upon the dark chapters in the history of syphilis, rabies, and other infectious diseases. He publishes in the *Centralblatt für Bakteriologie*, vol. xxiii., 1898, p. 865, his observations on a disease of rabbits, which he has had in his laboratories for the past two years. This disease first shows itself as a blepharo-conjunctivitis, which goes on until the eyes are closed and the small

opening between the lids is filled with a thick catarrhal purulent secretion. At about the same time there appear in different parts of the body small subcutaneous tumors of various sizes, and there is a general diffused thickening of the animal's skin and mucous surfaces. Death usually occurs in from two to five days, and there are found gelatinous subcutaneous tumors of an elastic consistence and rich in blood-vessels, hypertrophy of the lymphatics, orchitis, and hypertrophy of the spleen. Histologically, the body throughout would seem to be the site of a general myxomatous infiltration. This myxomatous material is the true cause of the disease, according to Sanarelli, and he has been able to convey the disease from one animal to another in as many as four different ways. This material—serum—obtained from the myxomatous virus, is absolutely sterile and contains no organisms that are appreciable to the eye, aided with the best optical helps. Mice, guinea-pigs, monkeys, and birds are refractory; in one case he was enabled to infect dogs to a minor degree. Experiments made upon man were, as a rule, negative. There was some slight œdema following the injections, reddening and reaction of the conjunctiva, but this soon disappeared. Experiments bearing upon the question of acquired immunity with the serum were negative. The observations are of interest, in that we here apparently have a disease-producing agent which, so far as yet known, has no organized units of structure.

ANTIVIVISECTION EXACERBATIONS.

Some of the non-professional journals, notably and most acutely *Life*, seem to be afflicted with a curious form of antiscientific mania, which manifests itself in violent opposition to some phase of scientific work or in violent advocacy of some "pathy" or "ology." *Life's* antivivisection hysterics, which occur at intervals, often lead it into pitiful imbecilities, and never by any chance assist in the propagation of wit or humor—the object and excuse for the existence of that publication. The good soul who writes the editorials for *Life* and the ignoramus who perpetrates the antivivisection "jokes" or satires seem to take the view—if people who know so little about a subject can be said to have a view—that that form of physiological and pathological investigation which they designate as vivisection is, in the first place, useless; and in the second, cruel and carried on cruelly by men whose senses are so blunted by the "sufferings" which they cause that they do not appreciate what they are doing; and, as an addendum to this side of the question, that the budding mind of the medical student is influenced in the same way. With such persons it is utterly useless to try to prove what experiment upon living animals has done for the advancement of medical science. Their mental condition does not permit them to weigh the value of evidence and to consider its source. The instances in which experimentation upon animals has been useful to the human race are so numerous, and the discoveries which have been led up to by such work are so important, that we should imagine that even the profound thinker who directs the mercilessly withering editorials and medical "jokes" of *Life* would find a few moments to cerebrate a little upon the subject. If he is capable of the latter process, there is still hope. The charge that experiments upon living animals are carried on with careless cruelty, and that in this way they incite the beholder to acts of cruelty and develop in him a disregard for suffering in helpless animals, is nothing less than monstrous. A very large proportion of experiments of this nature are carried on with the animal etherized or chloroformed, and the subject of experiment is never allowed to recover consciousness, so that there is no infliction of pain whatever. Objectors to this form of experiment ought to be strict vegetarians, ought never to wear leather shoes, and really ought not to take quinine if they suffer from malaria, for they might by so doing cause pain and death to the plasmodium, which is an animal. Another very large proportion of experiments upon animals consists in inoculations with various organic or inorganic matter by means of a hypodermic syringe, which causes an infinitesimal amount of pain and gives us a line of investigation which has led to enormously important results.

If the antivivisectionist writer will only stop to investigate, he will find that, in this country certainly, animal experimentation is rarely carried on before a large class, for the very practical reason that a large class cannot profit by the demonstration. Furthermore, on the rare occasions upon which such demonstrations are given in our medical colleges, the spectators are from the advanced classes of students and are not influenced by the details of the experiment, because they are interested in its result and the principle which it explains or elucidates. Better men than the editors of *Life* have mistaken coolness, self-possession, and decision of action on the part of an experimenter, or a surgeon for that matter, for indifference and cold-bloodedness. We do not doubt that occasionally pain is inflicted upon animals during experiment or investigation, but we do deny most emphatically that it is done needlessly or carelessly, and that the results do not justify the means. Physiologists and pathologists are not in the least more cruel or indifferent to suffering than other people, and there is a personal equation among them as among others—a fact which should not be forgotten.

However, argument with a layman on such a subject is rather profitless, even when the layman knows what he is talking about, and we cannot hope for much improvement from *Life*; but if any of the editor's relatives should have diphtheria, we hope that antitoxin will do what it almost always does, so that he may have a practical demonstration of what one line of animal experimentation has led to. We fear, however, that the editor in question is a "faith curist" and that the antitoxin would not have a chance. In the mean time we hope that the great intellect which presides over the destinies of *Life* will hire a first-year medical student, if he can do no better, to edit his medical "jokes" and criticisms, and will, we venture to add, have a few of his cartoonists led about and shown some of the physicians of this or any other large city,

so that they may correct the impression which they seem to have that such gentlemen look like bewhiskered gorillas in high hats and frock coats.

MEDICAL NOMENCLATURE.

The average worker in any scientific line apparently has not the time or the inclination to devote himself to the classics, at least enough of them to enter into word-building without encountering difficulties, and he often produces an etymological monstrosity when he names the products of his scientific brain. To the reader or the hearer who has some regard for accuracy in the formation and use of words, such combinations as "radiograph" are apt to give a shock. If such an observer remonstrates, he is likely to be called a purist in a somewhat sarcastic tone, and is certain to be thought "affected." There is, of course, no reason that new medical and scientific facts should not receive a properly constructed designation from the point of view of the etymologist, and it would be a good plan if they who may discover or invent a condition or a fact which they think requires a new name would be sure that they are correct in their etymology, or otherwise consult somebody able to put them right. One of the first and most important rules which it would be well to follow, and one which is perhaps most often broken, is to avoid combining in one word roots or stems from different languages. "Radiograph" is a particularly flagrant example of violation of this very simple rule, especially as there is a good Greek word corresponding to the Latin word *radius*, which would make a perfectly sound combination with the latter half of the word. Moreover, the word does not really express clearly the idea it was intended to convey, and lately the much more appropriate term "skiagraph" has supplanted it to a great extent. Medical nomenclature is exposed to enough sources of contamination as it is, and when we can we should see to it that no unnecessary monstrosities survive. Usually when objection is made to one of these mongrel terms, an attempt is made to silence the objector on the score of the convenience of the term; but this is only another way of saying that those who defend such manufactures are ignorant or careless, and it emphasizes the desirability of attempting in the beginning to direct such things properly on the part of those who have had better opportunity or more inclination to gain the requisite knowledge. After a defectively formed term once starts upon its way, it is very difficult to prevent its general distribution, and, as it is just as easy to form words properly as improperly and carelessly, it is worth the effort to keep our nomenclature as accurate as possible by care in launching new terms. There are already so many medical terms in common use now against which the above objection can be justly urged, that it seems almost hopeless to work against their retention in good usage; but a process of slow elimination might eventually rid us of the worst of them. There are so many of them that it is scarcely worth while to mention any, but two which will probably always be with us are "ovariotomy" and "appendicitis." The etymological objection to both of these terms is obvious, but their use is so frequent and of such long standing that to displace them is probably impossible. The most that we can really hope for is probably to induce the word formers to be a little more careful with their constructions, and also to restrict their production as much as possible.

"REPUTABLE" PHYSICIANS.

According to the *Medical Press* of September 28th, "Professor" Munyon, who is said to hold an honorary degree from the University of Tennessee, swore upon the stand in a suit against Dr. Deane, a qualified British practitioner whom he had hired to do certain work connected with his advertising practice, that he could get half a dozen reputable medical men in England to take Deane's place. The *Medical Press* deplores the fact that the assertion thus made under oath may be substantially correct.

To be sure, Dr. Deane's name has been taken out of the "Medical Register," and he can no longer be considered in any more favorable light than is his newspaper-advertising employer; still, when we know that twice as many physicians are graduated each year as can possibly make an honest and honorable living, it is not so surprising that a few fall by the way and seek employment from quacks and fakirs. This city is not without its establishments of healing, presided over by a genius for attracting the gullible public, often not a medical man at all, in which the treatment is carried out by regular graduates, not capable of self-support in more legitimate ways.

ANOTHER VICTIM TO THE CHRISTIAN-SCIENCE FAD.

The Christian Scientists number their converts not only among the ignorant class, but also within the ranks of the cultured. A striking example of the manner in which a brainy and talented person may be led away by perverted ideas has recently been afforded in the sad death of the well-known novelist and essayist, Harold Frederic. Although Mr. Frederic is an American, he has been residing for some time in England, and had been treated—according to a special cable to *The Sun*—by a local physician for a blood disorder and paralysis following rheumatism. The doctor was then dismissed, and Mr. Mills, the leader of the Christian Science fad, was summoned with Mr. Frederic's consent, and treated him according to the peculiar methods of the sect. He was permitted to eat and drink what he liked, and soon suffered a relapse. A physician was again summoned to attend him thirty hours before his death. He was then moribund, and it was impossible to revive him. Mr. Frederic's daughters and others testified that he was practically insane on the subject of Christian Science for a month before his death. The above facts were brought out at the inquest, which, under the peculiar circumstances attending the death, was deemed necessary. The investigation, however, was only a preliminary one, and

the inquest was adjourned, when the case will be thoroughly probed. It is to be hoped that the authorities will insist that in future the Christian Scientists and others of a similar kind will not be allowed to wreak their will on those misguided members of the community who are sufficiently weakminded to trust their own lives or the lives of their families in their hands. The principle of freedom of judgment, as in this instance, may be carried too far.

IMPORTED PLAGUE.

The dangers of dealing with the germs of deadly diseases in laboratory experiments have been long known, and not infrequently illustrated in deplorable loss of valuable lives. No more striking instance of direct and unmistakable transmission of fatal disease in this manner has occurred than that of the loss of three lives in Vienna from infection with bubonic plague, mentioned in our news columns. The latest victim, Dr. Müller, is well known to many American physicians, and the sad ending to his devotion to science and his untiring attendance on the first victim, Dr. Nothnagel's assistant, make his fate peculiarly sad.

Dispatches from Vienna report that all animals used in the laboratory experiments have been killed and cremated. These and all other precautions should be taken promptly to expunge by science that for which, in its efforts to benefit mankind, it has been directly accountable. Bubonic plague has flourished before in European countries and might do so again, but it would be a terrible blow to science should this prove the spark before the flame.

News of the Week.

Surgery in a Burning House.—A fire broke out in a house in Scranton the other day, while one of the occupants was being operated upon for appendicitis. The other occupants of the house and some of the neighbors fought the flames while the surgeons continued their work. The fire was extinguished and the abdominal wound was closed at almost the same moment, and the patient came out from under the anæsthetic to find himself poorer through both operations.

The Emperor of China is said to be dying, not improbably as the result of systemic poisoning. He was recently examined by the physician of the French legation at Pekin, who, according to a dispatch to the London *Times*, reported that the poor lad is suffering from albuminuria, incipient phthisis, and great debility. Skilled medical attendance is necessary, the physician reports, in order to save his life, and this the Empress Regent is not likely to provide, if the suspicions of poisoning are correct.

Election at the County Medical Society.—At the annual meeting of the Medical Society of the County of New York, held October 24th, the following officers were elected: *President*, Dr. S. Oakley Van der Poel; *First Vice-President*, Dr. Henry Clarke Coe; *Second Vice-President*, Dr. James Clifton Edgar; *Secretary*, Dr. William E. Bullard; *Assistant Secretary*, Dr. John Van Doren Young; *Treasurer*, Dr. John Sidney Warren. This is claimed as a victory for the advocates of a "wide-open" town, as regards the dispensing of free medical treatment.

The Yellow-Fever Scare is over for this year, frosts having cooled the heated imaginations of the Mississippians. The State boards of health of Mississippi and Louisiana have removed all quarantines, and doughty Governor McLaurin is now at liberty to attend to his duties at the capital or to go to his own home.

A Fire at Bellevue Hospital.—The Marquand pavilion in the Bellevue Hospital grounds caught fire on October 19th. A curtain in the operating-room on the second floor was blown in and set on fire by a gas jet. The nurses in the burning pavilion put out the fire. Nineteen years ago the burning of a pavilion in the hospital grounds resulted in the loss of several lives.

Official Drugs Only.—The trustees of the Cincinnati City Hospital have adopted a rule that the physicians in the hospital shall not be permitted to prescribe any remedies not included in the United States Pharmacopœia, all proprietary and secret remedies and such as are advertised at half-rates in the *Philadelphia Journal of Hypocrisy* being thereby shut out. The *Pharmaceutical Era* says that the patients will miss a host of good things, but thinks there will be some compensation in the fact that they "cannot henceforth be used quite so freely as patients of city hospitals generally are for the purpose of experimenting with new drugs, of unknown therapeutic action and chemical constitution."

The Plague in Vienna.—Much consternation has been caused by the appearance of bubonic plague in Vienna. There have been four cases, three of them fatal, according to the latest reports. The disease was contracted in the first instance in Nothnagel's laboratory, where work was being done with cultures of the plague bacillus. The first death was that of an assistant in the laboratory, named Barsch or Barisch, and the second was that of Dr. Müller, an assistant to Nothnagel and a worker in the same laboratory. A nurse who attended Herr Barsch was another of the victims. The disease is of the pneumonic form, which is said by Kitasato and Nakagawa, in their article in the "Twentieth Century Practice," to be exceedingly contagious and almost invariably fatal. In these cases, they add, the plague bacilli are found sometimes in pure culture in the sputum, and it is doubtless upon this fact of the elimination of an enormous number of the specific micro-organisms in the bronchial secretion that the extreme contagiousness of the pneumonic form depends. Every precaution has been taken to prevent a further extension of the disease. The sick, together with a priest and three nuns who assisted in administering the last sacraments of the church to the dying, are isolated in a pavilion of the Franz-Josef Hospital,

outside the city. Communication of outsiders with the medical attendants is had only by telephone. The plague cultures were originally brought from Bombay about a year ago by the Austrian commission sent there to study the disease. The pathological laboratory has now been closed, all cultures and animals under experiment have been destroyed, and lectures have been suspended. The outbreak of the disease among these workers is deplorable, but it would appear to have established the pathogenic nature of the bacilli beyond question.

Two Army Appointments.—The public press is responsible for the information that Surgeon-General Sternberg has selected two medical men from Houston, Tex., for special work in Cuba and Porto Rico. Neither one is eligible for membership in any of our regular county or State medical societies. One has been out of practice for several years, and is a great advocate of the dosimetric system of therapeutics; while the other is unclassified. The surgeon-general evidently wants to please all sorts and conditions.—*Southwestern Medical Record.*

Dr. Alphons von Rosthorn, of Prague, has been appointed to the chair of obstetrics and gynæcology in the University of Graz.

Drunkenness and Insanity.—The provincial asylums inspector of Ontario does not look upon alcoholic intemperance as a very important factor in the etiology of insanity. In his recently published report it is stated, on the authority of statistics of a large number of cases, that excessive drinking could be regarded as the cause of insanity in only thirty-five out of five thousand cases.

Methyl Blue is Recommended for Malaria by Dr. Cardamatis, of Athens. He has employed it, in daily doses of ten to twelve grains, in two hundred and seventy-five cases of acute and chronic malaria, and claims to have been successful in curing ninety-three per cent., and in preventing a recurrence in most of the cases, even though the patients continued to reside in malarious districts.

New Buttons.—Dr. I. B. Perkins, of Denver, has devised two buttons for intestinal anastomosis. One is made on the principle of the Murphy button, except that it is made in eight parts, and when in use holds the intestine just as does the Murphy button. These sections are held together by light catgut and a coating of gelatin, which dissolve readily, allowing the button to come away in four sections. The other button is also made in sections in the same manner, but gets its pressure from several strands of rubber instead of from the spring, as in the other button. The advantage claimed for these buttons is that with them the full lumen of the intestine may be preserved, and, coming away in sections, the button will easily be passed.—*The Colorado Medical Journal.*

The Southern Surgical and Gynæcological Association.—The annual meeting of this association will be held in Memphis, on November 8, 9, and 10, 1898. This promises to be one of the most successful sessions in the history of the association, and papers have been promised by many of the leading surgeons and gynæcologists in the country, especially of the South. Members of the medical profession generally are cordially invited to attend. The secretary of the association is Dr. William E. B. Davis, of Birmingham, Ala.

The Study of Malaria.—A commission for investigating the various questions associated with malaria has been appointed by the British colonial office and the Royal Society, and consists of the following members: Drs. C. W. Daniels, of British Guiana; S. R. Christophers, of Liverpool; and J. W. W. Stephens and Mr. John Lucas Walker, of Cambridge. Drs. Christophers and Stephens will go to Pavia to work in the laboratory of Golgi, and thence to Rome to work in Cetti's laboratory. The commission will eventually proceed to Africa, when its first work will be to determine the clinical varieties of malarial fevers occurring there. Robert Koch, who has been for some time in Rome, where malaria has prevailed to an unusual degree this summer, has found that tropical malaria is the same as the æstivo-autumnal form of Marchiafava and Bignami.

Dr. J. Crocq, of Brussels, died recently, in his seventy-fifth year. Dr. Crocq was a member of the Belgian Senate, as well as professor of special pathology and therapeutics at the University of Brussels.

Association for the Prevention of Tuberculosis.—Several societies have been founded in England during the past summer, having for their object the dissemination of knowledge concerning tuberculosis and its prevention. This is to be effected, according to the circular of one of the associations, by the education of public opinion and the stimulation of individual initiative by means of a central bureau for the collection and distribution of information as to modes of diffusion of tuberculosis and measures of prevention; the circulation of pamphlets and leaflets setting forth in plain language the results of scientific investigation of the above points; public lectures by men approved by the council; addresses at congresses and other public gatherings; co-operation with other societies having for their object the promotion of public health; the co-operation of the public press; the holding of periodical congresses and the issue of an annual report; the promotion of the establishment on a self-supporting basis of open-air sanatoria for tuberculous patients. It is also proposed to influence legislation looking to prophylactic measures.

Women and War.—Although women be perforce non-combatants, the services they are able to render to those who fight have been very much in evidence during our recent war. As an instance less generally known than some others, we would cite the fact that the New York Infirmary for Women and Children prepared a ward for the reception of soldiers returning from Montauk Point, and during the month of September twenty-nine fever patients were there successfully treated by the physician in charge, Dr. Helen Baldwin. The microscopical examinations of the blood that have now become a *sine qua non* in the

management of fever cases were made by internes who had been drilled in the laboratories of the Johns Hopkins School. Of six typhoid-fever patients, all of whom but one exhibited the Widal reaction, as tested by the health board, four also showed a large number of malarial organisms in the blood. Some of the malarial fevers were interesting, especially from the combination of parasites found in some cases. Two had the tertian combined with the æstivo-autumnal form of the plasmodium; one had a triple infection, double tertian and æstivo-autumnal; one had a single tertian; the remainder the æstivo-autumnal alone. Some peculiar forms of plasmodia were noted: thus the ring forms with rod-like appendages on one or two sides, making spindle or flask shapes, or forms appearing like a ring twisted on itself. One case of organic heart disease, one of apparently chronic nephritis, and one of incipient phthisis seem to have escaped the vigilance of the recruiting surgeons. The cases of mixed typhoid and malarial infection showed the course of temperature so often noted, the malarial fever seeming to be in abeyance during the *période d'état* of the typhoid, but reappearing in characteristic diurnal curves at the moment of convalescence from the typhoid. It was interesting to note the complete success of the cold-bath treatment in all the cases of typhoid fever, and the absence of all effect upon the malarial temperatures. On account of the predominantly remittent type of the malarial fevers, *i.e.*, of the æstivo-autumnal infection, quinine was given in five-grain doses every four hours throughout the twenty-four. One patient received ninety-five grains without experiencing the least symptom of cinchonism. All the patients recovered.

The Massachusetts Hospital for Consumptives, located in Rutland, twelve miles from Worcester, about twelve hundred feet above sea level, was opened October 1, 1898, for the reception of patients. It is built on the pavilion plan and will accommodate two hundred patients. Inasmuch as the primary purpose of the hospital is to arrest the disease, and if possible to extirpate it, only such patients will be admitted as are not too far advanced to admit of reasonable hope of radical improvement. In no sense is the hospital to be considered as a home for the hopelessly sick. Patients who do not improve after a stay in the hospital sufficiently long to test the effect of treatment will be advised not to remain, and their friends will be expected to arrange for their removal to surroundings primarily devoted or better adapted to their comfort. A uniform rate of fifty cents a day is charged, and no private patients are received. The superintendent of the hospital is Dr. Walter J. Marcley.—*Boston Medical and Surgical Journal.*

A Vegetarian Hospital.—We have heard of temperance hospitals, Presbyterian hospitals, orificial hospitals, and hospitals for the insane, but a vegetarian hospital is, we confess, new to us. The London correspondent of the *American Practitioner and News* writes concerning such a one, called the Oriotel Hospital at Loughton, in Essex. The treatment of the sick in this institution is carried out according to the strictest laws of vegetarianism, except that eggs, milk, and butter are allowed. But the ordinary dietary consists of porridge, bread and butter, some form of stewed fruit, and cocoa for breakfast; a savory, as macaroni, cheese, fresh vegetables, and pudding for dinner; and fresh fruit, bread, and butter for supper. Twice a week tea is allowed, oaten water and cocoa being on other days served in the afternoon. According to Haig and Roger Williams this is the sort of living (or existing) that is inimical to gout and cancer, and we trust the patients like it.

The Medico-Chirurgical Club is the name of a medical society organized recently in Nashville. The objects of the society are announced to be the promotion of social intercourse, the stimulation of professional activity, and the encouragement of original research. The organization is intended to be very select, the membership being limited to sixteen. The club will have no president, each member presiding in turn over the meetings for two successive months. A peculiar feature of the society, we learn from the *Nashville Journal of Medicine and Surgery*, is a clause in the constitution which provides for the assignment of every member of the club to different departments of medicine, in which he is to work for the period of one year. All the papers that each member will prepare during the year, upon topics selected by the essay committee, will relate to some subject belonging to that department of medicine or surgery in which he is expected to work during the time specified. The meetings are to be held once a week, the first and third meetings in each month being devoted to the reading and discussion of papers, the second and fourth to clinical exhibitions and reports of cases.

The Johns Hopkins Medical School.—There are two hundred and seven medical students at the Johns Hopkins Medical School. Of these, sixty-six were enrolled this session. There are thirty-five women in the school, of whom nine entered this season.—*The Maryland Medical Journal.*

Exits and Entrances. — The *Atlantic Medical Weekly*, formerly published in Providence, R. I., has ceased to exist. Its good will has been secured by a Philadelphia paper, which undoubtedly needs it. There will be no decrease in the number of medical journals, however, for the Ramsey County (Minn.) Medical Society will begin on January 1, 1899, the publication of a monthly medical journal. The society numbers one hundred and twenty-five members.

The Cumberland County (N. J.) Medical Society.—The semiannual meeting of this society was held at the Hotel Cumberland, Bridgeton, October 11th, under the presidency of Dr. A. R. Judson, of Newport. Dr. Hummel, of Deerfield, read a paper on "Peritonitis." An interesting paper on "Conservatism in Gynæcology" was read by Dr. Charles P. Noble, of Philadelphia. The society unanimously voted to celebrate its eightieth anniversary on December 8, 1898.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Abstract of the Proceedings of the Twenty-Fourth Annual Meeting, Held at Nashville, Tenn., October 11, 12, 13, and 14, 1898.

First Day—Tuesday, October 11th.

The association met in the hall of the house of representatives at the State Capitol, and was called to order by the chairman of the committee of arrangements, Dr. Duncan Eve.

Prayer was offered by Rev. James I. Vance, D.D.

Addresses of welcome were delivered by Hon. J. M. Head, on behalf of the city and State; and Dr. C. S. Briggs, on behalf of the profession of Nashville.

President's Address.—After the reading of the reports of the secretary and treasurer, which were accepted, the president's address was delivered by Dr. John Young Brown, of St. Louis, Mo. He selected for his subject "The Mississippi Valley Medical Association." He dealt with the history of the association, saying that it was organized twenty-four years ago. Its rapid growth had been due to the loyalty of its members and to the fact that from its inception it had been a distinctively working body. It had never been a mutual-admiration society. He gave suggestions for its improvement, and said that, inasmuch as the association contemplated the publication of an annual volume of transactions, he would propose that the dues be raised from $3 to $5.

Immunity.—Dr. Charles T. McClintock, of Detroit, Mich., read the first paper. Of late years a large part of the laboratory work in medicine had had to do, he said, with immunity. Many facts had been discovered; in a few instances these had been of immediate practical value in the treatment or prevention of disease. But for the most part these facts were not correlated, often they were contradictory, and their meaning was not clear. Hypotheses had been advanced, but as yet we had no theory that would even approximately explain the facts of immunity. The future of work in this line was full of promise. For the infectious diseases at least, immunity and cure were one and the same. A diphtheria patient would be cured only when his tissues were immunized against the attack of the diphtheria poison. There were several kinds and various degrees of immunity. We had a natural and an artificial or acquired immunity; apparently these were entirely different in kind, dependent on different functions of the body, effected by different substances. There was racial immunity. Again, we had an immunity correlated with age. Variations in susceptibility were noted in different varieties of the same species and even in different families. There was also an individual immunity. Still again, one part of the body, even one portion of the same tissue, might be immune, while the rest was very susceptible. These facts were not to be explained by general resistance, good health, etc. The most vigorous man might acquire small-pox or influenza. The healthiest cow was likely to take pleuropneumonia. Metchnikoff's theory (phagocytic) was the best explanation we had for natural immunity. Nuclein seemed to be the germicidal agent elaborated by the white corpuscle. If natural immunity was due to one or to several chemical agents, it followed that it was limited.

As to artificial or acquired immunity, after recovery from an attack of certain of the infectious diseases there was more or less of immunity to that disease. In some instances, as in scarlet fever or syphilis, this acquired immunity usually lasted for life. The immunity following recovery from disease was not proportional to the intensity of the disease process. The ability of an organism to resist the attack of disease germs or their products could be increased—trained, educated, it might be said. Thus, in producing diphtheria antitoxin, we often got our horses to bear without apparent harm several thousand times the dose of poison fatal for an untreated horse. It might happen that diphtheria or measles would after generations or centuries disappear, owing to the fact that the race had become immune. To what extent an acquired immunity could be inherited was both an interesting and an important question. This sort of immunity was usually lost, at least so far as tests showed, before the animal reached the adult stage. Inherited immunity was not the same as the immunity of the suckling. This was due to the fact that the immunizing bodies passed into the milk. The child received from its mother not only food, but disease-resisting power. There were active and passive forms of acquired immunity. The horse producing antitoxin was actively immune; his tissues were producing antitoxin. The child receiving a dose of antitoxin was passively immune. It had borrowed the strength of the horse. There was also an immunity to poisons. The wolf throve on putrid flesh, and some animals were immune to snake poison. The insusceptibility of the morphine user might be something more than mere tolerance; the drug might be in part destroyed, and this anti-power might have to do with the craving for the drug. There was no satisfactory explanation for the facts of acquired immunity. The various theories as to the nature of antitoxin and its mode of action were referred to by the speaker, with the conclusion that antitoxin, in some way as yet unknown, stimulated some portion of the body, and this in turn destroyed the poison. There was no antitoxin, but, in short, an immunizing body. Immunity and cure were the same thing.

Dr. George W. Johnson, of Dunning, Ill., said that he had had some experience with nucleinic acid in the treatment of pulmonary tuberculosis in cases of mixed infection, and had noticed a diminution in the number of pyogenic bacteria. He asked whether the phagocyte attacked the tubercle bacillus, the same as it did pyogenic bacteria.

Dr. McClintock replied that he knew of no reliable investigations that had been made with reference to that point.

Dr. Ernest B. Sangree, of Nashville, said it was believed by many investigators that the phagocytes eat live tubercle bacilli, and that in cases in which tubercle bacilli were included in the phagocytes the patients had a better chance to get well than in those which did not present this action.

Dr. Dudley S. Reynolds, of Louisville, said he was afraid that experimental observers had failed to note the necessary equilibrium between the circulating blood current and the lymph stream. Dr. Reynolds elaborated the theory of phagocytosis, and showed how phagocytosis could never be successful if obstructions existed in the lymph channels.

Hygiene versus Drugs in the Treatment of Pulmonary Tuberculosis.—Dr. C. L. Minor, of Asheville, N. C., read this paper. Under hygienic and dietetic treatment the author embraced all such non-medicinal measures as were directed toward an increase in the vitality of the organism and of its resistance to disease, and remarked that climato-therapy was but a branch of hygienic treatment, although he did not embrace it in his remarks, which were confined to the proper application to individual cases of exercise, gymnastics, massage, hydrotherapy, rest, sleep,

diet, amusements, clothing, and quarters. A partial and unsatisfactory use of such measures was more or less general, but unless directions were definite and specific they would fail of their purpose. The difficulty of getting a patient to yield implicit obedience to the doctor was dwelt on, the indefiniteness of the orders given being in part to blame. If the patient was to recover, he and the doctor must both work hard, no half-hearted seekers for pulmonary health being likely to recover. The necessity of carefully and fully writing out exact orders for every detail of the patient's life, to be followed religiously by him, was urged, such a prescription being in phthisis of more value than the more common one for drugs. All such measures were for convenience classed under three heads: those affecting the patient's surroundings, his life, and his exercise. The very common abuse of exercise was deplored by the speaker. The invariable rule, he said, was "exercise short of the point of fatigue;" and there was another, "No exercise with a temperature over 100.4° F." If these were followed, no mistake could be made. A very gradual accustoming of the patient to longer and longer walks, beginning with only fifty or a hundred yards in many cases, and increasing until finally from two to ten miles could often be easily tolerated, together with a judicious use later on of walks on increasing inclines, till steep hills were easily surmounted, was warmly recommended. Pulmonary gymnastics were especially dwelt upon for use in non-active cases, and among several methods recommended for chest development and the increase of vital capacity that form of Indian-club swinging called the double figure-of-eight was chiefly recommended. Finally, any intention to advocate nihilism in medicine was denied. In carefully selected cases certain drugs had undoubted value as adjuvants, never as the chief resource. The short life of most drugs in phthisio-therapy was noted, and ascribed to the fact that no man could treat this disease long and not realize that nothing which in the least degree upset the stomach could be anything but a curse to the patient. The only valuable results were those based on a vitalizing of the whole system, a stimulation of metabolism on a strengthening of the cells to oppose the invader. The thing to be attacked was not so much the lesion in the lung directly as the lowered vitality of the body, the diminished capacity of the lungs, and the deficiency of appetite; drugs directed to a conquering of the bacillus *in situ* were not to be compared with measures which enabled the organism itself to acquire the strength to overcome disease. These things could be brought about best by an improvement in nutrition, which must after all come from the stomach, and an increase of the amount of oxygen taken into the lungs. Air and food were the drugs which we could always trust; they would never deceive us. If a patient could be taught to get both in good amounts, wherever food could be assimilated and enjoyed and air breathed deeply, there was hope of cure. We should throw away two-thirds of our medicine bottles, and use the other third less often, carry out a hygienic plan of life, stimulate the appetite by nature's appetizer—air and exercise, which alone were permanent in their results, and which were as superior to gentian or quassia as sunlight was to darkness.

Congenital Scoliosis.—Dr. S. C. Baldwin, of Salt Lake City, Utah, contributed a paper on this subject. Scoliosis, he said, was, first, the most common of all deformities; second, it was most often found in children under ten, rarely beginning after eighteen; third, it was found more often in girls, in the ratio of five to one; fourth, the etiology was in a large number of cases very uncertain. Congenital scoliosis was very rare. Tubbey, of London, in the latest English work on deformities, had stated that he had been able to verify only four cases. The case reported by the essayist was first diagnosed as scoliosis when the child was twenty-one months old, but the father had noticed the "lump" ever since the child was first washed. The interesting feature of the case was that the curvature was in the lower cervical and upper dorsal region. There was some pressure on the cord, as shown by the more or less deficient development of the right side. The convexity of the curve in this case was to the left. There was partial paralysis of the forefinger of the right hand. There were sweating and flushing of the left side, with none on the right. The cause of the scoliosis in this case was thought to be the lack of amniotic fluid *in utero*, probably allowing the muscular walls of the uterus to press on the fœtus and hold it in a faulty position, and in this way to cause a wedge-shaped development of the bodies of the vertebræ. This theory had been advanced by Weissenberg, Hirsch, and Schanz in the last year. In this case the mother was very small, and passed at the time of confinement so little water that she did not know there was any, and felt no motion, comparatively speaking, during pregnancy.

Dr. Samuel E. Milliken, of Dallas, Tex., had seen one case of scoliosis in a child under one year of age, but he was not prepared to say whether it was congenital or not.

The Therapeutic Value of Marmorek's Serum.—Dr. William L. Baum, of Chicago, dealt with the literature of this subject in an exhaustive manner. Twenty-two cases had come under his observation in which the serum was used. Of these, nineteen were cases of erysipelas; one of erysipelas plus tuberculous nuchal glands; one of facial erysipelas during childbed without septicæmia; and one of erysipelas with puerperal septicæmia and double labial abscess. The last was the only fatal case. The deductions the speaker drew from an analysis of the literature and his own experience were: (1) In pure streptococcic infections the serum undoubtedly exercises a favorable influence on the course of the disease. (2) In the mixed infections the influence of the serum is noticeably demonstrable, but it merits further trial as an adjunct to other treatment. (3) Considering the grave character of the complications of a non-streptococcic nature reported, ordinary rules of therapeutics demand that in such cases, as with the diphtheria antitoxin, all indicated therapeutic procedures must be employed as well as the serum. (4) In view of the fact that erysipelas streptococci and phagocytes have been found to exist side by side in the lymph channels, it is fair to assume that the influence of the serum is directly exerted bacteriologically on the streptococci and not entirely through stimulation of phagocytic action. (5) The initial dose in all cases should be twenty cubic centimetres, to be followed by ten or fifteen cubic centimetres, according to the indications, every twenty-four hours.

Dr. Charles L. Minor said that his experience was practically confined to secondary infections in tuberculosis. He had used the serum with considerable satisfaction.

Dr. Samuel E. Milliken had used antistreptococcic serum in two cases, both of which terminated fatally. One was a case of abscess of the liver; the other a suppurative appendicitis.

Dr. William K. Jaques, of Chicago, called attention to infections in the pulmonary tract that he had found to be purely streptococcic, and in such cases he had advised injections of antistreptococcic serum with good results.

Dr. Baum, in closing, emphasized the importance of diagnosing the kind of infection present.

Dr. Albert Bernheim, of Paducah, Ky., presented

a paper and reported three cases of syphilis in which he administered blue ointment with satisfactory results by the mouth. He urged a thorough trial of this method, believing it would please the patient as well as the physician. The method of administering blue ointment by inunction was disliked by the patient, on account of its nastiness and inconvenience; hence if another method of using the ointment could be substituted with the same good and quick results, why not make use of it?

Address on Medicine.—Dr. James T. Whittaker, of Cincinnati, who delivered this address, selected for his subject "Diabetes Mellitus."

Mastoiditis, When to Operate and How.—Dr. Andrew Timberman followed with a paper with this title. The cause and symptoms of this affection were described. To know when to operate one must be able to exclude the diseases which were often accompanied by inflammatory conditions over the mastoid without actual involvement of the bone, and which quickly receded when the primary disease was properly combated. Every physician in his experience saw cases of simple furunculosis and diffuse external otitis presenting as marked symptoms painful and swollen mastoids. The tissues were boggy and the œdematous condition was determined by palpation and pain on pressure. As a *sine qua non* such diseases, as well as syphilis, must always be excluded before operating. The speaker said that he divided cases of mastoiditis into two classes—the first class comprising those complicating acute aural disease; the second class, those complicating chronic aural affections. This division ignored primary mastoiditis, which was very infrequent. The speaker drew these conclusions: Operative measures should be instituted: (1) To preserve the function of hearing as well as to prevent a fatal issue. (2) Earlier in mastoiditis due to scarlet fever, diphtheria, and the worst cases of influenza, than when due to colds, measles, typhoid, etc. (3) In the acute cases of mild infection, when subsidence did not occur within at most eight days (Schwartze). A shorter period was safer in a virulent infection. (4) Recurrent mastoiditis due to any cause. (5) In mastoiditis complicating a chronic suppurative otitis. (6) In acute cases, when there was a drooping of the lining membrane of the superior posterior wall of the external auditory canal, carrying with it the membrana Shrapnelli; in chronic cases, when at the same place a crater-like opening led to the recessus epitympanicus and aditus ad antrum, even though in neither case symptoms immediately menacing life were present. The author favored the typical or original Schwartze method of opening the mastoid antrum. Its success in given conditions justified its application; its failure in given conditions had resulted in a more perfect procedure styled the Schwartze-Stacke or radical operation.

Dr. J. Homer Coulter, of Chicago, maintained that the general practitioner should not treat cases of mastoiditis in which the symptoms were well defined, and no one who had not had considerable surgical experience should attempt the Schwartze operation.

Dr. J. A. Stucky, of Lexington, said that in many cases of necrosis of the malleus he had made a free incision along the posterior superior wall of the canal, curetted the diseased bone away, and tamponed the canal lightly with iodoform gauze. The patients had done well without undergoing the radical operation.

Dr. Dudley S. Reynolds laid stress on the importance of instituting constitutional medication in the stage of invasion in cases of mastoiditis, saying that an ounce of prevention at this time was most preciously bestowed.

Dr. L. B. Graddy, of Nashville, called attention to a point not mentioned in the paper—the differential diagnosis between mastoiditis and mastoid periostitis. If cases were carefully observed, there was as much difference between the two conditions as there was between a periostitis of the tibia and an epiphysitis. This differentiation was of paramount importance in the treatment, whether medical or surgical.

Prophylaxis in Nose and Throat Diseases.—Dr. J. Homer Coulter, of Chicago, read a paper on this subject. He said that there were many preventable pathological conditions in the nose and throat. That many of the ordinary diseases of this portion of the anatomy had evoluted into more serious and distinctly different affections would be admitted without question. He omitted any reference to such conditions as syphilis, tuberculosis, diphtheria, influenza, or the exanthemata, inasmuch as the possible prophylaxis in each affection was a matter of general knowledge. He also omitted reference to any technical details, which were at best mooted points with authorities. Surgery did not cure all conditions, nor did it even prove always a prophylactic blessing. So also local applications and constitutional treatment proved unavailing if universally depended upon. This was due in a measure to the lack of carefully exacting and eliminative diagnoses. With the development of our knowledge of the physiology of the nose and throat had come also new ideas of the connection between many diseases of those organs and of their relative etiological importance. The impairment due to ventilation and drainage was a most important factor, and one usually amenable to surgical treatment. "Taking cold" was not only a most frequent condition, but one most susceptible to prophylactic measures. Clothing, of all parts of the body, was a factor of paramount importance in prophylaxis. Too much clothing about the head and neck was just as disastrous as insufficient protection. Adenoids, polypi, spurs, exostoses, deviations, deflections, and sensitive areas were each amenable to surgical treatment, and demanded such interference as soon as recognized. On the other hand, too much surgery was quite as disastrous as too much conservatism. The tonsils were the cause of other and reflex pathological conditions as frequently as were adenoids. Mouth breathing should be recognized as a most significant danger signal. The speaker's conclusions were that anything which produced an alteration in the normal physiological metabolism of the mucous membrane of the nose and throat; any alteration in the nutrition of the parts; any abnormal variation in functional activity; any considerable change in the histological anatomy, were each and all remediable surgically or otherwise, and were therefore amenable to prophylactic efforts.

Peritonsillitis or Quinsy; Cause and Treatment.—Dr. J. A. Stucky, of Lexington, followed with this paper. Of ten authors consulted, seven, after citing hereditary predisposition, exposure, etc., mentioned rheumatism and gout as the most prolific causes of this malady. Close observation and careful testing in selected cases convinced the speaker that the rheumatic or, more probably, the uric-acid diathesis had more to do with the causation of this disease than any other factor. Coming to the treatment, he believed that, if the majority of cases of quinsy were seen within forty-eight hours after the first onset of the disease, they could be aborted to such an extent that suppuration would not take place. In cases that progressed to suppuration, he strongly advocated early and free puncture, just as soon as there was marked distention, in order to relieve pain and stop the destructive suppurative process. For this purpose he used a modification of an ear spoon, first described by Spier, and not a knife.

Second Day—Wednesday, October 12th.

Complete Inspection of the Rectum by Means of Newer Mechanical Contrivances.—Dr. Thomas Charles Martin, of Cleveland, Ohio, read a paper with this title. The newer mechanical means exhibited consisted of a set of proctoscopes which were provided with obturators of peculiar form; of an illumination apparatus, susceptible of adjustment to a number of positions; and of an improvement of the Yale chair, which facilitated the placing of the patient in the knee-chest posture without requiring any movement on the part of the patient after he was properly seated on the chair. The improvement consisted essentially of an upholstered board attached to the left arm of the chair, and a mechanism controlled by a crank and lever, which formed a part of the running-gear. The anoscope exhibited was an inch and one-half (1.27 cm.) in length, designed for the inspection of that part of the rectum which was surrounded by the pelvic floor. The proctoscope was four inches (10.16 cm.) long. It was, the essayist claimed, of sufficient length to reach into the inflatable rectum; it was not of so great a length as to obstruct a complete view of the rectal chambers, and yet was of sufficient length to reach the promontory of the sacrum when the pelvic floor was displaced upward by the proctologist's manipulations. Both of these instruments were seven-eighths of an inch (2.22 cm.) in diameter, this diameter having been determined upon as the result of calibration in many normal ani. The average diameter of the instrument was equal to the degree of painless expansibility of the anus. The obturators had contracted necks, which constituted these instruments ointment applicators. The middle part of the obturator was channelled; this qualified the instrument as a nozzle for rectal irrigation. Because of its contracted neck the obturator might be used as a self-retaining nozzle. The surface of each obturator was fluted in such a manner that it might be used as a two-way irrigator when properly fixed within its tube. The technique of the inspection was as follows: The patient was required to sit on the chair with his legs crossed and his body facing the knee board, which was attached to the left arm of the chair. The chair back was changed to the horizontal by a movement which put the patient into the Sims posture. The fixed rectum was now examined by means of the short anoscope. After this portion of the rectum was inspected, the chair's lever was extended, its crank turned, and the chair tilted to such an extreme degree of the oblique lateral position that the chair seat was almost perpendicular, and the knee piece, which was a part of the left arm of the chair and against which the patient's knees were pressing, was almost horizontal. Now, at a time when the patient was resting easily in a position which was equivalent to the knee-chest posture, the anoscope was introduced, the obturator withdrawn, and the inspection of the ballooned gut completed. The patient was passively returned to his feet by execution in the reverse order of the several steps of this procedure.

The Relation between the Genito-Urinary Tract and Rectum; In Operations upon the Female which Should Receive Priority?—This paper was read by Dr. John L. Jelks, of Memphis. The author championed the assertion that the gynæcologist should be as well prepared to remove hemorrhoids and treat an ulcerated rectum as to dissect a cicatrix from the cervix or repair a perineum. The rectal surgeon often found that although the rectum was involved to such an extent as to be chiefly complained of, the principal source of danger to the patient was a pus tube or some other disease. In other words, to relieve the patient and restore her to health and happiness, he must also dissect from the cervix uteri a cicatrix and repair a lacerated perineum. In another case he might be required to sever a urethral stricture.

Rectal Fistula in the Causation of Ischio-Rectal Abscess.—Dr. William B. Bruns, of Deckerville, Ark., reported a case with two large pus pockets. He opened the abscess, emptied its cavity, and subsequently did an operation for the removal of the fistula.

Hydrotherapy in Stomach Diseases.—Dr. George D. Kahlo, of Indianapolis, followed with a contribution on this subject. He said that water was essential to the performance of all physiological functions; yet its importance as a remedial agent was not so generally recognized. While he did not wish to be understood as opposing entirely the use of drugs in diseases of the stomach, he desired to say that he believed water ranked first among therapeutical resources. It might be used internally as a drink, in lavage, as a douche, and as a spray, and externally applied either locally or generally. Its effects, when administered internally, depended upon the conditions of the stomach in respect both to the taking of food and to the fact whether or not there was normal digestion, as also upon the amount and temperature of the water ingested. Cold applications of all kinds were antiphlogistic, and when prolonged were sedative. They were indicated in acute gastritis and in the control of vomiting and hæmatemesis, but to obtain their full effect it was necessary that their local condition should produce an active hyperæmia of the skin. Hot applications were useful in the treatment of gastralgia, hyperæsthesia, gastric ulcer, and chronic gastritis. While he did not ignore the beneficial influences of such agencies as diet, exercise, massage, and electricity, not to speak of a few of the more important drugs which were thus used (and in obstinate cases especially), physicians were not likely to rely wholly upon any one remedy, however valuable. To be successful, hydrotherapy, like all other forms of treatment, had for its governing factors an exact diagnosis, a thorough knowledge of the patient, a full understanding of the causative influence, and a clear conception of the effects of the remedial agent. To this must be added the confidence and co-operation of the patient.

Dr. Thomas Hunt Stucky, of Louisville, read a paper on "Auto-Intoxication of Intestinal Origin."

Abscess of the Liver.—Dr. Edwin F. Wilson, of Columbus, Ohio, read a clinical report of a case of abscess of the liver. In referring to the clinical aspects of abscess of the liver, he called attention to the essentials in diagnosis, and dwelt upon the history of the disease. He reported three cases. Of these, the diagnosis was confirmed in two cases by post-mortem; in the other one by aspiration. All three of the abscesses were chronic when they came under his observation. In only one of the cases was there a history of dysentery, although in another scars of healed ulcers were found in the large intestine. In these cases the speaker had found that the enlargement of the liver was upward. Hoover, he said, had made a diagnosis of abscess of the liver from a friction sound in the axillary line, between the eighth and tenth ribs. The essayist had not heard this sound in any of his cases, but the possibility should be borne in mind in making an examination in this region. Two of the cases reported were mistaken for malaria. This mistake could be avoided by the more general use of blood examinations. The absence of plasmodium would settle the question at once.

(To be Continued.)

Epistaxis.—The injection of a glass syringeful of lemon juice into the nose, after it has been cleansed of clots, it is said will stop bleeding when everything else has failed.

NEW YORK STATE MEDICAL ASSOCIATION.

Fifteenth Annual Meeting, Held in New York City, October 18, 19, and 20, 1898.

DOUGLAS AYRES, M.D., OF MONTGOMERY COUNTY PRESIDENT.

(Concluded from page 600.

Second Day—Wednesday, October 19th.

Notes on Neuralgic Affections of the Head.—DR. GUSTAVUS ELIOT, of New Haven, read this paper. He said that the most common form of neuralgic affection of the head was the supra-orbital variety, which was apt to recur at about the same time on several successive days, and be associated with tenderness over the point of exit of the nerve. The next most common variety was that affecting the temporal and auricular nerves. The two chief factors in the production of these neuralgic conditions were (1) a depraved condition of the blood and (2) nerve exhaustion. The symptoms indicative of the neuralgic character of a painful affection of the head were absence of fever and circulatory disturbances, absence of catarrhal disorders, recurrence on several days, a tendency for the pain to follow the course of certain nerve trunks and for the pain to pass from one side of the head to the other. During the attack, morphine might be given hypodermically, but for more prolonged use it was advisable to give quinine, five grains every four hours, with fifteen drops of the tincture or five drops of the fluid extract of gelsemium at the same intervals. Attention should be given to the functional condition of all the organs of the body.

Discussion on Intestinal Obstruction.—DR. PARKER SYMS, of New York, opened this discussion. He stated that acute intestinal obstruction was an absolutely curable condition if recognized early and promptly and properly treated. Being a mechanical condition, it was one which must be combated by mechanical means. Too often the physician, when first called in, made a superficial examination and diagnosticated the condition as simply one of constipation. Although in simple constipation the patient might be, through ptomain poisoning, very ill, it was possible in most instances to make an early differential diagnosis. It was unwise to give cathartics even in cases in which only impaction was suspected; it was far better to endeavor to relieve the patient by high enemas. If such treatment were not speedily successful, no time should be lost in seeking operative relief.

The Causes of Acute Intestinal Obstruction, with a Description of their Mechanism.—DR. E. D. FERGUSON, of Troy, continued the discussion by a consideration of this part of the subject. He said that in three cases in his own experience it had been possible for him to discover that the case under examination was not really one of intestinal obstruction, but an example of lead paralysis. He had already published an article showing that intestinal obstruction might be an exceptional result of intestinal ptomain poisoning. The mechanical causes of obstruction were: (1) Obstructions from conditions without the bowel; (2) obstructions from conditions within the bowel; and (3) obstructions from conditions relating to the wall of the bowel. Some mixed types also occurred from the combination of two or more conditions. In the first category were: (*a*) compression by tumors or displaced viscera; (*b*) compression by bands, cords, other loops of the bowel, and by traction; and (*c*) compression in apertures. The author then took up the subject of the mechanism of intussusception, dwelling upon the spasmodic forms of intussusception, and the action of the circular and longitudinal muscular fibres, and of both direct and reversed peristalsis. In over fifty per cent. of the cases of intussusception the ileum enters the colon, sometimes for a remarkable distance. Under the third head—conditions relating to the wall of the intestine—were mentioned stricture and volvulus. Twisting, the author said, might be produced (1) around the axis which extends through the transverse diameter of the bowel to the mesenteric attachment at the vertebra, and (2) more or less directly along the line of junction of bowel and mesentery. The former constitutes seventy-five per cent. of the cases of volvulus. Should the physician be unable in a given case to decide which of the forms of obstruction was present, under the doctrine of chances, before opening the abdomen, one would base an opinion on the following order of occurrence, viz.: (1) Intussusception; (2) strangulation by bands, orifices, etc.; (3) diaphragmatic herniæ; (4) obstruction by foreign bodies; (5) stricture; (6) compression by tumors; (7) volvulus; (8) angular bending.

The Causes of Chronic Intestinal Obstruction, with a Description of their Mechanism.—DR. GEORGE D. STEWART, of New York, discussed this topic. He said that by the term "chronic obstruction" was usually meant a partial obstruction occurring in persons giving a previous history of intestinal disease. Among the more common causes were: (1) Simple stricture, (2) dysenteric ulcers, (3) catarrhal ulcers, (4) syphilitic ulcers, (5) typhoid ulcers, and (6) tuberculous ulcers. Malignant strictures were either carcinomatous or sarcomatous, and each of these might be either primary or secondary. Paresis of the intestinal wall, with fæcal accumulations, was a frequent cause of chronic obstruction. According to Erichsen, about eighteen per cent. of all cases of intussusception ran a chronic course. Permanent narrowing of the bowel was caused either by an intussusception not becoming strangulated, or by its becoming more or less strangulated and undergoing certain structural changes. Adhesions were produced by (1) bands and (2) compression by diverticula or benign tumors in the intestine.

Intestinal Obstruction Due to Impaction of Fæces, Gall Stones, Foreign Bodies, etc.—DR. J. W. S. GOULEY, of New York, took up this phase of the general subject under discussion. He stated that these patients almost invariably said that the bowels were regular, because there were one or two stools daily, and for the same reason the fæces were allowed to accumulate until a large tumor was formed, and this was too often mistaken for malignant disease. In the treatment of this condition too much could not be said of the value of prolonged irrigations with hot saline water, but if the rectum was filled with large and hard masses these should be removed with the scoop prior to the irrigations. Laxatives should be given by the mouth for several days following the use of the enemas. Speaking of enteroliths, Dr. Gouley said that they were of five varieties, viz.: (1) Those with gall stones as nuclei; (2) those composed of fæcal matter, lime, magnesia, phosphates, and carbonates; (3) those composed of vegetable substances, fæcal matter, and calcareous particles; (4) those composed largely of solid medicinal agents, such as magnesium carbonate or bismuth; and (5) those with foreign bodies for nuclei. Referring to a series of fifty cases that had been collected, in which foreign bodies had been swallowed, the writer said that of this number twenty-six were in adult males, sixteen in adult females, two in male infants, one in a female infant, and five in infants whose sex was not given. Such foreign bodies might be impacted in the pharynx, œsophagus, stomach, or intestine, or they might pass through the stomach and intestine and be discharged with the stool. The swallowing of coins rarely caused inconvenience. The treatment consisted in extraction by the mouth,

propulsion through into the stomach, or extraction by œsophagotomy or gastrostomy. The paper closed with the narration of a number of remarkable cases on record, in which hair balls had been found in the stomach, and of instances in which knives, forks, pieces of glass, etc., had been swallowed. In one case a fork had migrated from the abdominal organs to the hip.

The Diagnosis and Indications for Treatment of Acute Intestinal Obstruction.—Dr. J. D. Rushmore, of Brooklyn, read this paper. He said that the more important symptoms of intestinal obstruction were pain, nausea, vomiting, tympanites, tumor, visible coils of intestine, and failure to pass either fæces or gas. Among the less important symptoms were fever, jaundice, diminution or suppression of urine. As hernia was a most common cause of intestinal obstruction, it seemed hardly wise for the text-books to consider this subject apart from the general one of intestinal obstruction. When there was doubt about hernia as the cause of the obstruction, it was well to make an exploratory incision over the hernial orifice under cocaine anæsthesia. By non-mechanical intestinal obstruction was commonly meant that form resulting from septic peritonitis. Peritonitis might usually be recognized by the pulse, temperature, pain, and facial expression, and the existence of these evidences of peritonitis prior to the development of the symptoms of obstruction would point to peritonitis as the cause of the obstruction. Exploratory laparotomy furnished the only means of exact diagnosis. It ought to be more frequently employed than it was, especially as there was no better, and at times no other, means of making a correct diagnosis. The dread of opening the abdomen had long since vanished among surgeons. When an operation seemed to be indicated, it should not ordinarily be deferred more than forty-eight hours. In competent hands, early cœliotomy for intestinal obstruction probably should not give a mortality of much over twenty per cent.

The Diagnosis and Indications for Treatment of Chronic Intestinal Obstruction.—Dr. Leroy J. Brooks, of Norwich, considered this part of the subject. He stated that chronic obstruction was rare in infancy. Malignant disease constituted an important cause of chronic intestinal obstruction. The true cancerous cachexia presented a pale, waxy countenance, which was characteristic; on the other hand, marasmus from auto-infection gave rather a jaundiced skin. It should be noted that jaundice was connected with less than half of the cases of obstruction associated with gall stones. Tuberculous structures were most common in the ileum; syphilitic and cancerous strictures in the sigmoid. The nearer the stomach the disease was located, the more severe were the nausea and vomiting and the cachexia. If the obstruction was situated in the colon, the vomiting occurred late, and might be stercoraceous for many days preceding death. As a rule, the pain of all obstructions of the small intestine was concentrated at the navel. In obstructions located in the small intestine, it occurred three or four hours after the taking of food, whereas in obstructions in the colon the pain bore no relation to the meals. Post-operative obstructions usually occurred at the junction of the small and large intestine. Constipation occurred in seventy-five per cent. of cases of obstruction of the bowel, yielding at first to cathartics, but rapidly becoming more and more complete. In the other twenty-five per cent., constipation alternated with diarrhœa. In cases of obstruction resulting from intestinal paresis, the most prominent symptom was the extensive tympanites, with a smooth abdominal surface and the absence of visible coils; but it was a condition which very frequently led to errors in diagnosis. Exploratory laparotomy should be done as soon as one was sure that an obstruction existed which could be removed only by surgical interference. Dr. Brooks said that he had occasionally observed post mortem stercoral ulcers in the region of the cæcum in cases of chronic obstruction of the bowel. These ulcers had perforated and caused peritonitis, the original cause being obstruction in the colon.

Intestinal Obstruction Due to Intussusception and Volvulus.—Dr. John F. Erdmann, of New York, discussed this subject. He stated that his own experience had led him to believe that intussusception was not so rare as one would infer from reading the text-books. Intussusception was the cause of fully thirty per cent. of all cases of acute intestinal obstruction, and the condition was most frequent during the first two or three years of life. The enteric variety was most commonly met with. Among the anatomical causes laid down were (1) a long and lax mesentery and (2) the musculature of the gut causing irregular peristalsis. Marked debility and former disease of the bowel were commonly stated to be the causes of intussusception, but certainly his own cases had not presented any marked debility. It would seem reasonable to suppose that anything which tended to produce vomiting or diarrhœa would predispose to irregular peristalsis, and hence to intussusception. In his own cases pain had always been present, but the vomiting, when present, had been a late symptom. Tenesmus and bloody stools were early symptoms, and persistent restlessness was a prominent feature. It was often impossible to recognize any tumor. In endeavoring to reduce the intussusception by mechanical methods, air and water were commonly employed. The former was less effective, and when the tumor was above the transverse colon the enema treatment was apt to fail. In no instance should the reservoir containing the water be placed more than three feet above the patient. In reducing the intussusception at the time of operation, it was best to make pressure through the intussuscipiens upon the apex of the mass in such a manner as to drive the intussusceptum through its receiving-coat. Men were considered to suffer from volvulus four times more frequently than women. The diagnosis of volvulus was made largely on the sudden onset of the symptoms, the presence of a palpable tumor, and a dull or tympanitic percussion note. The treatment consisted in the use of enemas or resort to operation.

Dr. Farquhar Ferguson, of New York, at the close of this discussion on intestinal obstruction, exhibited an excellent pathological specimen of a portion of bowel, the seat of an intussusception.

Third Day—Thursday, October 20th.

The Technique of Operative Treatment of Intestinal Obstruction.—Dr. Frederick Holme Wiggin, of New York, read a paper on this subject, which was intended as the closing contribution of the preceding day's formal discussion of intestinal obstruction. He said that the various conditions for which operations were usually demanded were: (1) Strangulation of the gut by bands; (2) volvulus; (3) intussusception; (4) obstructions due to neoplasms; (5) compression by tumors external to the gut; (6) obstruction from foreign bodies, such as gall stones and enteroliths; (7) obstructions caused by fæcal masses. When there was no time for the careful preparation of the operating-room, the movable furniture should be taken out and the carpet covered with sheets wet with a 1 to 20 carbolic-acid solution, or a 1 to 100 bichloride solution, care being taken that no dust was raised. Water, sterilized by boiling for an hour, should be used when practicable, but when time was precious water from the hot-water faucet might be used. After opening

the abdomen, the first effort of the operator should be to discover the cæcum, and if this portion of the bowel was found to be greatly distended it was probable that the stoppage was in the colon. The writer recommended, in cases of volvulus, the drawing out of the small intestine and its systematic examination, the bowel being kept warm and moist by being wrapped in gauze or soft towels wet with hot saline solution. No attempt should be made to reduce an intussusception by traction from above the tumor. When it was irreducible, Maunsell's method should be employed. When the intestinal obstruction was the result of the pressure of neoplasms, the latter could usually be removed at the present day. When this was inadvisable, a fistula was to be formed after the method of Nydls. Gall stones or enteroliths causing obstruction should be removed by an incision made a little above or below where they had been lodged. Fæcal accumulations were best removed by small doses of calomel and soda, aided by high enemas of warm saline solution, given by the physician or under his immediate supervision. A bulb syringe should not be employed for this purpose. When the gut was found to be gangrenous in a case of obstruction of the bowel, an end-to-end anastomosis should be effected, and for this purpose Dr. Wiggin preferred his modification of Maunsell's method. This modification had the advantage of much greater simplicity, as it consisted, in brief, in doing away with the invagination and the slit employed by Maunsell. A very common error in the after-treatment was that of giving too small quantities of food at too short intervals, thereby rendering the stomach irritable and improperly nourishing the patient. The bowels should be moved on the third or fourth day by small doses of calomel and soda. Perhaps the most important point to remember, in the opinion of the author, was that the chief factor in determining the prognosis in cases of intestinal obstruction was the promptness with which operative treatment was instituted.

Dr. H. O. Marcy, of Boston, said that personally he believed intestinal suture would ultimately give the greatest satisfaction of all the methods that had been advocated and practised. In this connection he desired to describe a simple method of intestinal suture which he had employed quite extensively, and with much satisfaction. A slit was made in each portion of the intestine, thus giving two straight openings and surfaces which could be quickly brought in apposition, and sutured. The small remaining slit was brought together, preferably with a double continuous suture. This gave smooth and unabraded peritoneal surfaces, and every stitch was turned in. It had long seemed to him that the profession had greatly underestimated the importance of a thorough reconstruction of the peritoneal planes after operation. The abrasions left after these abdominal operations, no matter how small, were apt to give rise to trouble subsequently. It was easy to close them in with a fine running suture, and he had repeatedly closed up the whole peritoneal surface of the pelvis in this way.

The Passing of Alcohol.—Dr. J. M. Farrington, of Broome County, read a paper with this title, in which he expressed the opinion that those of the profession who believe in the value of alcohol as a remedy were now in the minority. A great change in this respect had taken place in recent years. Alcohol, he said, was not a food, but on the contrary impaired nutrition. It was not a stimulant, but really a depressant. Recent physiological experiments showed that it retarded, perverted, and was destructive to normal cell growth. Life insurance companies had become convinced beyond question that alcohol, used in even moderate quantities, impaired health and shortened life. They declined to accept a risk unqualifiedly if the person used liquor in any form habitually. Railroad companies now required their engineers, brakemen, switchmen, and conductors to be total abstainers. The majority of Christian societies had banished wine from their religious ceremonies, and used instead unfermented grape juice. Notwithstanding the drinking usages of the time, he believed that there never was a period in the world's history when the use of liquor was considered so degrading. He attributed the superior accuracy of our gunners in the late naval engagements with Spain to the banishment of rations of grog. By order of Lord Wolseley, he said, careful experiments had been made regarding the staying qualities and health of the British troops using alcohol, as compared with those not using such drink. Certain regiments were allowed rations of grog, and from other regiments these were entirely withheld. It was found that those receiving the grog made a very impetuous dash in their charges, but after a few days they showed a great deal more fatigue and weakness than those who had had no grog. As a result of these observations, and not from any conscientious scruples, rations of grog had been forbidden in the present campaign in the Soudan. Difficult as was this important innovation on time-honored customs, the results had fully justified the change. Dr. Farrington thought the medical profession should be as active now in securing the banishment of alcohol as it had been in the past in placing it in a prominent position.

The Retirement of Alcohol in Pharmaceutical Processes.—Dr. E. R. Squibb said that it might be of interest, in connection with this paper, to learn of the work being done in the way of retiring alcohol as a menstruum for exhausting drugs. A good deal had been accomplished in this direction in the last two or three years. Of the other menstrua experimented with up to the present time, that which had given the best results was acetic acid in various strengths. It had been discovered that a ten-per-cent. solution of acetic acid was almost universal in its exhausting powers. There were now in use in veterinary practice and in some hospitals, extracts made with acetic acid. They were made according to the requirements of the pharmacopœia except that acetic acid was substituted for alcohol. Acetic acid when used with alkaloids gave the physician certain advantages in prescribing, owing to there being fewer incompatibles. In small doses the percentage of acetic acid in the extract was so small as to be hardly appreciable, and when larger doses were required the acetic acid could be neutralized by the addition of potash or soda.

Dr. H. D. Didama, of Syracuse, said that it did not seem to him that the use of alcohol by the profession had been abandoned, either socially or otherwise. It should not be forgotten that the value of negative testimony could never equal that of positive testimony, and that, therefore, the observations of those physicians who had tried alcohol in their practice and abandoned its use should have greater weight than the results obtained by those who had always relied upon it. For the last four years he had not given the equivalent of a teaspoonful of alcohol to all of his patients put together, and he was better satisfied with this practice than with that of previous years, in which he had used alcohol more freely.

Dr. Wickes Washburn, of New York, thought that in discussions of this nature it would be advantageous to divorce the questions of alcohol as a medicine and as a beverage. If alcohol were not a narcotic, we would not see "dead drunks." He used alcohol, in the critical stage of pneumonia, just as he did morphine, and to avoid its secondary or depressant action the second dose must be given before the second action of the first dose had developed. In his last forty-six cases of pneumonia he had given alcohol and mor-

phine—in some cases, morphine to the extent of one-fourth grain every forty-five minutes—and had met with none of the secondary or depressant effects, or any tendency to narcotism. Further, there had been no tendency to continue the morphine or alcohol after recovery.

Dr. Hiram A. Pooler, of New York, said that as a result of the experience gained through many years of practice he would say that alcohol must be prescribed with great care. He would not exclude it under all circumstances, but he would rather cut off his right hand than introduce it into a young person's system. It was without doubt very useful in the treatment of disease occurring in persons who had been addicted to the use of alcoholics for years, but he must confess with sorrow to having been responsible for sending two individuals to drunkards' graves by recommending alcohol when he should have advised the use of carbonate of ammonium, caffeine, or some similar stimulant. Sir Benjamin Richardson, who had had exceptionally good opportunities for the investigation of the effects of alcohol on the human system, had stated that alcohol was a deadly poison from its inception to its elimination from the human system; that it did not promote digestion, but, on the contrary, retarded and interfered with it.

Dr. Robert Newman, of New York, deplored the tendency of Americans to run to extremes. He felt that as a physician he had been instrumental, by prescribing alcohol, in saving several lives. At one time he had made a post-mortem examination on a man who he knew had been intoxicated almost daily for many years, yet he had failed in this particular case to find the ravages of alcohol so graphically described by those who believed its use should be entirely and forever abandoned. While it might be true that small doses of acetic acid were innocuous, he was positive that if the doses of drugs exhausted by the agency of this menstruum were large it would be found harmful, just as vinegar was prejudicial to health.

Dr. Farrington, in closing the discussion, said that he thought close investigation would show that alcohol was entirely contraindicated in pneumonia. Alcohol was not a stimulant; it lashed the nervous system into greater activity, but caused greater depression as a result.

Eye Lesions in Some Diseases of the Kidney.—Dr. H. S. Oppenheimer, of New York, read this paper. He said that the most frequently observed lesion of the eye in connection with disease of the kidney was retinitis albuminurica, with or without hemorrhages. Iritis occurred occasionally, but there was nothing unusual about its course. Hemorrhages were often found in the vitreous humor. The most important and frequent, however, were the lesions of the optic nerve and choroid. Choroiditis was rarely mentioned in this connection, because the exudation was often obscured from view. Retinitis albuminurica was almost always associated with hemorrhages, and the prognosis was worse when they were present, because it might be assumed that the same condition was present in the brain. Dr. C. S. Bull, in a paper published in 1886, reported one hundred and three cases. Eighty-six of these patients were dead at the time of the report, fifty-seven in the first, and eighteen in the second year. In four of the cases sugar was also present in the urine, and two of these patients had died within two years. In the opinion of Dr. Oppenheimer, the cause of this anatomical condition of the retina was to be found in the blood, in an irritant to the tunica intima, associated with hypertrophy of the heart and high arterial tension. Uræmic amblyopia was seen usually in nephritis of the exanthemata or during pregnancy. It was accompanied usually by headaches, nausea, and vomiting, and might occur during uræmic convulsions. The urine was ordinarily scanty and loaded with albumin. Vision was nearly or completely lost. Even though the patient was unconscious, there was often observed a reaction to light. The prognosis depended upon the condition of the kidneys. When the patient recovered from the uræmic attack, vision usually returned in from twelve to twenty-four hours. The reaction of the pupils to light proved the blindness to be of central origin. The differential diagnosis between retinitis albuminurica and uræmic amblyopia was easy. The former came on gradually and presented distinct retinal lesions; in uræmic amblyopia the patient was in bed, having suddenly lost the vision, and the ophthalmoscope revealed no appreciable lesions.

Some Observations of General Interest Regarding the Course and Management of Cataract.—Dr. J. H. Woodward, of New York, presented a paper on this subject. The special object of his communication was to call attention to three important facts in connection with the subject of cataract. They were: (1) That many cases of senile cataract showed no progressive loss of vision; (2) that improvement was often observed; and (3) that complete cataractous degeneration of the senile type was a process often requiring many years for its consummation. Thus in one of the cases reported by him, a patient, forty years of age, with cataract, first came under his observation in 1891, yet the vision was as good to-day as it was then. In another patient, ninety-one years old, the vision had remained good during the seven years the case had been under observation. In the management of these cases Dr. Woodward followed one cardinal principle —*i.e.*, that as a failure in the nutrition of the crystalline lens was probably the cause of the cataract, the physician should endeavor to keep up the nutrition of this part to the highest point. Errors of refraction must be adequately corrected, and every effort made to improve the general health and avoid eye strain. It was usually safe to allow these persons to read by a good light until they felt that the eyes were tired, but they must then promptly discontinue using the eyes until again thoroughly rested.

The Coccyx.—Dr. J. E. Walker, of Steuben County, read a paper with this title. He said that in a great many cases of coccygodynia the cause was to be found in direct violence, such as falling upon the horn of a saddle or from a hammock, but in others the only apparent cause seemed to be a depraved state of the system, such as neurasthenia. Morphine, atropine, hyoscine, and antipyrin had been used locally by hypodermic injection, and sometimes acted fairly well, as did also hot-water bags to the end of the spine. Electricity had proved disappointing in his hands, although both the galvanic and the high-tension current had been used. When these measures failed, operative treatment was indicated. The patient was placed in the left lateral position, and through a free incision the coccyx was easily excised. All bleeding having been stopped, the wound should be closed completely. Several cases were reported in which this operation afforded immediate and permanent relief. When the lesion was local or when there was a deformity, excision of the coccyx was indicated; but when the neuralgia was apparently the result of a constitutional condition excision was usually contraindicated.

Insanity following Surgical Operations.—Dr. W. D. Granger, of Westchester County, read this paper. The author said that out of two thousand cases of insanity studied by him, only two had followed upon surgical operation. One of these was the case of a woman of twenty-six years who had been insane twice after operations. One of the most important predisposing influences was heredity. Advanced age, puberty, the climacteric, syphilis, tuberculosis, and hys-

teria also predisposed to the condition. Clouston had described a delirious type of temporary insanity following anæsthesia, and apparently independent of the kind of anæsthetic employed and the duration of its administration. It seemed justifiable, however, to claim that the anæsthetic acted as a toxic agent. Insanity had been known to follow the simplest operation. The part operated upon seemed to exert a marked influence, insanity being especially liable to follow operation on the genito-urinary organs, and, with diminished frequency, operations on the abdominal viscera, the breast, and the eye (particularly for cataract), in the order given. It should be noted that extraction of teeth held a not unimportant place in this list. It could not be denied that the large majority of the cases of insanity occurring after surgical operations were among women, and this did not seem to be because so many operations were done on the genito-urinary organs of women, for it must not be forgotten that a great many such operations were performed upon men. The vast majority of cases of insanity occurring after operations developed, not immediately after, but at the end of a week or two. The writer believed that in women the menstrual period was an important predisposing cause. No age was exempt; a case had been reported in a boy of ten years, and another in an adult of sixty-five; and it was not improbable that the ages in these cases would prove to be the same as for insanity in general. In forty-six cases reported by Dewey, twenty-seven patients recovered, eight died insane, three within the week of the attack, and only six became chronically insane.

Dr. C. C. Frederick, of Buffalo, said that he had seen only one case, and that had occurred in a woman of thirty years, upon whom he had performed a simple curettage and an Alexander operation. He subsequently learned that three or four years prior to his operation she had had an attack of acute mania, lasting several months. About two weeks after the operation she began to act peculiarly, and in three or four days after this she was acutely maniacal. She then went to the Buffalo State Hospital, and completely recovered in about six months.

Dr. F. H. Wiggin also reported a case occurring in a woman upon whom he had operated for the removal of an enlarged ovary and an inflamed appendix, and who developed laryngeal diphtheria during convalescence from the operation. She insisted upon going to her home in Philadelphia before she had fully recovered, and shortly after reaching there developed an acute mania. She was in an asylum for about two months, but had now completely recovered. The exhaustion consequent upon taking this journey probably had much to do with her attack of mania.

Use of Catgut in Surgery.—Dr. C. C. Frederick, of Buffalo, read this paper. He said that up to four years ago there was no known method of sterilizing catgut without impairing its strength. Catgut would not slip if properly tied, objections to the contrary notwithstanding. As no surgeon knew when a non-absorbable ligature or suture might give rise to trouble if buried in the tissues, absorbable suture material should alone be used. Catgut could now be thoroughly sterilized, was as reliable as kangaroo tendon, and was much better because it could be obtained in various lengths and thicknesses. He had used catgut in several hundred abdominal and plastic operations, and had never known a knot to slip. Catgut could be chromicized to any degree so as to resist absorption for any desired period. The boiling-point of alcohol was 173° F., and neither catgut nor kangaroo tendon could be sterilized at that temperature, as had been proven by both clinical and bacteriological observation. The boiling of catgut in cumol was satisfactory as regarded sterilization, but the tensile strength was apt to be impaired, and the method required the most minute attention to details to insure success. He had used this process for over a year, preparing all the catgut himself. For the last two years he had used the formaldehyde process, and for sterility and strength catgut so prepared was superior to any other with which he was acquainted. The catgut was purchased in coils, and the surgeon also provided himself with a lot of small glass spools, having notches cut with a file on the edge of the flange. One end of the catgut was pushed through the barrel of the spool and passed over the notch in the flange. It was then held while one layer of catgut was wound tightly on the spool, and the end tied tightly to the first end with a double knot; otherwise the catgut would slip during the boiling. This secured it from unwinding and shrinking. Each spool held enough gut for one or two long sutures or ligatures. If more than one layer was wound on the spool, it would not be evenly subjected to the action of the formalin. The addition of thirteen parts of water to the ordinary commercial forty-per-cent. formalin solution, gave a three-per-cent. solution of formaldehyde, and this was the strength used for preparing the catgut. The same solution might be used repeatedly for months for treating successive batches of gut. The wound spools were immersed in the solution for a period dependent upon the size of the gut. Thus for No. 0, one hour was sufficient; for No. 2, three hours; for No. 3, six or seven hours. If the gut was left in the formalin solution much longer than this, it would become too brittle. After being taken out of the formalin, it was placed in a jar containing running water, and was left there fully as long as it was immersed in the formalin; but twenty-four hours' immersion would do no harm. The sterilization came next, and consisted in boiling the catgut for fifteen minutes in water. The spools were then removed with forceps, and were placed in glass jars previously sterilized by boiling, and containing ninety-five-per-cent. alcohol with a small percentage of glycerin. To chromicize the catgut, the wound spools of plain raw catgut were immersed for twenty-four hours in a solution consisting of one and one-half grams of bichromate of potassium, ten cubic centimetres each of glycerin and carbolic acid, and one litre of water. The bichromate of potassium should first be dissolved in the water, and then the glycerin and carbolic acid added. After immersion for twenty-four hours, the catgut should be hung up, drained, and dried. The treatment from this point on was the same as for the plain catgut. Such catgut would resist absorption for from six to eight weeks, except in the kidney and peritoneum, where it would be absorbed in about half that time.

What to Do to be Saved, Being the Conclusion of the Inquiry into the Abuse of Medical Charity.—Dr. Thomas J. Hillis, of New York, continued his inquiry into this evil by a parable. In this it was stated that a certain hospital, finding that it could not get the control of those in moderate circumstances that it desired, established "a dollar-a-month annex," and there the hospital governors doled out charity on three days of the week, with the help of medical talent that they had paid nothing for. As a result, the visiting physician became poor, but was assured by the hospital governors that if he should get sick they would take care of him at their dispensary, and, if the worst should come, they would use their influence with the superintendent of the poor and get him a ticket of admission to the poorhouse. Under the dollar-a-month plan the hospital became a rich corporation, and its governors domineering and insolent. Why should the visiting surgeon, the author queried, give his services so freely to such a corporation? It was not to gain experience in his art, because he must have demonstrated his ability and skill before being able to secure

his hospital position. The original motives were probably ambition and a desire to obtain indirectly some pecuniary advantage. But the glory of working for a corporation for nothing soon became irksome, especially when one was denied even the slight privilege of charging a fee to those coming under one's care who were abundantly able to pay it. In the older days there was a reason for asking the hospital surgeon to work without remuneration, for then the hospital was in swaddling-clothes; but it was not so now. The surgeon had found out all too late that he had been foully duped—he was but one more victim of ambition and the "charity fever."

Senility.—Dr. F. W. Higgins, of Cortland, read this paper. He said that as life was a constant balancing of the processes of assimilation and disassimilation, so old age was characterized by diminished assimilation. Old age began in the primary cell elements, and in due time became recognizable under the microscope as "fibrosis." The pathology of chronic alcoholism presented an almost identical array of lesions. Although senility could not be treated, senescence could, and it was the office of the physician to avert premature senility. The treatment of senility must necessarily be largely hygienic, attention being given to the quantity of food taken and the condition of the excretory organs. Alcohol was apt to do more harm than good, and care must be taken that medicines were not too strong.

Technique and Use of Saline Infusions.—Dr. Thomas F. Reilly, of New York, presented this paper. He advised cleansing the arm, making a short superficial incision over the vein in the right arm, passing a uterine tenaculum around the vein, and allowing it to hang while the vein was incised and the fluid injected. The tenaculum was then removed, and, if a ligature was not at hand a compress was applied. A sharp-pointed cannula was likely to injure the walls of the vein. In an emergency, a cannula might be extemporized out of a goose-quill or a medicine-dropper. Both experiment and clinical observation had demonstrated that there was very little danger from the introduction into the vein of small quantities of air. The saline solution was conveniently made by dissolving two small level teaspoonfuls of table salt in a quart of boiled water, and filtering. The quantity injected varied greatly, but it is rare for more than two pints to be required at one time, although the injection might often be repeated a number of times with advantage. Saline infusion was useful in: (1) Severe hemorrhage, whether external or internal; (2) in shock, both simple and post-operative; (3) in all toxæmic conditions, being preceded by venesection; (4) in cases of both vegetable and mineral poisoning; (5) any pathological state attended by marked diminution in the blood pressure.

Dr. J. W. S. Gouley commended the paper very highly, and stated that he was familiar with the technique as described and with the apparatus recommended by the author, and in his opinion they were superior to anything previously suggested.

Dr. M. C. O'Brien, of New York, compared the new method with the older and clumsier ones in a way which was most flattering to the reader of the paper.

Dr. Wiggin said that the plan of raising the vein out of its bed was a great improvement. Recently he had been very much pleased with the use of saline infusion in feeble persons who were unable to take sufficient nourishment after operation.

Dr. Joseph D. Bryant, the newly elected president, after a brief address, then declared the association adjourned. It is worthy of note that the attendance at this meeting was larger than it had been for eleven years, and that the number of out-of-town members present was over four times what it was last year.

Correspondence.

TORTICOLLIS.

To the Editor of the Medical Record.

Sir: In a recent article I stated that clonic contractions of the sterno-cleido-mastoid draw the head to the affected side. This is a mistake; it should read, to the "unaffected side." In mild contractions the deviation to the other side is not so perceptible as in spasmodic torticollis, where the severe clonic contractions of the sterno-cleido-mastoid produce a very decided deviation to the unaffected side. Under narcosis, the mistake has been made more than once, by very able surgeons, of operating on the wrong side. It offers a favorable opportunity for malpractice suits, and what a high opinion I have for those alleged doctors who testify against each other!

"A FORM OF AMBLYOPIA."

To the Editor of the Medical Record.

Sir: In the issue of the Medical Record of October 8th, in the article "A Form of Amblyopia," the following occurs: "June 20th to 24th. R. V., $\frac{6}{15}$; $\frac{6}{6}$ with + 5 S. combined with — 0.50 C., axis 105." This should be: "June 20th to 24th. R. V., $\frac{6}{15}$; $\frac{6}{6}$ — with + 5 S. combined with — 0.50 C., axis 105."

Norburne B. Jenkins, M.D.

Knoxville, Tenn.

THE LADY PHYSICIAN VERSUS THE MIDWIFE.

To the Editor of the Medical Record.

Sir: The interesting article on the midwifery question in a recent issue of your esteemed paper ("Some Remarks on the Midwifery Question—Must the Midwife Perish?" by Thomas J. Hillis, M.D., Medical Record, No. 14, October 1, 1898) has certainly attracted much attention. It has always been the opinion of the best representatives of the medical profession that it was their duty (outside of any monetary considerations) to fight against the practice of medicine as a whole, or of any branch thereof, by ignorant persons utterly unprepared for it scientifically. The intelligent physician is yet to be found who will dare to proclaim midwifery not a branch of medicine. I might fill pages with quotations from the best authorities on the subject, claiming midwifery to be medicine. And yet here we perceive a strong voice of a physician for the retention of the midwife, a voice doubly strong because it appears on the pages of the most important medical publication in this country, which is supposed to voice the most advanced scientific medical thought. It is exceedingly important, therefore, to examine into the reasons brought forward by Dr. Hillis, so as to decide once forever whether we should not put a stop to our war against midwives.

Dr. Hillis defends his thesis with a good many reasons, medical and otherwise. We shall devote our attention to the former only, for arguments like "She [the midwife] has withstood the mutations of time and fortune for over five thousand years; she will withstand them until time is no more," or "To destroy her would be to tear that [social] fabric to pieces and bring about a condition of social chaos" (? !)—such arguments, I say, can be brought forward against any innovation in scientific or political life. Their validity would mean no more, no less, than absolute stand-

still. What, then, is the medical reasoning of the author? It runs somewhat like this:

1. The midwife is not so bad as we represent her; for "nature spreads a network of protection, woven with immutable art, over the exposed surface." It is very touching, this faith in nature. But why, then, have any attendance at all, birth being certainly a natural act? May I ask Dr. Hillis, however, whether he follows the strictest aseptic and antiseptic precautions in his private practice, or leaves it to nature? And if he does (as we are sure), does he believe that the American midwife knows anything about it—the ignorant woman without the slightest idea of the causes of infection? What per cent. of midwives use thorough disinfection with corrosive sublimate? Tying the cord after a successful end of a normal labor does not require much knowledge, it is true, but the numerous emergencies that may arise and require instantaneous attention are, I hope, familiar to every physician.

2. The young physician practising independently, or as a member of some charitable institution, is often worse than the midwife. It is not easy to perceive of what importance this statement, if true, is for the midwifery question. If the young physician does not know enough, and does not know how, it is his duty to learn, and it is the duty of the medical profession to see to it that no inexperienced physician be allowed to practise on his own hook. But it seems to me that Dr. Hillis underestimates the value of the young physician just as well as he overestimates the value of the midwife. The young practitioner is certainly very careful in regard to cleanliness, perhaps more so than his elder brother who is getting used to it. The young practitioner is, with very few sad exceptions, only too easily frightened into calling his elder brother into consultation. As to the specific accusations Dr. Hillis makes against the young practitioner, they are exaggerated, to say the least. Did Dr. Hillis in the younger days of his practice make three hundred vaginal examinations, "jeopardizing if not destroying her life"? Did he stay a whole week in the house of the parturient woman, waiting for the delivery, and annoying and frightening the patient to death? I have never heard of such a thing before. I might add, for the benefit of not only Dr. Hillis but also many more "old practitioners," that their attacks on the young members of the profession are not at all in accord with the principles of ordinary generosity or professional ethics, for the young physician is not a being *sui generis*. We all go through that stage, some earlier some later, and to abuse him is to abuse one's self.

Dr. Hillis hints rather plainly at the practice of the lying-in hospital and similar institutions. Dr. Hillis may have a grudge against them, and a just one too, but I have gone through this hospital course, and so have thousands of physicians now successfully practising right in this city, and they will all protest against this unjust accusation. The statistics of the hospital, with more than five thousand cases per annum and hardly a fatal case, is the best evidence of its most successful practice. According to Dr. Hillis, every dispensary physician carries cephalotribes, symphyseotomy saws, transfusion instruments, and what not, and is given full liberty to use them; while every one who has been to the lying-in hospital knows that only the highest authorities of the hospital, including some of the best practitioners in the city, professors of our collges, etc., are allowed to perform even the slightest operation. The tremendous growth of the practice of the hospital, the desire of even well-to-do people to get their help, shows that from the standpoint of result the practice is successfully substituting the old-fashioned midwife.

3. To take away the right of practice from midwives, to force the male physician upon the woman who would rather have her old midwife in servitude, Dr. Hillis declares, is invasion of her rights, is limitation of her liberties! What shall we say in regard to this argument? If regulation of medical practice by law is limitation of personal rights and liberties, why not abolish license examinations, why not give right of practice to every one who desires it, why fight the quack, the clairvoyant, the Christian science man? Why not follow the illustrious example of England and abolish vaccination? Why not go back to the condition of so many years ago? The question Dr. Hillis raises is exceedingly important. Have we the right to interfere with one member of the community and prevent him from deceiving the others? Dr. Hillis ought to know that, if anything, we have too much "liberty" (if thus to be called) in medical matters here. In what civilized country are all the "patent-medicine" humbug, the secret-medicine cheating, the medical companies, institutes, etc., so much indulged in as they are in the United States?

But does abolishing the midwife really mean that we force the male practitioner upon the bashful woman (though everybody knows how strongly imaginary this bashfulness is, for women of all classes are rapidly getting used to the male physician and prefer him)? Dr. Hillis knows that it does not, for there is the lady physician for the bashful woman to apply to. And when Dr. Hillis comes to that, we suddenly exclaim, "Da liegt der Hund begraben!" For now we know why Dr. Hillis has become the knight of the midwife. It is because he is afraid that when the midwife goes, the lady physician will take her place, and this may do harm to the male physician. For the midwife "does not claim to be an M.D. If a prescription is to be written, he writes it; if a fee is to be obtained, he gets it." With a lady physician in the field instead of a midwife she may get all these good things; she may also keep the family, for "the physician who attended the liquor dealer's or grocer's wife in her confinement is most likely to be the person summoned when the baby has a colic, be that person man or woman." "Again the natural or assumed bashfulness of some women is to be considered, and as a matter of preference, if one cannot have her midwife she will choose the lesser evil and employ the woman doctor rather than the young practitioner so skilled in his art."

Whether Dr. Hillis is justified in his fears of the competition of the woman doctor we do not know. Dr. Hillis does not seem to be so very sure of it himself, for in another place he says that this is the sentiment of that great heterogeneous mass called the public: "As for the female doctor we don't know her, nor are we anxious to make her acquaintance. . . . We want none of her." We shall leave it to Dr. Hillis to settle the contradiction with himself.

All we want to say is this: What was the use beating so much about the bush? The second half of Dr. Hillis' article shows plainly enough what makes Dr. Hillis defend the midwife. It is not so much her own intrinsic value as her services as resistance to the entrance of the lady physician; in short, it is not the patient's interest but the male physician's interests that animated Dr. Hillis. Dr. Hillis had better let the cat out of the bag from the beginning and then we would have no cause unjustly to suspect him of antagonism to scientific midwifery and antiseptics.

Dr. Hillis may be very much against the lady physician; it is his personal privilege not to like her and even to fight her. But we hope the MEDICAL RECORD will not support him in this fight. We all believe the MEDICAL RECORD to be non-partisan; we believe it to be the organ not of the male physician but of the whole medical profession, and the MEDICAL RECORD can be

easily convinced of it by looking carefully through the subscription list. The MEDICAL RECORD has therefore no more right to defend an attack of the male physician against the lady physician than an attack of the brunet medicus against all his blond brethren. The lady physician is no more a possibility; she is a fact. The sectionalism will therefore do nobody any good.

As to the midwifery question, it can be easily settled. The great advantage the midwife had—her cheapness—has vanished. The poorer classes get medical help (whether male or female) for $10, and these are the only people who stuck to the midwife. Yet the midwife did not charge much less. She must go, and the field left open will perhaps satisfy even Dr. Hillis.

I. M. RUBINO, M.D.

307 HENRY STREET.

DURATION OF PREGNANCY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: A case has come to my notice which seems to me interesting enough to report, because of the coincidence in the length of two pregnancies in the same woman when the actual date of impregnation was known.

Mrs. X——, in the case of her first child, had her first intercourse on July 16, 1886, at about 9 P.M. Labor commenced by the rupture of the membranes, as the first warning, at 11 P.M., March 29, 1887—that is, after two hundred and fifty-six days and two hours.

Data as to the impregnating intercourse for the next three children are not known.

In the case of the fifth child, intercourse, after an interval of several months, took place December 22, 1897, again at about 9 P.M.; and labor commenced in the same way as before on September 5, 1898, at 6 A.M.—two hundred and fifty-six days and nine hours later.

Both children were healthy, fully formed bábies, with no indications of prematurity. The one weighed seven and one-half pounds, the other eight.

Has each individual woman her own special period of pregnancy, which is much more exactly determined than the average time for the whole human race, or is this that I have reported a mere coincidence? The character and intelligence of the couple concerned make the above statement absolutely reliable.

WILLIAM S. DODD, M.D.

CESAREA, TURKEY, September 26, 1898.

The Morphine Habit a Legal Defence.—A kleptomaniac in one of the British courts pleaded guilty, and her counsel assured the bench that she was in no want of money but had sufficient means to enable her to live comfortably; and asked that she be treated leniently, on the ground that the theft was due to the effects of the excessive use of morphine. According to the testimony she had consumed ninety-six grains of morphine in a single week. The magistrate suspended judgment, upon the defendant giving security in $250 to appear for sentence when required. De Quincey's daily consumption of laudanum was nine ounces, and there is a case on record where one hundred and twenty grains were taken at once, without producing death. The tolerance of opium and its salts proves in reality much more than old women's fables, and instances of enormous doses are in the possession of nearly every family practitioner. A poisonous draught of laudanum cannot be measured by cases on record.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 22, 1898:

	Cases.	Deaths.
Tuberculosis	166	130
Typhoid fever	122	24
Scarlet fever	84	6
Measles	57	4
Diphtheria	118	28
Laryngeal diphtheria (croup)	12	5
Chicken-pox	8	0

Marriage of the Unfit.—Theft and murder are considered the blackest of crimes, but neither the law nor the church has raised its voice against the marriage of the unfit, for neither has realized that worse than theft and wellnigh as bad as murder is the bringing into the world, through disregard of parental fitness, of individuals full of disease tendencies. This has been left to our own profession, and we shall be unworthy of its traditions if we do not, each of us in his own particular sphere, strive to bring nearer the day when, not in a heritage of woe but of blessing, the deeds of the fathers shall be visited upon the children unto the third and fourth generation.—DR. HARRY CAMPBELL, *London Lancet*, September 10th.

British Commission on Malaria.—The British foreign office in co-operation with the Royal Society has resolved to send out a commission of three medical experts to make an exhaustive study of African malarial fevers and black-water fever in particular. The gentlemen selected for this important task are Dr. R. S. Christopher, Dr. J. W. Stevens, and Dr. Daniels, formerly of British Guiana, and after certain preliminary investigations in Rome and India they are to proceed to Blantyre, where they will in all probability be engaged for about two years. The result of their researches into these dreaded African fevers will be awaited with the deepest interest.—*Sanitary Record.*

The Anti-Vaccination Act.—The anti-vaccination act, now a law, is in full progress. The Duke of Argyll's recent statement that an "immense plurality of blockheads indorsed it" has had no apparent effect. Parents are bringing up their children for certificates of exemption, with a pertinacity that steadily increases. Fifteen thousand of these printed forms have been requested by metropolitan magistrates. Queer mistakes are made by those who believe their children have been happily saved from the claws of the dragon. At Bow Street police court the other day a well-dressed man, who said he came from Wimbledon, approached Sir John Bridge with the now cut-and-dried formula of complaint—namely, his "conscientious belief" that vaccination would be prejudicial to the health of the child and his conscientious objection on that ground. Sir John Bridge: "How old is the child?" Applicant: "Three months and a half." Sir John: "Where do you say you came from?" "From Wimbledon." Sir John: "That is not within our district. I cannot listen to you or I might have applications from York or some other distant place." This is only one instance of many. It is apparent that they whom the gods would liberate from such awful tyrannies as those of the alleged venomous needle they first make stupid. "*Arma virumque cano*," runs the old story of how the schoolteacher addressed his pupil. "Translate that line, my lad." "Please, sir," was the reply, "its arms

and the virus I sing." Perhaps (who knows) that enterprising young student of Virgil had an antivaccinist father. Imbecilities among those seeking to avail themselves of the act abound everywhere throughout the kingdom. But sometimes we get a case in which the lawyer's opposite theories rather ludicrously crash with those of his interlocutor. One happened of late in Liverpool. Mr. Kinghorn (deputy stipendiary magistrate) gave audience to a young man who desired a certificate of exemption. "I wish to declare," said the sire of an unpunctured offspring, "that I don't believe, never did believe, and never will believe in vaccination." "Then you are hopeless," replied Mr. Kinghorn. "I don't know that anything else is needed."—*Collier's Weekly.*

The Impedimenta of the British Soldier in India.—The use of the valise—the supplanter of the knapsack of olden days—is, according to an English weekly journal, for infantry at any rate, doomed in the British Indian army. Ever since the occupation by England of that dependency, some two hundred and forty years ago, that article of "kit" and later of equipment has been as useless to the soldier in India as is the razor "served out" to the boy of a dozen years of age on joining the army. On embarking for the East each soldier is supplied with a strong canvas bag for his sea kit, into which very often he stows away his valise, and until his return to England, beyond a kit inspection, the valise is never used. Besides the valise each soldier in India, of whatever rank, is supplied with a black waterproof bag, together with a hempen cotton corded holdall, called a sullitah, into which when on the march, either by train, boat, rail, or road, he packs the whole of his belongings, the whole being carried, when on the road, on the back of the stately elephant, the patient camel, or in country carts. In barracks or in standing camps he is, in addition to all this, provided with a strong teakwood box, in which his entire kit is kept.

Scarlet Fever is extremely rare in both Asia and Africa.

India has perhaps a greater variety of plants than any other country in the world, having fifteen thousand native species, while the flora of the entire continent of Europe embraces only about ten thousand.

Artificial Teeth and the Aged.—A prominent doctor holds that artificial teeth are an evil in those of advanced years, because they enable such persons to masticate flesh. When the teeth fail naturally, it is nature's design that the individual should subsist on vegetable diet.

Vaccination and Small-Pox in Bavaria.—Considerable interest attaches to any information from Bavaria on the subject of vaccination, from its having been one of the earliest countries to adopt the practice and from the thoroughness with which in recent years it has been carried out there. The vaccination of infants was introduced into Bavaria as far back as 1807, though it was not actually insisted on until the child reached its third year. Even then a certain number escaped for one reason or another, but at six years of age a second line of defence was erected, because at that age school attendance is compulsory and every child on entering school is bound to produce its vaccination certificate. The result of this generally effective system of primary vaccination was well illustrated in the great pandemic of small-pox which attacked Europe in 1870–73. In 1870 there were 30,742 cases of small-pox in Bavaria, of which 29,429, or 95 per cent., were in vaccinated people. This at first sight appears to be a heavy indictment against vaccination, and has been used by antivaccinationists as such. But this assumption is entirely negatived when we learn that of the 5,070 deaths from the disease, only 137 were between the ages of two and five, and only 48 between six and ten—the period of highest protection; while 3,970 of them were over twenty years of age. These figures show in the clearest way that the mortality which increased steadily from eleven to sixty years of age was the result of the gradual weakening of the protection given in infancy. Further corroboration of the value of vaccination is derived from the experience of the Bavarian army, into which revaccination was introduced in 1843. From this date until 1870 only 6 deaths from small-pox occurred in it, while from 1828 to 1836 there had been 52 deaths. In 1874 Bavaria came under the operation of the general law of revaccination, which was applicable to the whole German empire, and the most recent results of that law are recorded in the consular report on Bavaria for 1897–98, presented to Parliament in July last. In this report the vaccination statistics for 1897 show that out of 164,800 children born, 150,942 were vaccinated for the first time, and 147,714 of them successfully. Of the 13,858 children who were not subjected to vaccination, only 1,050 evaded the law purposely; the remainder were excused on medical grounds, or were absent from home or not traced. Of the 124,277 persons liable to be vaccinated for the second time, 120,523 were successfully vaccinated, and only 235 evaded the law wilfully. With such effective vaccination as this, we are not surprised to be told that during 1896 only one case of small-pox occurred in the whole of Bavaria.—*British Medical Journal.*

History of Plague.—The first historical mention of plague is of an outbreak in Lybia, in the third century before Christ. Again we read of bubonic plague in the great plague of Justinian in 542 A.D. In the fourteenth century the "black death" appeared in southern Italy, 1346–47, and spread over Europe, reaching England in 1348, where it appears to have remained for five or six years. A second epidemic occurred in 1361, and a third in 1368. In the fifteenth, sixteenth, and seventeenth centuries outbreaks in Great Britain are recorded. The great plague of London in 1665, in which seventy thousand persons died, was the last English epidemic of plague. Plague occurred frequently in European countries up to 1841. In Russia it is endemic, sometimes of a mild type, but more often virulent. In India plague has probably existed since 1815, from time to time in a sporadic form and under various names in various parts of the country, with no reliable information as to mode of origin. In the autumn of 1896 a severe outbreak occurred in Bombay, which was preceded by an epidemic among rats of a fatal but hitherto unknown disease.—*Nineteenth Century.*

"What do I Get out of it?"—"What do I get out of it?" is one of the official stumbling-blocks encountered by the discoverer of a certain disinfectant, when he sought to induce the war department to use the germicide at the sick-camps. In his innocence and surprise the maker responded: "The assurance that by using it disease and fever will be greatly lessened and the ground rendered pure and wholesome." The official laughed in the speaker's face. "I know it is an excellent thing, but we won't take it just for that." Apparently humanitarian ideas do not influence men who run things on red tape, what-do-we-get-out-of-it principles. Is this one of the shameful mistakes which have cost so many of our brave boys their lives and health, or is it a well-understood "business transaction" sanctioned by the government? The "pull" in this war has been quite general, especially in the selection of camp sites.—*Sanitarian.*

DIFFERENTIAL DIAGNOSIS BETWEEN EXTRA-UTERINE PREGNANCY AND EARLY ABORTION.[1]

BY HIRAM N. VINEBERG, M.D.,

ATTENDING GYNÆCOLGIST TO ST. MARK'S HOSPITAL; TO MOUNT SINAI HOSPITAL, OUT-DOOR DEPARTMENT.

AN accumulation of experiences during the past few years has convinced me that the profession at large is still not sufficiently alert in the detection of ectopic gestation, nor even in suspecting it when it is actually present. The error that is most frequently made, judging from my own experience, is the diagnostication of early abortion for extra-uterine pregnancy. This mistake has been made not merely by careless and inexperienced men, but by physicians with extensive experience and who generally are very careful in the observation of their patients. The presence of an abnormally placed gestation never occurred to them, and it was only after one or more futile curettages that their eyes were opened to the probability that the case was not one of simple uterine abortion. It is more easy to fall into this mistake than may be imagined at a first glance. I have known careful and expert gynæcologists to commit it more than once. There are times when it is almost impossible to decide definitely whether a given case is one of early abortion with a thickened tube or one of early ectopic gestation with sympathetic enlargement of the uterus. The object of this paper, therefore, will be, by the narration of some illustrative cases occurring in my own practice, to emphasize the necessity of constantly bearing in mind the probable occurrence of an ectopic pregnancy in any given case presenting symptoms of early abortion. By following such a course we will avoid falling into error in the majority of cases, and thus be able not infrequently to save a life that otherwise would be sacrificed.

CASE I.—Mrs. Z——, thirty-two years old, married ten years, the mother of two children, the last being two years old; had always been well and the menses had been very regular, lasting from three to four days. On November 1, 1894, her menses set in at the usual time, but continued only for one day and were very scanty. About a week before this she had a severe attack of pain in the right lumbar region, which lasted for about two hours. From its position and severity it was looked upon as an attack of renal colic. On November 5th—*i.e.*, four days after the one-day menstruation—she had a slight show, lasting for only a few hours. Her physician concluded from the symptoms and examination that she was having a very early abortion, and so as to hasten the event introduced a laminaria tent into the cervix. A week later the patient had severe pain in the right groin and several fainting-spells, followed by fever ranging from 101° to 102° F., and other signs of pelvic peritonitis, which were interpreted as a complication of the abortion.

I saw her first on December 2d. On examination the posterior vaginal vault was found hard and tender. The uterus lay in anteversion and apparently was not enlarged. The diagnosis of a probable ruptured tubal pregnancy, followed by pelvic peritonitis, was made. As there were no urgent symptoms and the patient was progressing favorably, I advised waiting and continuing with the palliative treatment employed. The patient kept on apparently improving for the next three weeks, when suddenly one morning (December 23d) she passed about a teacupful of blood from the vagina, suffered severe pain in the left groin, and had several fainting-spells. When I saw her a few hours later she was moderately exsanguinated; the pulse, 120; temperature, 101° F.; and the abdomen was considerably distended. She was at once transferred to the hospital, and I operated upon her at 2 P.M. the same day. I found the abdomen full of liquid blood and blood clots of various ages, some quite fresh and others old and firmly organized. The right tube contained a fleshy mole of the size of a hen's egg. The patient made an uneventful recovery.

I based my diagnosis in the foregoing case not so much upon the physical examination as upon the clinical history. The flow was too irregular and scanty for a uterine abortion, but, above all, it was the fainting-spells that led me to suspect extra-uterine pregnancy. Of course after the second attack, with the sudden and profound anæmia, the diagnosis was no longer in doubt.

CASE II.—Mrs. T——, aged twenty-six years, married five years, the mother of one child, three years old; had always enjoyed good health. Her last normal menstruation was on July 28, 1896. On August 9th—that is, when she was three days overdue—she began to flow without any symptoms. On the 10th she had severe colicky pains, diarrhœa, and vomiting. As the weather was very hot, her physician pronounced it a case of "summer diarrhœa," and thought that in addition she was having an early abortion. On the 12th she had severe fainting-spells, which were attributed to the heat and to the continued diarrhœa. On the 14th the doctor dilated the uterus and curetted it. On finding it empty the probability of an extra-uterine pregnancy occurred to him.

I saw the patient on August 15th. She was profoundly exsanguinated. The doctor stated that he noticed the anæmia three days before when she had the fainting-spells, but it did not excite his alarm, as he thought she was merely pale as a result of the profuse diarrhœa. The abdomen was enormously distended and tense. The pulse, 140, was small and weak; temperature, 103° F.

I immediately performed a laparotomy, and on opening the abdomen blood poured out from it as water does from an open street hydrant. I rapidly passed my hand into the abdomen, caught hold of the left ruptured tube, clamped it first, and after ligation cut it away. The blood was washed away as well as possible, copious saline irrigations being employed, and the patient returned to bed almost pulseless. She rallied nicely from the loss of blood, but only to die twenty-four hours later from the septic peritonitis which was present at the time of operation.

I will not assert that the error in the foregoing case

[1] Read before the Harlem Medical Association, October 10, 1898.

was entirely avoidable, for the diarrhœa no doubt formed a misleading factor; but the doctor's suspicions should have been aroused on the occurrence of the fainting-spells and the marked anæmia. These, taken with the irregular flow when three days overdue, afforded a classical clinical picture of ruptured tubal pregnancy with considerable intraperitoneal hemorrhage. There is no reasonable doubt in my mind that had this patient been operated upon on the 12th, when presumably the intraperitoneal hemorrhage first occurred, her life would have been saved. From the time of the rupture of the tube until the operation was done, sufficient time had elapsed for the development of a septic peritonitis which irrigation with saline solution and drainage could not arrest. It is this feature of the development of a septic peritonitis which makes delay so hazardous in the occurrence of intraperitoneal hemorrhage in considerable amounts. It has always been my custom in these cases to operate at once, without waiting for the patient to come out of shock, as advised by some operators; for the twofold reason that good surgery requires us to clamp a bleeding vessel as soon as we possibly can, and that the contents of a pregnant tube are not likely to be aseptic; hence the sooner we remove such products from the free peritoneal cavity the less likely are we to have the development of septic peritonitis. I have operated upon a fairly good number of such cases, and have never lost a case from shock, but did lose two (the above one and another) from septic peritonitis which had existed prior to operation as a result of delay.

Case III.—On June 4, 1897, I was asked by a New York physician to go with him to Brooklyn to see a lady who had been a patient of his until she removed from this city about two years ago. He had been sent for that morning to consult with the physician in attendance, and, on finding a condition which he considered serious, requested that I should be called in consultation. The woman was thirty-two years old, had been married twelve years, and was the mother of two children, the youngest of which was eight years of age. In February, 1894, she had had a trachelorrhaphy done by Dr. Skene. During February and March of 1895 she was in bed most of the time with an attack of pelvic inflammation. She made a fairly good recovery from this, but continued to suffer occasionally from attacks of pelvic pain on exercise or on exposure to cold and wet. Latterly these attacks were growing less frequent and less severe.

In the beginning of April, 1897, when she was six days overdue (prior to that her menses had been regular), she was attending to her garden, and in trying to pull out a shrub she was suddenly seized with a severe pain in the back. She immediately went into the house and lay down in bed. The pain passed off in a few hours. On the following day she took a hot bath, presumably for the purpose of bringing on the menses. It seemed to have the desired effect, for she began to flow shortly after it and the flow lasted for two days. The usual duration of her menstrual flow was four days. Some days later she again began to flow rather profusely and to have labor-like pains. She thought she was having a miscarriage, and sent for her physician. He arrived at a similar diagnosis after making a vaginal examination. He treated her palliatively for a time, but as the flow was continuing he did a curettage, without narcosis, at which time he detected what he diagnosticated as a retroversion of the uterus. For the next five or six weeks he made frequent visits, at each of which he would try to bring the uterus forward and introduced tampons. The woman continued to suffer more or less, was having irregular hemorrhages, and, becoming dissatisfied with her medical attendant, sent to New York, with the result we have seen.

I found a pale, delicate woman, considerably emaciated, with a weak and rapid pulse, and a normal temperature. The uterus, somewhat enlarged, was in a forward position, and behind it was a tense, elastic mass filling the posterior quadrant of the pelvis and ascending upward to the right side. It was closely attached to the uterus, and was rather firmly fixed. On the left of the uterus was an oblong mass, the size of one's thumb; this was fairly sensitive. The patient stated that for some time past so long as she would remain in bed she would not lose any blood, but the moment she got up and walked about she would discharge it in fairly large quantities. My first examination was made while she was in bed, and there was absolutely no blood on the examining finger. In order to make a more satisfactory examination, I had her walk into the next room and get up on a table. To my astonishment I now found the vagina filled with a dark tarry fluid, which on further examination proved to come from the uterus. I made the diagnosis of ruptured tubal pregnancy forming a retro-uterine hæmatocele, which had opened into the uterus, and advised operative interference. She was taken to St. Mark's Hospital, and on the day following (June 5th) I performed a laparotomy.

The abdomen being opened, a moderate amount of dark liquid blood was found in the free peritoneal cavity. The mass behind the uterus proved to be a blood tumor with pretty thick walls, firmly attached to the posterior wall of the uterus and to the pelvic floor. The communication of the blood tumor with the uterus was found to be through an irregular opening in the posterior wall of the uterus just above the internal os. The right tube and ovary were totally disorganized and matted together into an indistinguishable mass. The left tube was the thickness of one's thumb, the abdominal end club shaped and closed completely. I amputated it, leaving the small ovary behind. The opening in the uterus could not be sutured, owing to the friability of the tissues; hence the cavity was drained with a strip of gauze emerging in the vagina. The patient made a rapid and satisfactory recovery. She soon gained in flesh and strength, and has since menstruated regularly without pain.

In the foregoing case it is not easy to account for the egregious error committed. The attending physician at his first examination found an enlarged uterus. When he attempted to curette, he no doubt pushed the instrument through the posterior wall of the uterus into the blood tumor, and, finding the instrument to pass in a backward direction, concluded that there was a retroflexion. The blood tumor posteriorly simulated the enlarged fundus which he made so many ineffectual efforts to bring forward. It is a wonder that the woman survived the treatment.

Case IV. was that of a woman, thirty years old, who had had four children, the youngest twelve months old, which she had nursed up to within two weeks prior to her visit to me on January 5, 1897. She stated that she had not menstruated since the birth of her child until eight weeks ago, since which time she had menstruated twice. A few days before coming to see me she began to have a slight show. She was then two or three days overdue. The show was attended with severe pains resembling labor pains. I found the uterus of normal size, and to the left of it an irregular mass about the size of a mandarin orange. The mass was closely attached to the uterus, was not easily mapped out, and was quite sensitive. I diagnosticated extra-uterine gestation and advised operative interference. Thereupon she entered one of our large hospitals, was kept there for a couple of days, during which time she was repeatedly examined by the attending gynæcologist, who told her she probably had had an early miscarriage, that there was no indication for an

operation, and she was discharged from the hospital. Upon returning to me with this opinion, I examined her again and adhered to my former diagnosis. She passed out of my hands, however, but was operated upon by some one else a few days later. The operation disclosed a ruptured tube surrounded by several soft blood clots.

I based my opinion partly upon the delayed menstrual flow, but chiefly upon the severe labor-like pains and upon the finding on bimanual examination. A woman does not suffer such severe pain with an abortion of a uterine pregnancy of a few weeks. A cystic ovary is rarely attended with pains of such a nature. An acutely inflamed tube gives rise to a more constant and throbbing pain, and usually is attended with febrile disturbances. But upon the latter symptom, or rather upon its absence, we do not want to lay too much stress, as a ruptured tube may give rise to a localized peritonitis and to consequent elevation of temperature.

Case V. was seen by me on February 24, 1898. She was a frail, delicate woman, who had been married six years and had one child, three and one-half years old. Her menses had always been more or less irregular, recurring in four, five, or six weeks, and were painless. During the preceding summer, while in the country, she had an attack of fever with nausea and was treated for malaria. About a month prior to my visit, after an interval of six weeks, a flow set in—presumably her menses. But the flow continued for a longer time than usual, and was attended with great pain. She therefore consulted her physician, who, after an examination, decided she was aborting and curetted her on two different occasions, both times without any anæsthetic. The flow ceased, the pain in the left iliac region continued, and the patient was suffering from obstinate nausea and vomiting. She had a slight elevation of temperature, and the pulse ranged from 110 to 130.

At the time of my visit I found the abdomen moderately distended, rather rigid, and a tumefaction in the left iliac region. On vaginal examination an irregular mass was found to the left of the uterus. The mass had no distinct outlines, and was closely attached to the uterus and pelvic wall. It had a varied consistence, being fluctuating at some points and moderately hard at other points. A diagnosis of probable extra-uterine gestation was made, complicated with general peritonitis. As the patient was in no condition to withstand a major operation, a vaginal incision was made over the mass, and about a teacupful of dark blood clots was evacuated. The cavity was gently irrigated with saline solution and packed lightly with iodoform gauze.

For the next three days the temperature ranged from 99° to 101° F., and the pulse from 116 to 130. The abdomen became flaccid; the patient passed flatus freely, and had several stools. Still I was not satisfied with her progress. The vomiting persisted with variable severity, and the patient made the impression of being a very sick woman. On the fourth day after the vaginal incision the pulse had improved very much in quality, and I felt that now the opportune moment had arrived either to do a vaginal hysterectomy or to open the abdomen and to be guided in my further course by what would be found. Another consultant was called in, and, as he was opposed to a radical operation, nothing further was done. The patient died three days later, the symptoms remaining about the same, excepting that twelve hours prior to death the pulse and temperature went up considerably. Flatus and stools were passed to almost the very last. The abdomen did not become very much distended. When the abdomen was opened after death the omentum was found in a condition of gangrene, the intestines were bathed in purulent fluid, and the peritoneum was of a dirty grayish color. There was no communication between the general peritoneal cavity and the cavity opening through the vagina. The right adnexa were not enlarged, but they were very much discolored. The patient therefore had, in addition to her pelvic hæmatocele, as a result of a ruptured tubal pregnancy a low grade of general peritonitis. The origin of the latter is uncertain, but it is more than likely that the two curettages under imperfect or no aseptic precautions stood in a causal relation to it.

In this case there may be some excuse for not recognizing the condition at the outset, but the patient's life would probably have not been sacrificed had the attending physician not tampered with the uterine cavity. If the attendant is satisfied that a curetting is indicated, then he ought to do it under anæsthesia and with the proper precautions. But more of this later on.

I will now narrate a few cases in which the opposite error in diagnosis was committed, an intra-uterine pregnancy being mistaken for an ectopic gestation.

Case VI.—A young married woman had passed her period for ten weeks, when she began to have pain in the lower part of the abdomen and slight hemorrhages. On examination I found a uterus the size of a gravid organ at ten weeks. The enlargement, however, was not uniform, there being a distinct bulging of the posterior wall, which made the impression of a tumor the size of a hen's egg. Without taking any credit to myself, I must frankly say the idea of ectopic gestation did not occur to me. I sent her to a well-known colleague, who is an excellent diagnostician, for the purpose of demonstration to a class of students. He diagnosticated ectopic gestation. In a week afterward I was sent for, and on my arrival found the ovum with its envelopes lying in the upper part of the cervix. I removed it easily with my fingers. It was simply a case of intra-uterine gestation, which had aborted at about the eleventh week from chronic metritis.

Case VII. is of special interest in this connection. The patient was brought to me by her physician, a most careful and able diagnostician, for operation for extra-uterine pregnancy, which he felt confident existed. When I heard her history prior to examination I was rather certain such was the case. She was thirty-one years of age, and had married three months before. The first two periods after marriage were regular. During the interval between the second and third period she had a slight show with some pain. The third period was delayed two days; the amount was about as usual. The flow ceased on June 14, 1897. On June 22d she had a show for about a day, unattended by pain.

I saw her June 30th. She then was having some pain in the hypogastrium. On examination I found a long cervix, and in front of this toward the left side a tense globular mass, rather sensitive to pressure, corresponding in size to a gravid uterus at ten weeks. On continuing my examination for some time and on catching the cervix with a tenaculum and pulling it down, I was enabled to determine positively that the cervix was directly continuous with the mass. I diagnosticated pregnancy in an undeveloped uterus, and predicted that the patient would probably abort. I received a letter from the doctor later, saying that the patient had aborted a week after I had seen her, and that the product of conception seemed to be that of the tenth or twelfth week.

In this case the doctor had mistaken the long cervix for the entire uterus, and he looked upon the globular tumor therefore as being extra-uterine. Some of these cases are extremely puzzling and necessitate at times an examination under narcosis. Hooking a tenaculum into the cervix and pulling upon it gently often very materially helps to clear up the diagnosis.

Irregular enlargement or sacculation of the pregnant uterus, as occurred in the foregoing case, may readily lead to an error in diagnosis. I drew the attention of the profession to this condition over three years ago, in a paper published in the *New York Medical Journal* for March 23, 1895. Since then I have met with a number of cases in which it was only after very careful examination that I could arrive at a correct opinion. As the phenomenon is usually met with in chronic metritis or in the presence of pelvic adhesions, in which condition there is a strong tendency to pain and uterine hemorrhage, the symptoms as well as the physical signs simulate an extra-uterine pregnancy.

Dr. M. McLean related a very interesting case at a meeting of the New York Obstetrical Society in the winter of 1894, which forcibly illustrated this point in differential diagnosis. The error was cleared up only after the abdomen had been opened and the uterus examined with the aid of the sight.

A retroflexed pregnant uterus with a long cervix has time and again been diagnosticated as an extra-uterine pregnancy. In this condition there is also a tendency to irregular hemorrhages and to severe paroxysmal pain, from the inability of the uterus to grow owing to the fundus being imprisoned below the promontory. On examination the enlarged and elongated cervix gives the impression as if it were the entire uterus, and the large, semi-elastic fundus as if it were a separate tumor. In a case which I reported in the paper already referred to, a sound had been frequently passed by myself and others. It entered in a forward direction, and indicated what we took to be a uterine depth of over two and one-half inches. The tumor in Douglas' cul-de-sac was then about the size of a fœtal head, and was looked upon as an ovarian tumor. The patient was then lost sight of for several months, when one night I was hurriedly summoned to her. I found her suffering from what I at once recognized as strong labor pains. The abdomen was filled with a tumor which was readily distinguished as a fœtus at about full term. On vaginal examination, however, the same small uterus was apparently felt, with a long narrow cervix which was tightly closed. As the pains had already lasted for some hours and there were no signs of dilatation or effacement of the cervix, I concluded I had to deal with an ectopic gestation at full term. The late Dr. James B. Hunter was sent for. He confirmed the diagnosis, asked me to remain with the patient over night, and transport her to the Woman's Hospital early in the morning, when he would be ready to open the abdomen. To subdue the pains, which were severe, I gave, with his advice, hypodermics of morphine; but in spite of these they continued to increase in severity. Toward morning the cervix began to open up, and before the time arrived for sending the woman to the hospital she was delivered of a good-sized female child.

Dr. Hunter told me of a similar case, that of the daughter of a well-known physician in the city. She had been seen by several of the leading gynæcologists, all of whom diagnosticated extra-uterine pregnancy at full term. The error was detected only after the abdomen had been opened. The patient died as a result of the operation.

The books say very little upon this topic. Fritsch[1] is the only author I have been able to find who lays particular stress upon this source of error in the diagnosis of ectopic gestation. He recommended in cases of doubt a thorough examination under narcosis.

Since the foregoing experience I have seen several cases in which I might have been led into error had not the case indelibly impressed itself upon my mind.

A class of cases that are frequently puzzling from the point of differential diagnosis are those in which an early uterine abortion has occurred and a tumor is found on one or other side of the uterus. They usually present the clinical and physical signs of extra-uterine pregnancy. There are uterine hemorrhages, pain which may be more or less severe, and which often is of a colicky nature. On examination the uterus is found enlarged, corresponding in size to that which is met with in tubal pregnancy; the cervix is closed, giving no indication of the preceding event. A tumor is found near the uterus, which probably is sensitive to pressure, the shape and size of a pregnant tube of an early date. Practically these cases are of no great moment, as operative interference is indicated in either contingency. But in the one case immediate operation is imperative; in the other time does not form such an important factor. In any given case presenting this complex problem, it is more safe to cast the doubt in favor of immediate operation.

Another class of cases presenting a knotty problem to solve in differential diagnosis is formed by those rare instances in which gestation occurs simultaneously within the uterus and in one of the tubes. The rupture of the tube may precede, accompany, or follow the uterine abortion. In a few instances the uterine pregnancy has been known to go to term.

During the past summer I was called to a case in a neighboring town, in which this contingency had to be considered. The patient was thirty-three years of age, had been married fourteen years, and had four children, the youngest being two years of age. The woman was in the habit of frequently resorting to the intra-uterine use of a catheter whenever she was over time. Four weeks prior to my visit on August 16th she had gone twelve days over time, when she made use of the catheter. This failing in the desired effect, the aid of a midwife was called into requisition. The latter's efforts were apparently crowned with success, for on the following day a decided flow set in, attended with severe pain. Two days later the patient was seen by the local physician, a very capable man. He found the uterus moderately large, and a temperature of 103° F. and a pulse of 110. He immediately curetted her under full anæsthesia, removing about a teacupful of decidual tissue. The uterus was lightly packed with iodoform gauze. The patient shortly afterward had a severe chill and the temperature went up to 104° F., but fell to the normal on the next day. She apparently made a good recovery, remaining in bed for a week. On getting up she began to suffer from frequent attacks of abdominal pain resembling labor pains. These increased in severity, so that for the past week she had to keep to her bed. The temperature had been normal until the week previous, since when it ranged from 100° to 101° F. The flow had not recurred since the curettage. While she was under the anæsthetic, the doctor detected behind the uterus a roundish tumor of varied consistence and about the size of a large orange. This tumor had increased in size during the four weeks she was under his observation.

I found a thin, wiry-looking woman, with a face having the expression of acute suffering. She stated that prior to this illness she had been free from any pelvic symptoms. On examination I found the uterus slightly above the normal size, and with the cervix rather large and somewhat patulous. Behind the uterus and closely attached to it lay a tumor about the size of a cocoanut, which was moderately fixed. It was of varied consistence, being partly soft and elastic and partly moderately hard. The left adnexa could not be palpated, owing to great rigidity of the abdominal wall and sensitiveness of the patient. The diagnosis lay between a retro-uterine hæmatocele complicated with pelvic peritonitis, as a consequence of a ruptured tubal pregnancy, or a dermoid cyst with some

[1] "Die Krankheiten der Frauen." Berlin, 1894. p. 486.

local peritonitis. The absence of any symptoms prior to the present trouble, and the fact that the tumor had appreciably increased in size since it was first detected four weeks previously, favored the diagnosis of extra-uterine pregnancy occurring simultaneously with the intra-uterine. On opening the abdomen a few hours later I found a dermoid cyst of the right ovary with considerable adhesion. There was a cyst of the left ovary about the size of a mandarin orange. Both cysts were removed, and the patient made an uninterrupted recovery.

An additional feature of interest in the case is the circumstance of the woman having conceived so recently when both ovaries were evidently completely disorganized. At the time of their removal there was absolutely no ovarian tissue appreciable to the naked eye.

It occasionally happens that the abdominal and uterine walls are so thin that the normally situated fœtal sac is felt as if it lay in the abdominal cavity. I met with a remarkable instance of this kind.

In the summer of 1897 a physician came to my office to tell me he had that day referred to my service at St. Mark's Hospital a patient who had an abdominal pregnancy at about the fourth month. He considered an operation imperative, as the woman was suffering severe agony. He informed me the diagnosis had been made at a special hospital in this city which the patient had entered, but that she refused to be operated upon after remaining there a week. The woman herself told me she had been shown to a number of doctors in the hospital, all of whom came to the same conclusion and urged her to submit to an operation.

What immediately struck me upon palpating the abdomen was the remarkable thinness of the anterior wall. It did not seem thicker than ordinary skin. The fœtal parts could be mapped out with surprising distinctness. On vaginal examination I found a large, flabby, and thin uterus, which was difficult to outline. After an extended examination I came to the conclusion that the pregnancy was uterine. To verify my opinion I had the woman anæsthetized, dilated the cervix so that I could introduce my index finger, when I unmistakably felt the fœtal parts within the uterus. The patient was put to bed and small doses of opium were administered. The expected abortion did not occur, and she was discharged from the hospital three days later. She went to full term and had a normal delivery, as I was afterward informed by her physician.

I can account for her not aborting only by the usual irony of fate—she was in extreme poverty and already had a large family.

This was the only instance in which I resorted to dilatation of the cervix and direct exploration of the uterine contents with the fingers. The measure is justifiable only in very obscure cases and when we can arrive at no definite conclusion by other means. Had it not been for the great respect I entertained for the opinion of the gentlemen who had made the diagnosis of abdominal pregnancy, I should not have thought it necessary to resort to it on the above occasion.

Even the small collection of cases outlined in this paper teaches us that there is no symptom or group of symptoms upon which we may place absolute reliance in the differential diagnosis between early abortion and ectopic pregnancy. The symptoms that are usually given by writers on the subject as pathognomonic of the latter state are: (1) irregular hemorrhages following a longer or shorter delay of the menstrual period; (2) the discharge from the uterus of decidual membrane; (3) colicky pains. We have seen that irregular hemorrhages, resembling those encountered in ectopic gestation, may occur in uterine pregnancy, as in Case VII. There is nothing in the appearance of the blood which is indicative of the one condition or the other, unless it be that in uterine abortion the flow is apt to be much more profuse.

It is true that an irregular flow or a mere spotting coming and going in a woman who has always been regular, but who has now gone one, two, or three days over time, should make us suspicious of ectopic pregnancy. The symptom, however, should only put us on the alert, for we ought not to attach too much importance to it singly.

The question whether a uterine hemorrhage consequent upon a ruptured tubal pregnancy or tubal abortion may occur before the onset of the next menstrual period—in other words, without amenorrhœa—must be answered in the affirmative. Quite a number of such cases have been placed on record by reliable observers. In these cases rupture of the tube takes place before the time elapses for the next menstruation. Of thirty-eight cases that I have seen during the past five years, operated upon by myself and by others, there were four in which there was no amenorrhœa. In one case the uterine hemorrhage occurred seventeen days after the last regular menstrual period. In two cases the menses recurred at the usual time, but after they had continued for a day or two in the usual manner, the flow became irregular, being profuse one day, absent or scant on the next, and again profuse on the third day, and so on. In a fourth case (Case I.) the menses set in at the usual time, but lasted only one day. Four days later the irregular flow occurred.

Great stress has been laid by many writers upon the discharge of decidual membrane or tissue from the uterus. There can be nothing more misleading than this symptom. In the first place there is no membrane discharged in a great number of cases, the decidua either being cast off in shreds or undergoing degeneration. In the second place it may be expelled unnoticed in the blood clots. Thirdly, when questioned, the patient will often reply that she has passed a membrane, when what she actually passed was a semi-organized blood clot. Lastly, and most important of all, is the fact that even the most expert microscopist cannot distinguish between the decidual tissue of a uterine pregnancy and that of a tubal gestation. This fact nullifies the advice given by some authors to curette the uterus in a suspicious case and examine the tissues removed for decidual cells. Not alone would the finding of decidual cells form no proof of the existence of tubal gestation, but it would be no proof even of uterine pregnancy,[1] for so able a microscopist as Carl Rup[2] has stated that in the absence of the pregnant state he found decidual cells in diseased conditions of the uterus.

We have heard a great deal about colicky pains as being characteristic of extra-uterine pregnancy. This is another misleading statement. The pain attending rupture of a tubal pregnancy and of the subsequent intraperitoneal hemorrhage is as variable in its character as the color of the chameleon. At one time it may be sharp and lancinating; at another it may resemble the bearing-down pains of dysmenorrhœa; at a third it may simulate ordinary colic; in a fourth (most commonly met with in my experience) the patient will tell you that the pain is exactly like that of labor; in a fifth it may be of a throbbing nature, like that occasioned by an inflamed ovary.

The one symptom in my experience that has afforded me the strongest clew has been the occurrence of fainting-spells with the attacks of pain. But this symptom is frequently absent, and may occur even in

[1] Of course the discovery of chorionic villi in the discharged products would be proof evident that the gestation was intra-uterine. But such a fortunate occurrence is exceedingly rare and is not likely to be met with in the cases under consideration.

[2] Centralblatt für Gynäkologie, 1881.

uterine abortion in a nervous or hysterical subject. I have frequently met with Russian and Polish women who stated that they had had several fainting-spells, when on examination I found they were suffering only from an ordinary miscarriage. But in women not belonging to these nationalities and who are not subject to fainting-attacks, the occurrence of this symptom in association with irregular uterine hemorrhage and pain should always lead us to suspect very strongly intraperitoneal hemorrhage.

Neither the scope nor the purpose of this paper will permit a description of the objective signs of tubal pregnancy. The classical cases with slight enlargement of the uterus and readily distinguishable mass of a globular or egg shape lying behind or to one or other sides of the uterus do not concern us. It is the difficult and obscure case in which these conditions do not obtain that must engage our attention.

The detection of these cases by examination cannot be learned from any description, no matter how full or lucid. One practical point may be mentioned now which has already been touched upon. In a given case of supposed uterine abortion calling for a curettage, the patient should be fully anæsthetized, both for the purpose of enabling one to make a thorough and satisfactory examination and for the proper performance of the curetting.

I have not been able to present you with any pathognomonic sign or symptom which would enable you to differentiate in a given case between early abortion and a ruptured tubal pregnancy of an early date. If, however, I have been able to furnish you with a few points which may serve as mere finger posts in the intricate mazes of the differential diagnosis between these two conditions, I will remain satisfied.

751 Madison Avenue.

DERMATITIS VENENATA: A RÉSUMÉ OF ITS ETIOLOGY, SYMPTOMS, DIAGNOSIS, AND TREATMENT.

By JACOB SOBEL, M.D.,

NEW YORK.

While in the strictest acceptation of the term, dermatitis venenata comprises numerous cutaneous inflammations of different degrees and extent, which are produced by the action of medicinal, chemical, animal, and vegetable substances, still, as it is used today in the unmodified sense, and as I shall endeavor to discuss the subject, it refers to the skin lesions resulting from the irritation of the rhus toxicodendron or poison ivy. Inasmuch, however, as other plants of the Rhus family (Rhus venenata, poison sumach; Rhus diversiloba, poison oak), as well as cowhage, nettle, mezereon, and arnica, may give rise to similar inflammatory conditions, it may not be altogether amiss, before entering into the subject from an etiological, symptomatic, diagnostic, and therapeutic standpoint, to describe briefly the main characteristics of these plants, and also to make mention of a few others with which they may be confounded.

The Rhus toxicodendron of American authors is a shrub vine of North America, sometimes low and erect (Rhus radicans, Linné), but more commonly a climber along trees, rocks, fences, etc. It consists of alternate dull green leaves with three leaflets, the flowers hanging in loose green panicles, the fruit smooth and pale brown. The whole plant, especially the root and leaves, contains a poisonous, caustic, milky juice, which becomes black when exposed to the air.

"The Rhus toxicodendron is distinguished as the three-leaved ivy from the innocuous Virginia creeper or five-leaved ivy. It is often confounded with the common clematis, but the trifoliate leaves of that plant are opposite and not alternate as in poison ivy."[1]

Rhus venenata, or poison sumach (poison elder, poison dogwood, poison ash), is a small, handsome tree, growing in the swamp borders of eastern North America. It is even more poisonous by contact or vicinity than the poison ivy.

"The leaves have from seven to thirteen leaflets, and, like those of other sumachs, become brilliantly red in autumn. In this condition they are unwittingly gathered for ornaments. It is distinguishable from other sumachs by its smooth leaves, entire leaflets, axis not winged between the leaflets, and the white fruit."[1]

"The poisonous sumach bears white berries; the red-berried varieties may be handled without harm."[2]

The Rhus diversiloba, or poison oak, found in Pacific North America, is similarly poisonous but not high climbing.

Etiology.—The disease stands in direct causative relation to the ivy plant, but the exact nature of the poison has thus far not been definitely determined. Whether it be, as has been generally accepted, the volatile toxicodendric acid discovered by Maisch, of Philadelphia, or whether an oil, the toxicodendrol of Pfaff,[3] be the real etiological agent, still remains an open question, which must be left to the future investigations of pharmacists and physiologists.

Pfaff, believing that the poisonous oil, found in varying amounts in the roots, leaves, fruit, branches, and stems, is the prime factor in the production of the disease, naturally maintains that direct contact with the poison ivy must occur, in order that infection may take place. He states that during the course of his laboratory experiments, none of the many hundred persons who passed in and out were affected, unless they handled the plant or the free oil. It would manifestly be unfair to say that all these persons were not susceptible to the poison; still, experience seems to teach that in many cases actual contact is unnecessary.

Dr. Louis Frank, of Milwaukee, who has devoted considerable attention to the subject of Rhus toxicodendron, has on two occasions thoroughly applied the free oil to his arms and to those of his druggist, without any inflammatory reaction. However, he says: "Possibly neither of us is susceptible to the poison, and further experiments are necessary."

At the outset, mention must be made of the very wide limit within which the susceptibility of different persons varies. That such a thing as a predisposition to ivy poisoning exists, no one who has had very wide experience with the condition will deny. While one may come with perfect impunity into the closest contact with the plant (handling it, rubbing against it), another has but to be in the neighborhood of its growth to become the subject of a most extensive infection. In the latter cases it seems as if the very winds themselves waft the poison to the victim. Not ony does this susceptibility vary qualitatively, but there are quantitative differences, if I may use the term. Some predisposed individuals will have but mild attacks, again and again, while others will present a most pitiable sight at every recurrence. This variable extent of the lesion would seem to depend upon the susceptibility of the person, the condition of the patient's health, the virulence, concentration, and amount of the poison, and the length of exposure to its influence. The inflammation may be limited to a very small area or diffused over the entire body. The individual lesions may be discrete or confluent. Some will have but an erythema with a few scattered vesicles on the extensor surfaces of the hands, especially at the interdigital folds; others will present an extensive outbreak of vesicles, pustules, and bullæ

over the extensor surfaces of the hands, arms, the face, breasts, and genitalia.

The period of incubation varies from a few hours, as a rule, to three or four days in rare instances. The disease lasts from one to six weeks, according to the severity of the attack, the condition of the patient, and the promptness with which treatment is instituted. The acute symptoms last from four to five days, the majority of cases ending in recovery in a fortnight.

There is a popular belief, held by some, that a first predisposes to subsequent attacks, because the poison is "still in the system." This is a view certainly based upon faulty premises, and recurrences under these circumstances are due either to a second exposure to the plant, or to clothing which had been worn at the time of the first infection. As Hyde[4] remarks, "It should be remembered, however, that articles of clothing may, for brief periods of time certainly, furnish sources of further trouble, being worn at the moment of contact with the plant, then laid aside, and, the occasion being forgotten, being subsequently employed. Thus a pair of undressed kid gloves have sufficed to re-awaken the disease." However, it is quite possible that the initial attack has rendered the skin peculiarly susceptible to an eczematous inflammation, which may recur with regularity at certain periods of the year and which may resemble in appearance the dermatitis of poison ivy.

Under this heading, the influence of season on the causation of the disease might be mentioned. There are periods of maximum and minimum intensity; the former corresponding to the flowering season, the latter to the autumn and winter months.

Symptoms.—After a visit to the park or cemetery, or a trip to the country, or during a stay at the summer resorts, the patient experiences an itching between the fingers or on the back of the hand. At this stage there may be no change in the skin or only an erythema with a few scattered papulo-vesicles. The itching and burning continue, and in a few hours there appear vesicles, pustules, bullæ; in severe cases, abscesses and gangrene subsequently develop. The vesicles are generally very numerous, situated on an inflamed and œdematous base, and vary in size from that of pin points to that of split peas. They may remain discrete, coalesce to form bullæ, or become pustules. This is accompanied by redness, heat, and swelling of the parts, with the subjective sensations of itching, burning, pain, pricking, and smarting.

The fate of the vesicles varies. With care they may remain intact and their contents dry up. More frequently, however, they rupture spontaneously or on account of violence (scratching, removal of dressings, etc.), and the contents desiccate into yellowish crusts.

The eruption spreads to a great extent by auto-infection, the poison being conveyed to other regions of the body by means of the hands, which are the parts usually first affected. Consequently the face is often the seat of eruption. In some cases the eyelids are œdematous even to complete closure, the lips thickened, the cheeks swollen, reddened, moist, and crusty. Aside from this secondary infection, the face is frequently the primary and only part affected. Attention to the necessities of nature causes the penis, and the breasts and genitalia in the female, to be favorite sites. The discomfort is for the most part local, and constitutional symptoms rarely develop. A moderate elevation of temperature (100°–101.5° F.), constipation, coated tongue, headache, and general malaise may form prominent features.

Diagnosis.—As a rule, instances of irritation caused by chemical or animal substances offer little difficulty, because the history is clear. Among the numerous substances which may give rise to cutaneous inflammation resembling ivy poison are croton oil, cantharides, turpentine, iodoform, mustard, chrysarobin, mercurial ointment, tartar emetic, arnica, aniline dyes, and excessive secretion of sweat.

In poisoning by Rhus toxicodendron the diagnosis is generally easy, the patient frequently coming with the statement: "Doctor, I have ivy poisoning"—or, as the dispensary patient often puts it, "ivory poison." Here, as in other forms of dermatitis, the history is an important factor. Possible exposure, followed by the occurrence of an eruption, as already described, between the fingers, on the extensor surfaces of the hand and forearms, and involvement of the face, breasts, and genitalia, form a typical picture. In the very early stages the involvement of the lateral surfaces of the digits aids in the diagnosis, as has been pointed out by Dr. J. C. White, of Boston.[5]

There are a few skin lesions with which dermatitis venenata may become confused.

Eczema is distinguished by the history, the localization of the lesions, the involvement of exposed parts and those most likely to be touched by the hands, the greater number of minute vesicles and bullæ, the greater amount of the swelling and œdema. The occurrence of the lesions on the inner surfaces of the fingers, the breasts, and genitalia is corroborative of ivy poisoning. In eczema the eruption is more polymorphous, whereas in dermatitis venenata there is more uniformity of vesicles or pustules. In the latter the lesions are sometimes "ridged" or in linear distribution, giving the impression that the patient brushed up against and along the plant.

Dermatitis ambustionis, or sunburn, presents a more diffuse redness, the degree depending upon the length of exposure. The eruption is more localized to the exposed parts, viz., the face, back of the neck, shoulders, arms, and hands. The breasts and genitalia are free. In this condition vesicles and bullæ are rare, unless the exposure is prolonged.

Scabies, which on account of its localization to the under digital folds, penis, and breasts, may be confounded with ivy poisoning in its pustular stage, is differentiated by the history, the presence of the cuniculus or burrow, and the discovery of the acarus scabiei under the microscope. The face, which is frequently involved in Rhus toxicodendron poisoning, is never affected in scabies, except perhaps in infants and children. Should doubt still exist, one may have recourse to the therapeutic effect of powdered sulphur. If it be scabies, the itching will be relieved; if we are dealing with dermatitis venenata, the condition will be aggravated or not influenced.

In erysipelas there are an initial chill, a rise of temperature (102°–104° F.), and more marked constitutional disturbance. The disease begins at one point and progresses by a well-defined, raised margin. There are greater tension and infiltration in the part, the skin is bluish-red and shiny, and only when the inflammation is pronounced do vesicles and blebs form over the patch. In erysipelas the blebs are usually larger and the fluid contents are more yellowish.

When the vesicles and bullæ have burst, the resulting yellowish crust may suggest impetigo; but the crusts are less friable and less "stuck on." The coexistence of pediculosis capitis and the absence of any great degree of inflammatory action are points to be remembered in differentiation.

Treatment.—There are perhaps few skin diseases in which a greater array of remedies has been recommended and tried than in the one under discussion. A great many of them have this point in their favor—they do no harm. Dermatitis venenata is a self-limited disease in most cases, it is true, and often subsides satisfactorily when the parts are protected from external irritation. Still, while we may not always be able to cut short or diminish the severity of the attack, we

can at least alleviate the sufferings, which at times are severe. One has but to observe the marked relief afforded by some of the remedies now to be enumerated in order to become a firm believer in therapeutic effort. It is not my intention to tabulate all or yet most of the remedies which have been vaunted, but simply to mention those which I have personally used or seen used at the Good Samaritan Dispensary, in the dermatological service of Dr. Charles Warrenne Allen.

Treatment is both prophylactic and palliative. None of the remedies is curative, in the sense of being a specific. Prophylaxis is all-important for the prevention of the attack, as well as for the spread of the disease to other parts of the body. Patients about to leave for a prolonged stay in the country, or even those taking single-day outings to the parks and neighboring summer resorts, should be instructed to avoid all "ivy-looking" shrubs, even though they be the innocent Virginia creeper. This fact is to be especially impressed upon the minds of those who have already suffered from one attack.

The cases observed by me gave a history of having contracted the disease at Cypress Hills and Washing-

Fig. 1.

ton cemeteries, Central, Bronx, and Bay Cliff parks, Riverside, Fort George, and Bayonne. Prophylaxis, then, would also require that the city authorities eradicate the vines from all places which prove sources of infection. A person with a susceptible skin should thoroughly wash his face and hands with warm water and soap or baking soda on returning from a walk in which contact with poison ivy might have occurred.

To preserve the vesicles and bullæ from rupture, to soothe the burning, itching, and smarting, to diminish pain and restlessness, are the chief aims of the remedies to be enumerated. I will first mention them in the order in which they have proven most efficient, and then enter into the special indications and conditions under which they are to be used. The list which has served me well is liquor Burrowi, picric acid, lotio nigra, salol, lotio plumbi et opii, liquor plumbi subacetatis dilutus, Allen's L. L. L. (formula given below), ichthyol, permanganate of potassium, bicarbonate of sodium, and lime water.

Liquor Burrowi (also known as liquor aluminii acetatis) is an astringent cooling lotion, which acts remarkably well in this condition, as it does in all contusions, sprains, and superficial burns, especially sunburn. The solution when properly prepared is clear, colorless, with a faint odor and a sweetish astringent taste. It is practically a solution of acetate of lead and alum, and may be prepared as follows:

Formula No. 1.

℞ Plumbi acetatis cryst. 100
Aquæ destill 300

Formula No. 2.

℞ Aluminis. 66
Sodii sulph. 12
Aquæ destill 500

Mix 1 and 2 cold, and let stand for two days at a temperature of 10° C. Filter, without washing the precipitate.

This liquor Burrowi is not kept in most drug stores, and, therefore, I have been accustomed to prescribe a "modified" Burrow. I generally write:

℞ Plumbi acetatis ..... ʒ i.
Aluminis ..... ʒ iij.

M. S. Add to one quart of water and use as a wash, after stirring well.

When this powder is placed in a quart of ordinary water, a very cold white solution is procured, which proves soothing and agreeable as soon as it is applied. The disadvantage of this modified Burrow, however, is the formation of a precipitate (the insoluble sulphate of lead), if it be allowed to stand for any length of time. To avoid this, it is advisable to tell the patients to filter the solution or stir it well before using. Some have cautioned against using liquor Burrowi over extensive surfaces, but I have never seen any ill effects from its use, either in the original or the modified form. Wherever and whenever I have had occasion to use this solution, it has always proven far superior to the time-honored lead-and-opium wash. It is not advisable to use the modified Burrow when extensive bullæ exist, for if the powder be not thoroughly dissolved the dressing is apt to cling to the part and tend to burst the blebs upon removal. The original or the filtered modified Burrow may be used in any form of the disease with perfect safety, and will, I am sure, give the greatest satisfaction. It is in those cases with marked œdema and swelling of the face that liquor Burrowi has been productive of the best results. The face is to be covered with a gauze mask and the solution continuously applied.

As far back as 1889, Calvelli[6] recommended a solution of picric acid (6 to 1,000) as a useful lotion in erysipelas, eczema, and lymphangitis. It was reserved, however, for the French school of dermatologists, and for Dr. Paul Thièry, of Paris, in particular, to bring this drug more prominently before the profession and to insist upon its great usefulness in superficial burns, erythemas, and other skin lesions. Among the latter, acute eczema and dermatitis venenata occupy conspicuous positions. As in burns, the main effect of this drug in ivy poisoning is the almost immediate disappearance of the pain and smarting. It is interesting to observe how instantly some patients are relieved by a single application. A one-per-cent. solution should be used; a stronger one is unnecessary. Esbach's reagent for the quantitative determination of albumin is the solution which I use. It is composed of picric acid, 10; citric acid, 20; water, 1,000—in other words, a one-per-cent. picric and two-per-cent. citric acid solution. Dr. E. M. Alger has lately suggested this method of application in the treatment of burns of the first degree.[7] In the use of this fluid, it may be spread over the parts by means of a large camel's-hair brush or a swab, or the regions may be enveloped in soft gauze bandages which have been dipped into the solution. Applications are to be made once in two days. Like so many other efficient remedies (methylene blue, permanganate of potassium, etc.), its greatest disadvantage lies in the fact that it stains everything with which it comes in contact. On account of its staining qualities, it is also rarely to be used on the face. As the acid is readily decomposed by heat, accidental stains may be removed from the undercloth-ing by boiling. In staining of the body, a subsequent washing in alcohol will often remove all traces. A previous smearing of the hands with vaseline or lard

frequently lessens the disadvantage of staining, if it does not entirely obviate it. Poisonous symptoms were never observed after its use, even though large surfaces were medicated. Authentic instances of poisoning have been reported,[8] and therefore extensive medication must be guarded against.

Lotio nigra or black wash is one of the oldest and most efficient remedies. Consisting as it does of calomel and lime water (ʒ i.–O i.), one can readily understand its action. Calomel is frequently given for the itching diseases—pruritus ani et scroti, lichen planus, etc.; lime water for burns and superficial erythemas. Therefore, in giving this solution we relieve the itching and cause the burning and smarting practically to disappear. The parts may be bathed with this three times daily for twenty minutes at a time, or a wet dressing may be lightly applied. This is one of the favorite remedies of Dr. J. C. White, who cautions against its use in extensive cases. In affection of the extremities this solution was used with excellent results. Should the officinal preparation (ʒ i.–O i.) prove too irritating, it may be diluted to suit the exigencies of the case.

A remedy for dermatitis venenata which I have learnt to respect during the past summer months is salol. I was taught to use it in three-per-cent. solution by Dr. Allen, and can now speak in the highest terms of its efficacy. While this drug did not afford so great and so prompt relief as the former remedies, still it seemed to act more favorably upon the course of the disease. In most cases in which it was applied it fulfilled all anticipations. A three-per-cent. solution is the best; four per cent. was found a little too strong, two per cent. not quite strong enough. As this drug is insoluble in water, it is necessary to add a sufficient quantity of alcohol in order to procure a proper solution.

Lotio plumbi et opii and liquor plumbi subacetatis dilutus often prove useful in relieving the unpleasant sensations and making the patient more comfortable.

Allen's L. L. L. ointment for burns is a very serviceable remedy in the disease before it has gone beyond the erythematous and papulo-vesicular stage, or in

Fig. 2.

the declining period of a severe attack, when the bullæ have broken and crusts have formed. It is a soft white ointment, composed of lanolin, 1; lard, 2; lime water, 3. It is indeed a soothing application, as one can convince himself by using it in this condition.

Ichthyol was used exclusively in the form of a ten-per-cent. collodion solution and only in cases which were seen at the very beginning. As in impetigo contagiosa, its greatest advantage was the formation of a

Fig. 3.

protective dressing, which sometimes prevented the dissemination of the virus to other parts of the body. This method of application has limited the disease to definite regions, and the eruption has healed kindly beneath the dressing.

Permanganate of potassium (one per cent.) was used principally on account of its deodorizing properties in pustular eruptions, and in cases in which the parts had not received proper attention and which presented an ulcerated, foul condition.

Bicarbonate of sodium (one teaspoonful to a glass of water) and lime water are inexpensive, easily obtainable, and very beneficial in affording prompt relief.

I am aware that there are a number of drugs which I have not mentioned: grindelia robusta, hyposulphite of sodium, chloride of ammonium, sweet spirits of nitre, creolin, bichloride, decoction of chestnut leaves, aristol, and hamamelis. These have all found their champions, but I have wished to confine myself to those which have proven of worth in my hands.

The constitutional symptoms are rarely of such a degree of severity as to require attention. Should indications arise, however, the restlessness and general malaise may be relieved by bromides, chloral, and sulphonal.

In conclusion, I desire to express my thanks to Dr. C. W. Allen for placing his clinical material at my disposal.

Epistaxis.—The injection of a glass syringeful of lemon juice into the nose, after it has been cleaned of clots.—*Western Medical Review*, June 15th.

OPERATIVE CURE OF INGUINAL HERNIA IN MEN.[1]

By E. D. FERGUSON, M.D.,

TROY, N. Y.

When we reflect that on a reasonable estimate there are in this country over four million cases of hernia, the majority of which are in men and inguinal in location, the importance of the subject is manifest. A risk of incarceration or strangulation belongs to each case, in addition to varying degrees of discomfort due to the infirmity itself or to the wearing of retentive apparatus. To these risks and discomforts should be added the fact that each person having a hernia must be classed as unsound, and is prevented from entering some vocations by reason of that unsoundness. It is hardly necessary to advance arguments to show the importance of measures that produce a permanent relief of the malady whenever operative interference is indicated for any cause. Since the risk attending herniotomy has been so largely reduced, the indications justifying the operation have advanced until now many subjects of hernia are ready to submit to operation to avoid simply the disability due to the trouble, provided we can offer them a reasonable expectation of cure.

Those of us who are free from hernia can hardly estimate the sense of disability that comes to many who are thus afflicted. The depth of this sense of affliction is strikingly illustrated by the readiness of many to submit to the extremely painful and dangerous expedients resorted to by itinerant "rupture surgeons" one and two centuries ago. Castration, the actual and potential cautery, and many kindred devices were used for ages before the invention of efficient mechanical retentive devices. This shows in an unmistakable manner the great desire of these patients to be rid of hernia. With the invention of efficient trusses the occasion for operation in most cases was so reduced, and the mortality and uncertainty of favorable results in cases requiring operation were such, that operative interference came to be regarded by the profession as justifiable only when conditions existed directly threatening life. This aversion to operation still exists, for it is difficult to throw off the traditions connected with our professional training. This is particularly manifested in the prolonged and often forcible manipulations resorted to under the abused title of taxis. Recently I was requested to operate in a case in which "taxis" had been used from Saturday until Tuesday evening, and the results were decidedly touching. It is hardly necessary for me to describe the condition of the structures in the groin following such abuse. While I am not prepared at present to advise that all cases of hernia that cannot be reduced should submit to operation, I am sure in my own case I would feel that fifteen minutes of even gentle manipulation would be sufficient to justify herniotomy as the lesser evil.

It is not probable that we can at present properly urge the possessor of a hernia which is comfortably retained by a truss to submit to an operation, even in view of the very slight risk that is incurred; but when we consider the tendency of most hernias contracted in early adult life to become "direct" in their course and with enlarging rings to become less and less under the control of retentive apparatus, we can appreciate the probable widening of the field for operative interference. In those cases which have reached the stage where trusses are useless, or uncertain in action, it seems there should be no hesitation to advise operation if there be no concomitant circumstance to contraindicate it. In view of the experience of the past few years it is hardly in the nature of a prophecy to affirm that the proportion of patients who will properly submit to operation will materially increase. If such be the case it is manifest that we should carefully consider the elements entering into the operation, with a view of giving those who confide their interests to us the best opportunity for successful results.

The steps which have led to the present status of herniotomy do not mark a straight line, but show a devious route, and in fact often lead into closed lanes whence it has been necessary to countermarch, though often not until considerable confusion had arisen as to the true route to the highway.

This uncertainty as to course was often due to want of appreciation of the value of the different structures entering into the abdominal walls in preventing hernia where it has never existed and in curing it where it did exist. The amount of discussion on that point and the scholastic learning often shown are amazing, in view of the comparatively simple view that now seems justifiable. Not a tissue entering into the layers of the hernial tumor, which are laboriously studied and proudly repeated in our student days, but was considered at different periods as a more or less important factor in the prevention or cure of the disease.

Even at the present time some of our highest authorities place an importance on certain structures which seems hardly justifiable. I refer in particular to the muscular element of the abdominal walls. That muscle is an important factor in giving strength to the belly walls is manifest, but the readiness with which the fibres can be longitudinally separated illustrates how slight the protection would be against hernial protrusions if muscles alone were the boundaries. Whoever will consider carefully the different tissues concerned in retaining the abdominal contents can hardly fail to conclude that the main factor in protecting against hernia is that firm, strong, and dense aggregation of connective-tissue cells known as fascia or aponeurosis. The rarity of hernia at any point except where this layer is weakened or absent is evidence of its value as a preventive agent, aside from its known physical qualities. In my judgment a full appreciation and consideration of the value of strong fascia in protecting against hernia is the beginning of genuine success in the cure of these cases. And right here let me urge the importance of the fact that no scar tissue possesses the protective influence of normal fascia. Scars may be so deep and strong, and so blended with normal tissue, as to afford for a time a good and even efficient protection, but the usual tendency of scar tissue is to change gradually to the character of ordinary connective tissue, a condition manifestly not adapted to prevent hernial protrusions.

The history of the measures adopted for the cure of hernia is filled with evidences of the truth of this criticism of the scar. Let us go back only to the Heaton method of treatment, whereby it was sought to introduce into the tissues about the ring, and occasionally probably within the neck of the sac, some extract of oak bark, which would induce the deposit of "plastic lymph," and by the bulk of this exudate, its adhesive or contractile properties, so lessen or close the ring as to cure the hernia. That a temporarily favorable result was secured in many of the cases so treated is well known, but it is also a matter of history that with time the exudate thus produced was quite generally absorbed and the parts usually relapsed into the original condition.

All operations which leave the peritoneal pouch in the inguinal canal fail to secure the coaptation and intimate blending of tissues calculated to bear the strain of forcible pressure on the abdominal contents, though the method of Wood, who sought to approximate the pillars of the ring by a buried suture, applied

[1] Read at the annual meeting of the New York State Medical Association, October 18, 19, and 20, 1898.

often without any incision, was the best of all the "blind" methods of operating, and in fact gave in the hands of the originator a large percentage of cures.

The fact that this method was developed in pre-antiseptic days gave it a value it does not now possess. Many of the operations, even down to very recent years, have included the preservation of the sac, which was treated in various ways, *i.e.*, simply shoving it back into the abdominal cavity, infolding it, and making a "buffer" of it, as in McEwen's method, or quilting it backward and forward as proposed by Kocher and J. D. Bryant. While opening the sac was regarded as notably increasing the operative risk, such a course was justifiable; but now that proper care removes that risk the sac is to be looked upon as pathological, and as such is to be removed, except in instances in which it is so small that it can readily be replaced within the abdominal cavity, but even in such cases adhesions to viscera may thus be overlooked, so that it seems wise to open the sac in practically all cases submitted to operation.

The "open" method of McBurney was based on the idea of a deep and permanent scar which would effectually close the canal, but time has shown that even scar tissue constructed aseptically (which could not occur as a rule, for open wounds in the inguinal region will usually become infected) would finally be absorbed and the hernia would recur.

It seems now virtually settled that if we are to expect wounds to heal with a restoration of practically normal conditions, we must comply with four considerations: 1st. Parts of identical structure must be coaptated by an amount of surface to equal or exceed the normal thickness of the tissues. 2d. They must be maintained in apposition a sufficient time to allow the preliminary stages of repair to pass over into a thorough blending of the parts. 3d. The material used to secure coaptation must be so applied as to retain the parts without disturbing the nutrition, and not interfere with repair. 4th. Septic processes must be prevented, for they imperil and usually prevent a normal union, and in the case of hernia, if related to the deep structures, are usually followed by a recurrence of the descent of the bowel or omentum.

Many things enter into the application of these four principles, but we will briefly consider some of the more important. As to the first item, "that tissue must be united to identical tissue," it seems hardly necessary to adduce arguments; nor, again, is it needful to insist that the aponeurotic tissues of the belly are the strongest of the abdominal layers. There is one point, however, which is practical and should not be lost to sight, *i.e.*, that if we are to approximate identical tissues in a deep wound, we must make our incisions in extent and location so as to have thorough access by sight and touch. A too short incision is a common fault. A needlessly large cut is to be condemned, but let us not try to do our work in so small an incision that we must work in the dark.

In estimating the surgical value of the several parts that form the abdominal parietes in the inguinal region it is quite possible that needless division and subdivision have been made. The essential elements to consider are related to the fact that the fibrous or aponeurotic layers are so situated and divided that in the normal condition the structures constituting the cord enter the transversalis fascia above Poupart's ligament, receive an investment from that fascia, pass downward and inward along the upper border of Poupart's ligament with the fascia transversalis within and the aponeurosis of the external oblique without, and finally escape from this "tendinous" canal through a division of the fibres of the tendon of the external oblique at what is known as the external ring. It is proper to know of the conjoined tendon the intercolumnar fibres, etc., but the general facts concerning the course of this canal are the important elements, for it is evident that in a normal condition intra-abdominal pressure tends to close the canal rather than to dilate it, and it is only when a "thin wedge" is entered at the inner extremity of the canal that the conditions favoring hernia may be said to exist. Should the inner extremity of the inguinal canal approximate to a position opposite to the external ring, a condition favoring the occurrence of hernia manifestly exists, and it seems probable that this state of affairs occasionally occurs.

The steps to reconstruct this canal when it has been changed by hernial protrusion will vary according to circumstances, but in general terms may be said to include the placing of the tissues of the cord at the extreme upper and outer portion of the internal ring, *i.e.*, the outlet through the transversalis fascia. The external layers of tendinous structures having been opened so far as needed, and then after clearing from the opening all extraneous material by scraping so as to expose the fibres of the tendons, unite from below upward and outward the posterior and superior portion of Poupart's ligament with the conjoined tendon and transversalis fascia to a point just short of injurious constriction of the cord, a point manifestly only to be settled by the judgment of the operator, but usually defined by closing so as to include firmly the cord and a portion of the finger of the operator, which on removal will insure against undue constriction.

The tissues entering into the tendon of the external oblique should then be closed over the cord so as to reconstruct the canal, though in some old hernias the relations of these layers may not be clear, in which case we have to depend largely on the thoroughnesss with which we approximate the fascial borders of the tendons about the normal opening; and the leaving the cord at the upper and outer portion where the pressure will be at a minimum, though it is hardly wise to extend the incision in the fascia transversalis so as to displace the internal ring further outward and upward (as has been suggested by Potemski and others), or to place the cord in an opening in the bone, as has been recently proposed. In cases in which the testicle may properly be removed the closing becomes a very simple affair, and the cure should be definitive, for no place is left to begin the "wedging" process. In some cases I have found it justifiable to excise the testicle, and I must confess that I felt a certain satisfaction in doing it, in that the remaining steps of the operation were rendered so simple and efficient. Of course in all this it has been assumed that the sac has been closed at the general peritoneal level and excised.

The second element of success noted was that the tissues "must be maintained in apposition a sufficient time to allow the preliminary stages of repair to pass over into a thorough blending of the parts." It is scarcely possible to give definite metes and bounds to this period, though it is probable that it extends over several weeks, possibly two or three months. As the subject presents itself to me, the risk of recurrence varies at different periods according to the procedure adopted. If the fibrous tissues are well coaptated by good suture material, the risks of recurrence immediately or soon after the operation are practically *nil*. If the suture material is of a character soon to weaken or disappear, say in a week or two, then there comes a period of great risk, to be bridged only by rest and the good fortune that for some weeks no strain from cough, constipation, etc., has resulted in the trickle that will eventually make a flood.

If on the other hand the approximation has been maintained until a thorough blending has occurred, time will probably only serve to render the parts more and more like unto those which have never known the surgeon's knife.

Should the closure be by inflammatory exudate, the protection will be the greatest at a short period after the operation, but will soon begin to diminish, possibly to disappear.

On the other hand if permanent suture material be used, and tension is put on this with the idea of holding the parts together by non-living material, then one of two conditions is liable to arise: first, if the parts are held by the tension of the stitches, the stitches will cut into the tissues until they no longer hold the parts securely; or, second, by virtue of being a foreign body they furnish a convenient locality for the home of some wandering bacillus from the blood current, and an inflammatory process arises that changes the new union into ordinary scar tissues, with a tendency to absorption and weakening.

This selection of suture material is manifestly an element of first importance, in fact more important than many of the elements that go to make up so much of the recent "improvements" in curative herniotomy. We may vary somewhat the steps of the operation without very materially affecting the results, but without good suture material we must fail in attaining the highest practicable degree of success.

Experience has convinced most operators that suture material to be used in uniting tendinous structures should possess strength sufficient to bear all possible strain, a durability of at least two or three weeks in a state of fair tensile strength, with absorbability within a reasonable time, and the ability to render it aseptic. Few operators now leave metallic sutures buried in herniotomy wounds, so that practically we are reduced in our choice to silk, catgut, and animal tendon.

If silk were more readily absorbed it would be an ideal suture material, but the spontaneous reopening of wounds, months after closure, for the discharge of ligatures and sutures of silk is too common an occurrence to be ignored in making our selection. The difficulty of sterilizing catgut and the uncertainty of its durability under any method of preparation are grounds for hesitation in accepting it, in particular for closure of the aponeurotic tissues, though we may concede that recent improvements in its preparation have added to its safety and efficiency.

At present, however, the tendon from the tail of the kangaroo appears to afford the best suture material, particularly in herniotomy. It does not seem improbable that in the domain of synthetic chemistry lies the possibility of the manufacture of a material that will yet serve us when sheep and kangaroos may fail, and in the sterility, strength, and absorbability of which we may have perfect confidence.

In my own work I now use kangaroo tendon, but should I be unable to secure that I would resort to catgut carefully sterilized and "tanned" by chromic acid or formaldehyde, and only in emergency would I use silk, though it is readily and extemporaneously sterilizable, and hence occasionally to be used.

Our third condition, to wit, "the material used to secure coaptation must be so applied as to retain the parts without disturbing the nutrition and not interfere with repair," gives us possibly a certain choice of methods, and yet there is undoubtedly a good, a better, and a best way, though I will not assume that the best way is yet discovered. The interrupted suture, if applied so as to bring the entire line in apposition, must either be introduced at such short intervals as to be technically objectionable, or drawn so snug as to strangulate when placed farther apart. The running or overhand stitch does not coaptate well where strain is to come, though the rapidity of its application is a commendable feature.

The cobbler's stitch when placed well back, say, a full quarter of an inch from the edge of the incision, and drawn with just sufficient force to coaptate the tissues, will secure a broad surface of union, for the suture should not cross over the edge at either end, but begin sufficiently back in the uncut tissues to give an unconstricted strip along the edge of the incision. If this "band" should gape at the edge, a light running stitch will suffice to hold the edges in apposition, but the "cobbler" will bear the strain. Not to cross over the line at either end seems to me important, and to make this certain introduce the needle (with an eye near the point) without threading, thread, withdraw, reintroduce, unthread, and thread with the other end, and so on to the end.

Stitches of a third to a half inch in length or even longer will secure excellent adjustment of the parts; but above all draw so as only to apply well the surfaces to each other before tying the final and only knot. I always add an extra loop to the knot to insure against untying. The remaining portions of the wound above the aponeurosis may be brought together in any way, but a to-and-fro use of the suture material with a final subcutaneous strand seems to me the preferable method. If done carefully the parts will be left in a state favorable to thorough union.

Our fourth condition, that "septic processes must be prevented," seems hardly worthy of insistence at this stage of surgical development. I do not bring it forward to insist upon the details of sterilization in instruments, operators, assistants, and material, for that is all accepted. It is only in view of the fact that the skin of this region is especially liable to septic contamination, both before and after operation, that I call attention to the necessity for the thorough use of all reasonable measures to cleanse the surface and follicles of the skin before operation, and to urge the usefulness of sealing the wound, after it is closed, with some impervious and secure material.

The use of a thin layer of sterile cotton, saturated with iodoformized elastic collodion, over the entire extent of the incision, is my usual course. It is possible that other means or measures may serve, but this is easy of application and fairly efficient. In view of my experience, whereby I have known many wounds in the inguinal region to have been aseptic so far as operation was concerned, only to become contaminated by the patient in the care of his person, I feel a certain sense of comfort and security when the seal is placed and thoroughly dry. This seal can be readily placed over an interrupted suture if that form of closing of the skin is preferred, though it seems more satisfactory to apply it to wounds closed subcutaneously.

With a good seal on a wound in aseptic tissues, closed aseptically, we may confidently expect normal union. The principal quantity in our work now relates to those germs which hide in the follicles of the skin, and are liable to work to the surface some time after our work is done. These enemies are still existent, though fortunately our cleansing is becoming more destructive to them; but if a colony of them come to the surface just at the margin of the wound within, two or three days after the operation, they will generate mischief. If, however, the wound has been closed in layers and at the first evidence of trouble the seal is removed, the deeper structures will probably not be involved, and hence the final success of the operation will be only slightly imperilled.

In view of recent work in herniotomy, we may now assert that in uncomplicated cases the danger to life from the operation is very slight, less than one per cent., and we may almost say the patient recovers with less liability to hernia at that point than exists with one who has had no hernia.

Before closing the subject I wish to add a few words on the history of the operation. Though medicine knows no nationality, still there is among us a sense

of justice and "fair play" that creates in us a desire to see credit given where credit is due, and in addition there is just enough of right and use in a proper sense of patriotism to justify our claiming for our country that which is her due. It is not necessary for us to be constantly requiring the statement that "I am of Paul" or "I of Apollos," but during several years my attention has been so repeatedly attracted by reference to herniotomy under the name of some person credited with having devised the operation, when the facts failed to justify the appellation, that it seems a duty to enter a formal protest. Leaving out of the question at present the slight modifications that are connected with certain names, I wish to call attention to the fact that it is usual now to hear in our discussions and to read in our text-books and journals of "Bassini's operation for the cure of hernia." Now what are the facts? Bassini's operation embraces three points: 1st. The use of animal suture (though he applies it as a continuous suture) after excision of the sac. 2d. The closure of the internal ring from below upward. 3d. The closure of the remaining fibrous structures over the cord, so as to reconstruct the inguinal canal.

The relative importance of these items is in direct order of their statement, and priority may properly be claimed in use and publication for American surgery.

Bassini first made his method public in 1888, and a statement that he had been operating by that method since 1886 is hardly admissible in a claim for priority in view of the following facts:

In October, 1871, Dr. H. O. Marcy, of Boston, read a paper on "A New Use of Carbolized Catgut Ligatures," which was printed in the *Boston Medical and Surgical Journal* for November 16, 1871. Lister had recently given to the world his experiments on the ligation of arteries with catgut, the ligature being buried and allowed to remain for absorption. This paper by Dr. Marcy included the advocacy and description of the use of catgut to approximate the walls of the ring, so as to secure by buried sutures the healing and lessening of the hernial opening.

This was supplemented by a paper before the American Medical Association at its meeting in 1878, and printed in its transactions, in which he advocated the use of animal sutures to close or diminish the hernial openings, giving his reasons for such use from a practical and experimental standpoint.

So far as the evidence is available, these publications are by several years the first that bear directly on the subject, having as an object the teaching of the use of buried animal sutures in closing or reducing the hernial opening.

I think it was in the same year that Tilanus and Lucas Championnière read papers at the Amsterdam meeting of the International Medical Congress, in which they advocated the use of animal sutures, and Championnière gradually developed his method of mattress suturing of the tissues about the ring and canal, a method still used by him in several hundred cases with excellent results.

About the same time Czerney gave to the world his views in favor of excision of the sac and the approximation of the pillars of the external ring with animal suture.

Again in 1881 at the meeting of the International Medical Congress in London, Dr. Marcy presented the subject[1] and advocated the excision of the sac and to "refresh the pillars of the ring or walls of the opening and to close by sutures" of carbolized catgut, though he also used tendon suture from the moose and caribou.

At the meeting of the American Medical Association in 1887, and again in 1889, he discussed the subject, and in the two papers brought out all the points now regarded as important, to wit, the excision of the sac, the use of buried animal sutures, the closure in layers, the restoration of the obliquity of the canal, and the sealing of the wound.

It is possible that some references which would be germane have escaped me, I have omitted some as unnecessary, and I have entirely neglected to refer to the many expedients which are not directly related to the three points considered as essential, or have been dropped as inexpedient or useless.

As the record stands it is not just to American surgery to designate modern herniotomy by the name of a foreign operator. The wisdom of applying the name of any man to a procedure is open to some objection, but convenience often justifies it; and should it be applicable in this instance, we should not speak of the Bassini operation for inguinal hernia, but of the Marcy operation, for Bassini in no single item of importance has preceded other operators, while Marcy was manifestly first in advocating and using buried animal sutures, in the use of cobbler's stitch, in the subcutaneous suture, and in sealing the wound by an impermeable and adherent dressing.

Many operators are now using these expedients in total and unjustifiable ignorance of their origin and under a false appellation.

REMARKS ON ANTITOXIN, DIPHTHERIA, THE PRACTITIONER, AND HISTORY.

By ADOLPH RUPP, M.D.,

FORMERLY AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY, ETC., NEW YORK.

When diphtheria antitoxin was supposed to be obtainable in that degree of perfection which seemed to justify laboratory workers or scientists, in their own estimation, in proclaiming it a scientific product of surprisingly great curative value, it was forced rather than argued into the hands of practitioners. The force exerted was not that of legislative action, but that of public opinion. This opinion was created and developed by the influential voices and pens of many prominent scientists and clinicians, and not the least by the lay or political press. The amount and extent of hopeful expectancy thus aroused generally among practitioners and the laity made it extremely impolitic for most practitioners to entertain, and much more so to practise, views and convictions of their own not in accord with the teachings of Behring and Roux and others. The jubilations of some practitioners amounted to—in some instances do so still—claims of infallibility for the remedy and their own individual wisdom. Those who did not and do not think and do as they think and do, they accused and accuse of dulness, even of crime. These enthusiasts always meant and mean well. Infallible people always mean well.

Concerning the use of antitoxin as a remedy in individual cases of diphtheria, the practitioner has rights as well as duties to urge him on. It is not a question of right only or of duty alone, but of both duty and right. He deals not only with cases of disease; he deals with his patient and the patient's friends. And his first-all-around duty is to do all the good he can, and, if possible, no harm of any kind. In doing so it is not necessary for him to be either a tyrant who must have unquestioning submission, or a martyr who fails to have his will recognized and applauded. It is also a duty of his to give observations and facts, opinions and fancies, considerate attention and study, even though such do not fall in graciously with his own observations and with facts

as he sees them, etc. But it is his right to trust his own senses and his own reasoning powers. In attending to his duties, and in generously maintaining his rights, he should be actuated by a modesty and objectivity that will leave him too proud to be vain and wise above his stature.

After observation and experimentation have done all they can to give us facts we are obliged to build up ideas with our facts. Our facts are useless unless something is made of them. But facts are odd things and hard to understand sometimes. To some people a fact is valid because some influential person claims it to be fact. Others would call "a fact" anything that can gain the assent of a majority of competent judges. Thus, to gain a fact a minority of competent judges is pushed aside, and satisfaction is got. Facts of this kind have been abundantly accumulated on the doings of antitoxin in diphtheria. History teaches over and over again that neither a great name, nor a majority of great names, necessarily determines the reality and validity of fact definitely, or once for all. Great names demand attention, and a unanimity of many great names demands from us a greater amount of attention and consideration. But great names should not command submission and self-abnegation. Neither do minorities monopolize all wisdom. Minorities often go wrong no matter how select their make-up may be. The wrong interpretation of facts, so-called, on the one hand is due to incomplete or partial perceptions, and, on the other, is made when much preconception or theory has been projected into the fact which is really not justified in being there. Diphtheria is a fact, and so is antitoxin. But both these single words comprehend not a single fact, but in many respects a rather intricate mass of fact and theory which is struggling into a final disentanglement and definition. The simple eloquence of some writers and debaters who glibly use these words—diphtheria and antitoxin—is as charming as it is illusory. They use substantialized abstractions that have no real properties. They refuse to argue. They are sure of their fact, and they feel that they need not analyze it. Men of genius and extraordinary talent have erred in this respect. The unknown elements that are a part of all facts—like the ashes of chemical analyses—are lightly thought of. It took nearly a half-century of hard laboratory work and fervid discussion finally to demonstrate that Liebig was not altogether wrong and Pasteur not altogether right concerning the facts of bacteria and fermentation.

Although many able practitioners and scientists claim that antitoxin for diphtheria has ceased to be a question, and that all argument concerning the fact of its utility is futile labor, other equally able observers and equally well-equipped practitioners claim that it is a fact that the remedy is useless and at times harmful.

Whatever the inclinations and tastes of practitioners may be concerning the contentions of opposing authorities, they have three sources open to themselves from which to gather facts and opinions for justifying their own ways of thinking and practice: 1, history; 2, laboratory reports; 3, clinical experience.

I do not purpose to deal in this paper with either the laboratory aspect or particularly with the clinical character, quantities, and facts of diphtheria-antitoxin questions. All that is intended now is to direct attention to what may be called the historical or traditional conception of diphtheria, and in a way to compare it with present-day notions. We may thus get rid of some misconceptions and attain to some certainty of meaning, of definition, and, to a certain degree at least, be enabled thereby to judge—for we all must finally judge in these matters—to what extent, if at all, we may or may not be justified in accepting what some authorities claim for antitoxin in the treatment of diphtheria. All definitions are something more than a mere statement or epitome of leading facts. They also imply theories concerning the facts. The bare facts are unchanging. The theories, the explanations, are tentative only. Looking at the history of diphtheria reveals to us that the interpretation of the phenomena of this disease resolves itself into a dissolving conception, which for a time again solidifies into a fixed and standard conception. The facts, the phenomena of diphtheria we are always willing enough to believe to be true; and the will to believe is often stronger than the energizing theory.

What is diphtheria supposed just now to be? It is defined as being an acute infectious disease. It was always considered to be that. But our modern teachers—many if not all—supplement their definition and statement of leading facts with a theory. They say that diphtheria is caused and developed by the growth of a specific bacillary organism. This specific bacillary organism is a revolutionist. It has changed and modified the concept of this disease. The bacillus claims almost undivided attention. We knew in days before the bacillus was pilloried that diphtheria was chiefly and generally limited to the upper respiratory tract. We also knew that abraded surfaces of the skin sometimes became affected with membranous deposits. In the present day we are taught that the disease first appears as a local disorder. This local disease is characterized by inflammation and a false membranous deposit. This was not the generally accepted doctrine in prebacillary days. The disease was supposed to be primarily constitutional. Whether it be considered primarily constitutional or primarily local, much theory goes mixed with the facts. There is such a condition as a predisposition—the constitutional or organic condition that makes the specific cause a possible rioter—a successful cause and developer of disease. To-day our teachers say that the system is secondarily affected—a general disease is produced which is a consequence of the local one. Older and antibacillary theories made the facts consort the other way. First came blood changes, and then local manifestations developed. And yet even before bacilli became important facts in our reasonings, some observers had leaned toward an impression that diphtheria is first a local disease and then a constitutional trouble. In days gone by the eye made the diagnosis. An inflamed throat with peculiar patches on the pharynx, palate, or tonsils, or on all three together, in connection with constitutional symptoms more or less marked, justified a diagnosis of diphtheria. Bretonneau had stated that when there was no pseudo-membrane there was no diphtheria. From this type—from mild cases to severe ones—the variations have been, since the days of Bretonneau, very considerable. The chief factors giving rise to the variations from a mild type are enveloped in such notions as that epidemic influences hover in the air or are secreted in the earth. Individual predisposition is another factor. In times gone by much stress has been laid on these factors in giving definition and clearness to the diagnosis of diphtheria. Older physicians also noticed that diphtheria was sometimes complicated by gangrenous and septic processes. They had observed too that the constitutional symptoms were sometimes grave, out of all proportion to the local signs; and the obverse was sometimes the case. But in whatever manner the local and constitutional conditions consorted, as to character and degree, epidemically or individually expressed, the diagnosis was determined by the pseudo-membranous deposit. No deposit, no diphtheria. All the records of this disease, from Bretonneau to Behring and Roux, are based on this conception of diphtheria—a disease which varies from a

benignity so mild as to escape attention to a malignancy which is as disgusting as it is disheartening. The conception was not formed in the course of a single epidemic, or in the course of a single endemic cycle; it is the result of centuries of observation and correction, and is the final entity of thought and being resulting from dissolving contradictions of all kinds which make up the natural phenomena of a disease and the phenomenon of the concept of that disease as it establishes itself in the minds of successive generations of men.

The modern definition of diphtheria differs very much from the historical definition as it existed up to five or ten years ago. Laboratory scientists, who more or less rigidly fix conditions to fit what they hope to prove, get a disease which they call diphtheria. Accepting all their preconceptions, and the conditions they surround them with, the result of their labors and cogitations must necessarily be accepted as being logical. But logic is only method; logic is not nature. Nature, too, is logical, but on a broader basis than can be found in our laboratories at the present time. Our scientists, and those who aspire to compel us to concur in their notions of exceptional exactitude, tell us that we have diphtheria when we have a sore throat in which the Klebs-Loeffler bacillus is found. The bacillus and the sore throat settle the diagnosis. The presence of a pseudo-membrane is of secondary importance only in so far as diagnosis making is concerned. The membrane may or may not be diphtheritic. This conception of diphtheria is clinically inadequate. It does very well for the laboratory. In the laboratory excellent results are obtained by treatment with antitoxin. We clinicians cannot but admit that these laboratory observations, experiments, and successes have added a factor to our conception of what diphtheria is. The factor is the Klebs-Loeffler bacillus. This minute factor also carries a good deal of theory with it, which is too often accepted as fact. Henle used to say that a theory is to be valued not so much by what it can prove, as by how much or how little it assumes. The scientist theory proves everything and demonstrates only a modicum, and leaves a good deal unaccounted for which it lets shift for itself. The scientist overlooks the importance of the historical conception of diphtheria—and he overlooks the importance of other bacilli at work in the local uproar. Neither oversight acts kindly toward the theories of specific antitoxin therapeutics, either in the specific and limited methods of logic characteristic of laboratory workers, or in a practical demonstrative way.

From a study of definitions or conceptions—the historical or traditional, and the scientific or laboratory conceptions—we may conclude, and properly so, that they are, taking everything into consideration, unlike, although similar in a few respects; and it must follow as surely as the day the night that what will cure in the one case cannot cure in the other, except perhaps in such a limited way as the few points of similarity may justify or give hope for. Furthermore, when the results of treatment of historical diphtheria are taken as a standard for showing off the superior virtues of antitoxin in the treatment of modern or laboratory diphtheria fallacies are committed. How great the contrast becomes when we change our methods of diagnosis because we change our conceptions of a historical disease is glaringly illustrated by Dr. McCallom, of the health department of Boston. His figures are no doubt honest and scientific. He tells us that from 1891 to 1894—a period of four years—ten hundred and sixty-two cases of diphtheria were reported. These cases were diagnosticated by the eye and by other traditional methods. But from the 1st of September, 1895, to the 1st of October, 1896, nineteen hundred and seventy-two cases of diphtheria were reported. He explains this great increase thus: "The number of cases of diphtheria reported was largely increased on account of the larger number discovered among the pupils of the public schools, by the medical inspectors of the schools, and the bacteriological tests in the otherwise unrecognized cases." Thus laboratory methods discover the disease which eluded the eye. This may be bacillary diphtheria, but it is not diphtheria in the historical sense. It is not the diphtheria in the old clinical sense. In contrasting these nineteen hundred and seventy-two cases of bacillary diphtheria, collected within a period of thirteen months, with the ten hundred and sixty-two of clinical diphtheria observed in four years unlike things are contrasted. The difference is almost as great as between eight and one. He gives the rate of mortality of diphtheria diagnosed by old methods as being forty-five per cent. The rate of mortality of bacillary diphtheria—that is, the diphtheria diagnosed in the laboratory on scientific principles—is thirteen per cent. What do these percentages prove? Dr. McCallom naively claims in his report that they prove the beneficent curative qualities of antitoxin. They do nothing of the kind. Not only are unlike things contrasted, but, if his contrast is allowed to pass as a comparison, he conveniently fails to credit the four years' collection of diphtheria with the proportion of cases that were not recognized because school inspectors and bacteriological tests were not on the track of the bacillus. According to Dr. McCallom's figures, clinical diphtheria falls in point of frequency about eight points from a standard of one which is the Boston, or scientific diphtheria. All other things concerned in the comparison fall in a like manner proportionately. Thus, if all things are taken on a basis of equality, historical or clinical diphtheria is, according to Dr. McCallom's honest figures, seven times less frequent than that of the health department of Boston, or scientific diphtheria. Science so-called has done this much—it has increased the figures of an old disease sevenfold. But what science means, and what clinical observation has meant, are two different things. The scientific inflation deals with new definitions which do not cover the older ones, and, comparing these exaggerated figures—exaggerated in comparison with those obtained by traditional methods—they can only be said to have a nominal, but not a real relevancy. If the scientific methods (Dr. McCallom's) of obtaining a superior death-rate percentage were equal to the scientific methods of increasing the numerical morbidity, then Dr. McCallom's death rate ought to be about five or six per cent. and not thirteen per cent. And then *the* argument in favor of antitoxin would not be remarkable, or even worth serious attention. Dr. McCallom has confounded elementary conceptions, unlike in kind, and has arrived at results that are unlikely.

In a subsequent essay I shall discuss the practical arguments and supposed facts which some clinicians and scientists claim do prove that antitoxin is the remedy for diphtheria. Aside from all speculative and theoretical considerations, and dissimilarities of definition, these practical arguments and proofs resolve themselves into an enumeration of authorities and cases.

406 West Thirty Fourth Street.

Hegar's Method of Diagnosticating Fibroma.—The finger is passed into the rectum and pressed against the tumor; at the same time the uterus is drawn downward by a volsellum. If the tumor be ovarian, it will not move; if uterine, there will be great resistance to drawing down the cervix, which will clearly be continuous with the morbid growth.

Progress of Medical Science.

Pathogenesis of Delirium Tremens.—Dr. P. Hertz concludes as follows: A kidney affection is a constant accompaniment of uncomplicated delirium tremens, and this simultaneous occurrence seems to show that the kidney affection is primary and the delirium secondary. The anatomical basis of the kidney disease is an acute nephritis, which develops in all probability into a chronic nephritis. The course of this kidney affection corresponds so exactly to that of the delirium that we can with certainty assume a pathological connection between these two phenomena. Inasmuch as delirium and uræmia present so much in common, we may look upon the former as an acute auto-intoxication psychosis due to renal insufficiency, which is dependent upon the acute nephritis. A special form of the delirium is seen in chronic alcoholism. It is very likely that the delirium of pneumonia is not due to the pneumotoxin, but to the existing kidney affection. —*Deutsche Medizinal-Zeitung*, September 29th.

Addison's Disease in Children.—Dezirot (*Klinisch-therapeutische Wochenschrift*, September 18th) has observed three cases of Addison's disease in children, at Variot's clinic during the past year, and has collected from literature forty-eight instances, all told, which occurred in children from seven days to fourteen and one-half years of age. This disease rarely occurs in childhood; the etiology in almost all of the cases was tuberculosis of the suprarenals. The onset was frequently overlooked and the first symptoms appeared slowly. At first general weakness and fatigue without apparent cause showed themselves. The children had no desire for play, but were rather weak and apathetic. In other cases gastro-intestinal symptoms —nausea, vomiting, diarrhœa, and constipation—ushered in the disease. The latter seems to be the general mode of onset in children. Discoloration of the skin was rarely observed at the beginning. Inasmuch as many of the symptoms of Addison's disease occur in the course of a tuberculosis, a localized tuberculosis was not infrequently found in the lungs, kidneys, glands, joints, and bones. In other cases the disease assumed a galloping type, similar to a poisoning, so that in a few months the characteristic symptom complex of asthenia, gastro-intestinal symptoms, pain, and skin coloration was fully developed. The asthenia proved the most characteristic sign of the disease; it was practically never absent. The intellect was clear, but the patients could hardly answer questions on account of the fear of fatigue. The gastro-intestinal symptoms were important. At first there was loss of appetite; the children showed a special desire for certain food stuffs, especially meat; nausea and vomiting of a uræmic nature occasionally occurred. At times there was constipation, and again diarrhœa. The pains were less constant. They were for the most part spontaneous, and were situated in the back, abdomen, hypochondriac or epigastric regions. The hyperæsthesia of the abdomen may be so great as to give the impression of a peritonitis. Some patients complained of severe headache and pains in the bones. The pigmentation of the skin was frequently overlooked, the parents thinking that the child was sunburnt or icteric. The discoloration was more or less uniform over the entire body; less frequently was it partial. On the exposed parts—face, neck, hands—and in those regions where pigmentation is normally greater—navel, genitals, axillæ—the eruption was darker. The mucous membranes always presented disseminated brown spots, which are for the most part so characteristic that they form a pathognomonic symptom, at least in children. Besides the cardinal signs of this disease, other symptoms, such as rise of temperature, rapid pulse, convulsions, and epileptiform attacks, were observed. The course of the disease showed remissions and exacerbations. In some cases death occurred suddenly. Death usually occurred within a year, as a result either of cachexia or of intercurrent disease.

A New Tricophyton.—Drs. Matruchot and Dassonville, working at the Sorbonne under direction of Gaston Bonnier, have isolated, cultivated, and re-inoculated both in the guinea-pig and in man with positive results a fungus similar to but not identical with that described by Sabouraud and Bodin. The observations were made to determine the nature of an epidemic attended with a herpetic eruption affecting some forty horses of a cavalry regiment.—*La Tribune Médicale*, September 28th.

Splenomegalia.—The question of enlargement of the spleen in association with hepatic cirrhosis has been made the object of some new studies by Banti (*Policlinico*, No. 5, 1898). In commenting upon three cases, he designates three stages: that of anæmia, an intermediary period, and a period of ascites. It seems probable to the writer that the spleen gives off certain substances or products, which, in passing through the liver, produce in this organ connective-tissue hyperplasia. If the spleen be removed the anæmia disappears and the cirrhosis ceases. In an instance observed in which pronounced febrile attacks were preceded by violent rigors, a marked diminution in volume of the spleen was made out during the attack, and it was thought that the organ had emptied its contents into the splenic vein and that the symptoms were due to the rapid penetration of toxic material into the circulation. In one case splenectomy arrested the cirrhosis in its incipiency. This radical measure is warranted and advised by Banti, since medical treatment is of no avail.

Arterial Sclerosis. — Local scleroses are but the beginning of general sclerosis, always to be found by those who look for it. The chief characteristics of syphilitic sclerosis are: (1) It is nodular and not diffuse. (2) It has a tendency to invade portions only of a vessel wall. (3) Its onset is usually chronic. (4) The points of attack in order of frequency are: (*a*) Cerebral arteries; (*b*) aorta, especially ascending portion of arch; (*c*) arteries of heart; (*d*) arteries of pericardium. (5) It has a tendency to obliterate vessels. (6) It has a tendency to form aneurisms. (7) In analogy with tuberculosis it has a tendency to obliterate arteries, to form aneurisms, and to become localized.—Dr. C. A. Penrose, *Johns Hopkins Hospital Bulletin*, June.

Amaurotic Family Idiocy. — The characteristic symptoms of this condition, according to Sachs, are: (1) A psychical defect, which is observed in the early months of life. (2) Weakness of all the extremities, even to complete paralysis, with or without spasm. (3) Normal, increased, or diminished reflexes. (4) Diminution of vision, which eventually leads to total blindness. The disease usually ends fatally, with symptoms of marasmus, within two years. The first symptoms appear between the third and eighth month of life. Lack of interest for its surroundings and inability to hold up its head direct the attention of parents and physicians to these little patients. Toward the end of the first year the children are usually complete idiots, and present a more or less intense diplegia. The electrical reaction of muscles and nerves is practically always normal. The disease occurs in families; whether or not it is hereditary cannot as yet be definitely stated.—*Deutsche medizinische Wochenschrift*, 1898, No. 3.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, November 5, 1898.

VEGETARIANISM.

THE old controversy between those who term themselves vegetarians and those who pin their faith to meat as a necessary article of food has once again broken out, and with renewed energy, in England. The pending discussion was initiated by an editorial in *The Times*, apropos of a vegetarian congress recently held in London. The writer of the article in question animadverted in a decidedly vehement and sarcastic strain against what he designated the faddism of vegetarians, thereby bringing down upon his devoted head the ire of all that well-meaning but misguided class. Other English journals have taken part in the wordy fray, and in language more or less emphatic have scored the upholders of a vegetable diet. *The Times* presents the case for the antivegetarians in the following well-considered words: "The truth is, if there be any question which has been thoroughly threshed out by physiologists and physicians, it is that of diet. By scientifically conducted experiments, sometimes upon individuals under laboratory conditions, sometimes upon masses of men in barracks or prisons, and sometimes upon nations by observation of their habits and of development, whether physical or mental, which these habits have produced, we possess complete information upon all questions relating to food and the influence which it exerts. We know that the maintenance of a high standard of bodily and mental capacity requires the consumption of proteids, hydrocarbons, and salt in definite quantities and proportions, and that so far as the effects are concerned it is a matter of indifference in what proportions these are furnished by the animal or by the vegetable kingdom. The vegetarians have a somewhat unpleasant habit of seizing upon any opinions in the slightest degree favoring their views, expressed by high authorities, and immediately claiming these men as out-and-out supporters of their creed. The remarks made may have simply been to the effect that the majority of people consume more meat than is good for them, but it matters not; the author is forthwith enrolled a member of the army of vegetarians and his name is cast in the teeth of disbelievers, as a convincing proof of the soundness of the arguments. In this manner Sir Henry Thompson has long been cited as a thoroughgoing adherent of the flesh-abhorring band, and his name has been used as a battle cry to strengthen the faith of waverers and to rally fresh recruits to the ranks. So much has this been the case that Sir Henry Thompson has in self-defence been compelled to state clearly his true opinions and thus set himself right with the public at large. This he has lately done in the *Nineteenth Century* in no uncertain tones; and his words are so excellent an exposition of the whole subject that we quote a portion of them."

Referring to the influence of climate upon the question of diet, Sir Henry says: "For climate is an important factor in relation to food. Man, wherever he exists, has to maintain his body at a constant temperature of at least 98° F.; and it is obvious that an enormous difference must exist between the needs of the individual who lives near the equator, with all surrounding objects at a constant temperature of 85° to 95° F., and those of one who inhabits northern latitudes, where it is continuously below the freezing-point, 32° F., often to the extent of many degrees. In each case the body must be maintained at 98° F., or a little more, or man will cease to exist. In the large and populous zone we inhabit, which forms so extensive a portion of Europe, Asia, South Africa, America, and Australia, and is known as the 'temperate zone,' there are very few persons, indeed, who can sustain their health and a fair amount of strength for many years on a strictly vegetable diet. . . . Hence it is only possible to regard man—considered as an inhabitant of the world at large and manifesting as he does a strong and increasing impulse to explore and colonize in any part of the globe—as now naturally omnivorous; in other words, possessed of a constitution which requires for his well being a mixed diet of animal and vegetable foods in relative proportions, varying according to temperature and activity of life." There is no doubt that more flesh is eaten by many persons than is necessary, especially by those persons who are in easy circumstances and lead a sedentary life. These persons should live on a lighter animal food than beef or mutton, and use plenty of vegetables. On the other hand, those who take much exercise or perform hard manual labor, exposed to all weathers, are able to digest and thrive on meat in larger quantities. The whole matter resolves itself into a question of environment and manner of life, not forgetting the constitution of the individual. If a man finds that he is in better health on a vegetable diet, he should by all means use that description of food, but it is absurd to contend that with all persons, under all conditions of life and in all climates, such a procedure is most suitable.

A New Hospital in Havana.—The Nuestra Señora de los Angeles was opened on October 16th, on the site of the old La Integridad Hospital, where the unfortunates from the fosos find a refuge. The bishop of Havana presided at the opening exercises. The civil governor and his wife were present at the ceremony, as were the mayor, the staff of the hospital, many prominent families, ten sisters of charity, the three house surgeons, and the visiting physicians.

THE STUDY AND TREATMENT OF CANCER.

The crusade now being carried on in all parts of the world against tuberculosis is deserving of all praise, and it appears that, with our knowledge of the disease and with our efficient means of combating it, it is not too much to hope that the day is not far distant when its ravages will be effectually checked. But although consumption is a fearful scourge, the fact that cancer is an even worse one has been pointed out on many occasions recently by several acute observers. It therefore behooves scientific investigators to endeavor to probe the mysteries which at present envelop this dread disease. To the man who proves conclusively the origin of cancer, no honor will be too great. The *British Medical Journal* of October 1st has an article treating of the subject and discussing the point as to whether it is advisable to operate for the relief of cancer. Dr. Severin Robinski has lately written an important work, in which he states as his opinion that in cases of cancer operative measures are not indicated. The *British Medical Journal*, referring to this statement and after drawing attention to the two theories—the embryonic and parasitic—now held as to the cause of cancer, says:

"If we assume for the sake of argument that cancer is, in at least some if not in all cases, parasitic in origin, then there must unquestionably be a time when the growth is localized at the point of inoculation; and, if so localized, there can be no doubt that early operative and medical removal is a means of cure—so far at least as that inoculation is concerned. Robinski's statement that operation is not justified in cancer must therefore be decidedly and strenuously negatived. It lacks the smallest shred of evidence or observation, clinical or experimental, to support it. The local deposit of cancer is diffused, as we know, mainly through the lymphatic system. If, then, it is at first local and becomes constitutional by diffusion through the lymphatic system, it is further necessary that the complex system of the lymphatics should be studied with greater accuracy than before. . . . The question, then, as to the propriety of the use of the knife in malignant disease can be considered permanently settled. Our efforts must now be directed to a close study of the earliest manifestations of malignant growths in their various sites, and to a laborious and exhaustive investigation of the intricate lymphatic channels. With knowledge thus perfected, we can until the day of inoculation arrives feel justified—nay, rather compelled, to advocate the most prompt and intelligent active surgical interference in all cases of accessible malignant growth."

We cordially agree with the writer of the above remarks that the prompt use of surgical measures is decidedly the proper course to be pursued in cancer, and also that the sooner the knife is brought into play the better; but we would also point out that there are many difficulties in the way of an early diagnosis of malignant disease. The chief obstacle is the sufferer and relations. No one likes to believe—indeed, in too many instances will not believe, until it has made great headway—that the disease with which he is afflicted is cancer. If the fact could be impressed upon the minds of individuals that the safest and wisest path to follow is in any case in which cancer is suspected immediately to seek the advice of a competent physician, there can be no doubt that the death rate from this cause would be immensely decreased. It would be well, too, that the ordinary medical practitioner should make himself better acquainted with the manifestations of malignant disease than he usually is, or, if he doubts his own knowledge, that he should advise his patient wherever possible to obtain the opinion of a specialist.

THE TREATMENT OF THE INSANE IN THE LAST CENTURY; AND THE WORK OF PHILIPPE PINEL.

It is difficult to realize now the position of an inmate of an asylum for the insane in the old days. Even under our improved and enlightened conditions, the lot of those unhappy beings from whom the light of reason has fled is—in some civilized countries and in parts of the United States—not altogether what it should be. Yet, compared with the asylums of a hundred years ago, those of the present time are palaces of delight. To two men is largely due the great and enduring honor of bringing about this change. Dr. Philippe Pinel, the Frenchman, was the pioneer in this good work, closely followed by Tukes, the English Quaker. In this country, where the rational treatment of the insane has reached its highest development, a woman, Miss Dorothea Dix, was mainly responsible for introducing the beneficial reforms. To many the name of Pinel is unknown, while it is safe to say that few are acquainted with his life and work. From this oblivion Mr. Francis Tiffany has rescued the great French philanthropist, and in a small work recently published has given an illuminative sketch of his humanizing labors. It appears that Pinel was born in 1745, and that his father was a poor country doctor. In appearance he was small and insignificant, and of a painfully shy disposition. After failing as a country practitioner he went to Paris, and after many hardships and vicissitudes succeeded at last in making powerful friends and in obtaining the appointment of physician to the Bicêtre, the largest madhouse in Paris, and which is thus described by the great scientist Pariset, in his "Éloge de Pinel":

"Vice, crime, misfortune, infirmity, diseases the most varied and the most revolting—all were heaped together and treated alike. Men crouched there, covered with filth, in cells of stone—narrow, cold, dripping, without air or light, and furnished only with a litter of straw, rarely renewed and soon infected: hideous lairs, in which one would have hesitated to shut up the vilest animal. The insane thrown into these sewers were at the mercy of their keepers; and their keepers were malefactors from the prisons. The wretched patients were loaded with chains and tied with ropes like convicts. Handed over thus to the cruelty of their guardians, they were made the butt of insulting raillery or of blind and wanton brutality."

One of the first steps taken by Pinel, after for some

time he had endeavored to gain the affection and confidence of his patients by kindness, was to procure an order from the government to allow their fetters to be struck off. This request was after much hesitation conceded by the "powers that be," and in one day Pinel knocked off the chains from eighty insane of both sexes. To the surprise of all, this action was followed by no disastrous results, and soon the fact was recognized on all sides that Pinel had to a great extent solved the difficult problem of how madness should be treated, and that kindness and not brutality was the most effective method. It is satisfactory to be able to state that the great French physician—unlike so many benefactors of their kind—died full of years and honors.

News of the Week.

The Yellow Fever in the South has practically come to an end, the breath of frost which invaded the Mississippi Valley last week having destroyed the infectious principle. The Marine Hospital officials are not relaxing their precautions, however, and it has been ordered that the regulations governing the active Marine Hospital quarantine stations be amended to continue all such stations until November 15th. The necessity of this action is obvious, as the transports are still carrying troops between Cuba and our ports at home, with the consequent liability of infection being brought into our own ports. By the middle of this month, however, the disease will have practically disappeared in Cuba. Even after that time the inspection of all vessels at all quarantine stations will be continued, though merely as a precautionary measure.

The Plague in Vienna.—Fräulein Albine Pecha, one of the nurses who attended the victims of the bubonic plague at Vienna, died from the disease on Sunday morning. She was twenty-two years old, and was strong and healthy until infected by the plague. The physicians, sisters, and priests who ministered to those who have had the plague are detained in quarantine, but none of them has as yet shown any symptoms of the disease.

The Death of Colonel Waring.—Col. George E. Waring, Jr., died of yellow fever, on last Saturday morning, at his home in this city. Colonel Waring went to Havana a few weeks ago, as the head of a special commission of this government to find out the exact sanitary condition of that city, and to devise some plan for improving the condition of affairs. The plan of the commission was to place the city of Havana and the coast towns of Cuba in such a good sanitary state that the recurrence of yellow fever or its entrance into the Gulf cities of the United States would be prevented. The commission was also instructed to select sites for the camps of the United States troops that are to occupy the island next month. The work of sanitary inspection necessarily took Colonel Waring into the filthiest of Havana's slums, the choicest breeding-places of all manner of filth diseases. He showed no symptoms of the disease until just before his arrival here on the Tuesday preceding his death. No one even then suspected the nature of his malady, which was thought to be a slight cold or a malarial attack. He was to have gone to Washington the day after reaching here, in order to present a report to the President. Fortunately his report, which is said to contain an elaborate and detailed plan for the sanitation of Havana, was written before his arrival; but the loss of the master mind, by which all these details could have been developed into practical form after the evacuation of the city by the Spaniards, is a great public calamity. Colonel Waring was the first man in the country to whom every one naturally turned when it was known that Americans were to have an opportunity to clean out the Cuban pesthole, for every one knew that he could do it. Colonel Waring was born in Pound Ridge, N. Y., on July 4, 1833. His first work of public importance as an engineer was the designing of the drainage system of Central Park in this city. He first attained prominence as a sanitary engineer, however, at the time of the outbreak of the yellow fever at Memphis in 1878, when he changed the sewage system of that city by introducing methods of his own, which separated house drainage from surface drainage. His system has since been adopted in a large number of American cities as well as in some towns abroad. In 1882 he was appointed a member of the national board of health, a position which he held for a number of years, and in 1894 he became assistant engineer of New Orleans. In 1895 he was appointed street-cleaning commissioner of New York, and lifted from our city the stigma of being one of the dirtiest of the large cities in the world. The death of Colonel Waring is one of the saddest and most nearly irreparable of the casualties of our war against Spanish misrule and insanitation in America, but we have cause to rejoice that he lived to sketch the plan of campaign and to point out the means by which the yellow plague may be made a stranger to the coast towns of Cuba.

A Plague Ship at San Francisco. — The French bark *Du Chesscanne* arrived at the port of San Francisco from Hong Kong, on October 28th, with plague aboard, and has been detained in quarantine indefinitely. On August 20th, at sea, Captain Cervany died of the bubonic plague, and on September 20th Seaman Ange Menier died of the same disease. No further cases had occurred among the crew up to the arrival of the vessel, but there were fears that the disease was epidemic among the rats aboard the bark.

Yellow Fever in Mexico. — The officials of the State of Nuevo Leon, Mexico, report the occurrence of several cases of yellow fever at Monterey. It is not thought that the disease will spread, however, for the same cold wave that put an end to the disease in Mississippi has extended also into Mexico.

An American Physician Honored.—The Shah of Persia has recently conferred upon the veteran medical missionary, George W. Holmes, M.D., the highest decoration of the Order of the Lion and the Sun, except one which is reserved exclusively for the prime minister.

Dr. Holmes went to Persia in 1874, and is now in charge of the Presbyterian Medical Mission in Hamadan, Persia. Formerly he resided in Tabriz, where for a number of years he was the chief consulting physician to the present Shah, who was then crown prince. Since ascending the throne, the Shah has repeatedly invited Dr. Holmes to become his personal physician and to have charge of the health of the royal harem. In a land of intrigues, where a cup of coffee may contain a potion that will end all, the calling in of a physician becomes a very serious matter, and no higher compliment could be paid to Dr. Holmes by His Imperial Majesty than was paid when he invited him to become his physician.

In Memory of Dr. John Blair Gibbs.—By direction of the President, the general field hospital at Camp Hamilton, Lexington, Ky., has been designated as John Blair Gibbs General Hospital, in honor of Assistant Surgeon John Blair Gibbs, of New York, who died on June 12, 1898, from wounds received in an engagement with Spanish infantry at Guantanamo.

The Craig Colony for Epileptics.—The annual meeting of the board of managers of this institution was held at the colony on the 11th instant, and the following officers of the board were re-elected: Frederick Peterson, M.D., *President;* H. E. Brown, *Secretary;* John F. Connor, *Treasurer.* The annual report of the medical superintendent, Dr. William P. Spratling, was presented and read. The most gratifying feature of the report was the discharge of seven patients during the year as recovered. It was also reported that marked improvement had taken place in the majority of all cases admitted to the institution. The industrial showing for the year was very satisfactory, the value of all articles grown and manufactured by the colony during the year amounting to $36,889.03. Eighty-six per cent. of all male patients and eighty-three per cent. of all female patients were reported as engaged in labor designed to reduce the cost of maintenance. On the first day of October applications were on file for the admission of over six hundred patients, who could not be received on account of lack of room. The managers have decided to ask the coming legislature for a large sum for dormitory construction. In view of the demonstrated practical value of this institution the legislature will doubtless grant any reasonable request that the managers may make. The colony is one of the few medical charities worthy of a grant of the taxpayers' money, one of the few that may not be charged with pauperizing the people and impoverishing the profession. We trust the legislature will aid it to increase the measure of its usefulness.

A Tri-County Medical Association.—The members of the county medical societies of the counties of Warren, Sussex, and Morris in New Jersey met at Hackettstown, on Tuesday, October 11th, for the purpose of organizing a tri-county medical association. The officers elected were Dr. John S. Cook, *President;* Dr. E. Morrison, *First Vice-President;* Dr. Levi Farrow, *Second Vice-President;* Dr. C. B. Smith, *Secretary;* Dr. F. W. Flagge, *Treasurer;* and Dr. H. A. Henriques, *Reporter.* After the organization of the society and the adoption of bylaws the members listened to two very interesting papers, one by Dr. Philander A. Harris, of Paterson, on "Troubles of the Obstetrician," and the other by Dr. H. A. Henriques, of Morristown, on "The Diagnosis and Treatment of Appendicitis." The next meeting will be held at Washington, N. J., on the second Tuesday in October, 1899.

The Southern Surgical and Gynæcological Association.—The eleventh annual meeting of this association which was announced to be held in Memphis, Tenn., Tuesday, Wednesday, and Thursday, November 8th, 9th, and 10th, has been postponed till Tuesday, Wednesday, and Thursday, December 6, 7, and 8, 1898, on account of the quarantine regulations in some parts of the South.

Dr. L. J. Ladinski has been appointed visiting surgeon to Gouverneur Hospital.

Guarding against Leprosy.—The California State board of health has commissioned Dr. C. A. Ruggles, president of the board, to visit the Sandwich Islands, to learn the extent of the presence of leprosy, and to report measures to prevent its introduction into California. Unless Congress passes a special measure to prevent it, the inhabitants of Hawaii will be free to come to San Francisco and other Pacific ports, and it is the intention of the board of health to prepare a report for submission to the coming legislature which will suggest safeguards against the spread of the disease.

The New York Obstetrical Society.—At the last annual meeting of the New York Obstetrical Society the following officers were elected for the ensuing year: *President*, Dr. W. R. Pryor; *Vice-Presidents*, Dr. LeRoy Brown and Dr. Edwin B. Cragin; *Recording Secretary*, Dr. Joseph Brettauer; *Assistant Recording Secretary*, Dr. E. E. Tull; *Corresponding Secretary*, Dr. George W. Jarman; *Treasurer*, Dr. J. Lee Morill; *Pathologist*, Dr. George C. Freeborn.

A Palatable Meat Extract.—The *British Medical Journal* says that the authorities recently seized in London forty-four barrels of decomposing livers upon premises devoted to the manufacture of all kinds of "table delicacies" and a pure meat extract. All the livers were decomposed, although the manager is reported to have expressed the opinion that they were "all right." They consisted for the most part of pigs' livers which had been exported from Ireland to Hamburg for the manufacture of German sausage, and so much of the supply as was in excess of the demand was sent over to England, to be used in the preparation of a meat extract. The defendant was made to pay £100 fine and costs, and lost his much-travelled livers.

The Tri-State Medical Association of Mississippi, Arkansas, and Tennessee will meet in Memphis, on Tuesday, Wednesday, and Thursday, December 20, 21, and 22, 1898. Titles of papers to be read at this meeting should be sent to Dr. Richmond McKinney, secretary, Continental Building, Memphis, Tenn.

Correspondence.

OUR LONDON LETTER.

(From our Regular Correspondent.)

MEDICAL SOCIETY—ANTISTREPTOCOCCIC SERUM IN PUERPERAL SEPTICÆMIA—"CHRISTIAN SCIENTISTS"—MEDICAL DEFENCE—IN MEMORY OF GREIG SMITH—LISTER AT LIVERPOOL—CHADWICK LECTURES.

London, October 14, 1898.

Monday was the opening day of the one hundred and twenty-sixth session of the Medical Society of London. Mr. Edmund Owen took his seat as president for the year, and congratulated the fellows on the satisfactory state of the finances. He called attention to the value of the library, in which are many old and rare volumes. Among the manuscripts is the diary of Rev. John Ward, M.A., Oxon., from 1662 to 1681, in which there are references to Shakespeare's existence and death. This book the president passed round, and went on to remark that one of the early presidents of the society was several times fined for taking away journals, without making a proper entry of his doing so. Cheap printed matter in these days, Mr. Owen added, and the multiplication of journals left no inducement to run the risk of being fined for borrowing, and for his part he had never come across a journal which he was tempted to abstract. I commend this somewhat dubious compliment to the editors of the journals or to their contributors, according as they may feel oppressed with the "watering down of literary talent," which Mr. Owen thinks he sees in the inconvenient growth of medical journalism. Mr. Owen concluded by proposing to devote an evening to the discussion of "surgical failures," to which he promised to contribute. A journalist's aside to this suggestion is "surgeons' failures too."

Dr. Allchin then read a paper on "Considerations Preliminary to the Study of Dyspepsia," in which he deprecated the vagueness of thought and method with which the subject of indigestion has been described and investigated. He would include in the term digestion all the changes undergone by the ingesta throughout the alimentary canal. Gastric digestion he regarded as probably the least important, as its defects could be made up for at a later stage, a proof of which is the recovery of a patient after total extirpation of the stomach. He did not include absorption, which, he said, was quite different in nature from digestion, but later on he included defective absorption of digesta among the disorders of digestion from a causal point of view, the others being: (1) Errors of diet; (2) diseases of the digestive organs, whether structural, nervous, or dependent on blood or lymph changes; (3) improper bacterial action in the alimentary canal; (4) abnormal excretory processes. He objected to the term "functional disease," as the conditions so spoken of were associated with structural change. And yet his own classification hardly supports this dogmatic statement. Errors of diet and improper bacterial action do not suggest change of structure.

Dr. Maguire remarked that the several digestive functions disappeared in an order inverse to their development. Thus the power of digestion for fat was first lost, then for starch, last for proteids.

Dr. Allchin in reply said he could not accept this view without further evidence.

Antistreptococcic serum was talked of at the Obstetrical Society's meeting on the 8th inst. It was used in a case of puerperal septicæmia, related by Drs. I. and A. R. Walters, of Reigate. At the time of the first injection the temperature was 103° F.; pulse, 120. Some hours later the temperature fell to 98° F. Next day it rose to 100.4° F. and another injection was given, with a similar fall. This was followed by great depression, lasting several days, and there was transient albuminuria.

Dr. Amand Routh remarked that septicæmia was not always due to the streptococcus, and when this was not the case the injection of it would be dangerous.

Dr. Eden also urged the importance of restricting the use of this serum to cases caused by the streptococcus, and referred to Haultain's three cases, in one of which Loeffler's bacillus was found, and which ended in recovery under the use of antidiphtheritic serum. In the second, the streptococcus being present, the appropriate serum was used, and recovery ensued. In the third the bacillus coli was found and the patient died, no appropriate serum being known.

Dr. Drummond Robinson had not much confidence in precise differentiation or in this serum. His first five patients all died; the sixth recovered, but looked hopeful before the serum was resorted to.

Dr. Cullingworth considered that antistreptococcic serum ought to be given in every case of septicæmia, although many cases are due to a mixed infection. If not fully armed, we should use the arms we have. In reply to a subsequent question, he admitted that a member of St. Thomas' staff had had serious symptoms after an injection of the serum for a poisoned wound of the finger, but he said in that case the quality of the serum was doubtful and its age unknown. He had been informed by those with large experience that untoward results were very rare with fresh antistreptococcic serum.

Dr. J. Phillips had a case of acute septicæmia, in which the serum had immediate effect in calming wild delirium and the patient recovered, though she had a long convalescence. Various rashes followed the injections.

Dr. W. H. Tate had a case in which the first few injections relieved, but the response grew less and less and the patient died.

Dr. McCann urged the use of the serum as a preventive whenever there was extra risk of infection, as in parturient patients with foul discharges.

Dr. Herman related a case of removal of a large suppurating cyst, followed by collapse and apparently approach of death. On the rally from this there were a rise in temperature and fresh collapse. Serum being injected, temperature and pulse fell, and the patient made a good recovery.

The quacks who call themselves "Christian scientists" have had a rude shock in the exposure of their doings that took place last Saturday at an inquest concerning the death of Major Lester. This officer, only thirty-eight years old, was appointed in 1892 instructor in military topography at Sandhurst—a sufficient indication of his service. In August he was attacked with tuberculous peritonitis and attended by two surgeons-colonel, and two physicians were called in consultation. On September 5th the doctors were dismissed and a Mrs. Grant, said to come from America, was called in to give "Christian treatment." She said she began treatment on receipt of the wire, before seeing the major. This treatment she described as "taking up the right thought of the omnipotence and love of God." When asked how she would treat a broken leg, she said she "would ask a surgeon to treat it." She said she never gave any material remedy whatever, but continued her treatment when away from the patient. She added, "Christ never sent the sick to physicians," upon which the coroner remarked that "Christ had a power these people are trying to usurp—trying to make themselves out equal to God." Mrs. Grant stated her charge for treatment to be a guinea a week. The coroner in his summing up said that he could not help

thinking "some of these people would be better—and very much safer—in a lunatic asylum." The jury found that the major died of tuberculous peritonitis, and expressed their "strong sense of abhorrence of the so-called treatment by Mrs. Grant."

When we see people who seem to have a pretence to education trusting to such quackery, we need not so much wonder at the "peculiar people," who are mostly very ignorant and can understand only the text on which they rely as a literal command. But if education has such results, there must surely be something amiss in the manner of carrying it on.

The Defence Union lost a case last week. A midwife, said to be the niece of a judge, was sued under the apothecaries act. The defence was that any one could sell medicine as a chemist, except scheduled poisons, and any midwife could treat diseases.

The jury refused to convict. It would seem that both the Apothecaries' Society and the Pharmaceutical Society need to look after their privileges, if every woman who calls herself a midwife is to set them at naught. The Obstetrical Society should also again be hauled over the coals for selling its worthless diplomas.

The new operating-theatre at the Bristol Infirmary, built as a memorial of the late Greig Smith, was opened on Saturday, when all the local celebrities were present, as well as the president of the London College of Surgeons. Sir W. MacCormack spoke, and contrasted the losses in the Egyptian campaign with the awful mortality from sepsis in former wars.

Liverpool also had a gala day on Saturday, for there the Victoria University, with imposing ceremony and in the presence of a distinguished and gorgeously robed audience, conferred its honorary D.Sc. on Lord Lister, who delivered an address in which he showed the enormous value of research. His remarks have roused the ire of the antivivisectionists, and already certain newspapers are pandering further to the faddists. Lord Lister afterward formally opened the Thompson-Yates laboratories and in the evening was present at the lord mayor's dinner, where Virchow was also present and spoke of him as his "old friend of many years."

Prof. M. Foster, who spoke at this dinner, said the sight of the new laboratories had produced a double physiological effect on him. "They took away my breath and made my mouth water."

The first course of Chadwick lectures, inaugurated in memory of Sir Edwin Chadwick, was opened on the 12th inst. Prof. O. Chadwick, son of the great sanitarian, delivered an address, sketching the history of the foundation and the value of practical work.

THE DOCTRESS AND THE DOCTOR.

To the Editor of the Medical Record.

Sir: Having read the ambitious screed of Doctress Jarrett, printed in the Medical Record of the 22d inst., as one of the unfortunate male doctors against whom the lightning of her wit has been fulminated, by your courtesy I venture to call her attention to a fact or two, *in re* the female physician.

1. The practice of medicine is a business. Business knows no sex. No first-class male milliner would think for a moment of making capital out of the fact of his masculinity. *Per contra*, most doctresses do use their femininity as a part of the goods they have to sell; this is the crux of the whole matter.

2. No honorable physician can rightly object to honorable competition, be the competitor male or female; but when the accident of sex is included in the category of the professional attainments, and flaunted in the eyes of the public as a claim to a heaven-born right to treat the diseases of women and children more skilfully than a brother practitioner can, an earnest protest must be entered, not only on behalf of the profession but also in the interest of the laity; for, given two physicians of equal attainments and experience, the female cannot be granted precedence.

3. It is a sad truism that the world-wide conflict of "sex against sex" is continuously waged, alike in the hovel and in the palace. To be honest the doctress must deal with each side with impartiality. Does she do it? The reply must, in most cases, be in the negative. Her very inability to do this is the strongest reason for opposing her more general recognition as an honest competitor in the field of physic, and is the cause of her being, from time to time, regarded by the head of the family as a secret foe in the midst of his household fold.

In individual cases, when the doctress does not exploit her sex, her brother physician should always extend to her the hand of friendship and a courteous consideration, which her position demands. As a matter of fact he generally does.

Newport, R. I., October 25, 1898.

THE MEDICAL PROFESSION IN HAWAII.

To the Editor of the Medical Record.

Sir: Your article on the health of Hawaii and the need of a commission appointed by our government to segregate the lepers, suggests to me that possibly you are not aware that for several years Hawaii has had a most efficient board of health, which has given special attention to leprosy. Dr. R. P. Myers has done splendid work for the board, and is active in an experimental bacteriological station already established in Honolulu.

Persons suspected of having early symptoms of leprosy are required to report to the station at intervals, and if found infected are at once banished to Molokai.

The profession in Hawaii is represented by men of the highest repute and ability, and, as in other lands, is full to overflowing. There are few or no openings for young doctors, save on the sugar plantations, where the isolation is extreme. J. C. Bowker, M.D.

Lawrence, Mass.

A VISIT TO WILLARD STATE HOSPITAL.

To the Editor of the Medical Record.

Sir: A few days ago I had the pleasure of attending the regular monthly meeting of the Willard State Hospital Medical Society and Journal Club. These meetings are held in the hospital, and are of the most interesting and instructive character. I understand that a project is in contemplation for making the various State hospitals, to a certain degree, educational centres for the general practitioners in their respective districts.

At the meeting referred to, exceptionally able papers on the subject of paresis were read and discussed.

While this subject belongs properly, perhaps, to the alienist, yet to me as a general practitioner its presentation on this occasion was most enjoyable. The members of the medical staff are untiring in their efforts to make the stay of their professional brethren pleasant and profitable; indeed, one visit will hardly suffice to get more than an outline of the work which is being done in this extensive and well-conducted institution.

Time and space limit me to the briefest reference to but one phase of the care and treatment of the more than twenty-two hundred inmates—the industrial.

This system is being developed more extensively than ever before. All the clothing, including shoes, is made on the premises; carpet weaving, basket and rug making, and various other industries occupy the time of the patients. Several hundred men are employed on the farm, which consists of eleven hundred acres, thus subserving a double purpose in the health-restoring and economic problem, which is being solved by this model institution. But the point which I wish to emphasize is that the general practitioners in this district should avail themselves of the opportunity for instruction offered by Willard in these monthly meetings.

In the intelligent commitment of the insane we, as general practitioners of medicine, need something of the special training here afforded. Then, when we have acquired all this, let us hope that the law may be so amended and modified that the findings of the duly accredited physician in relation to the insane may not be reversed by the say-so of neighbors, or even by the *ipse dixit* of a judge who has no especial qualifications for the work.

Poplar Ridge, N. Y.

APOMORPHINE.

To the Editor of the Medical Record.

Sir: In Dr. Visanska's article of July 2d in the Medical Record were stated many facts. With the partial exception of the remark on epilepsy, not a step was taken upon uncertain ground. Furthermore, he stopped far short of giving full justice to this most valuable friend of the physician. We who have dealt long with the hysterical, the epileptic, the malingerer, and the criminal insane have learned to look upon apomorphine as a friend in need. Among these and kindred unfortunates it is a relaxant, a disciplinarian —yea, even a reformer of matchless potency. The writer has yet to find a case of hysteria that refused quickly to bend the pliant knee to its soft, persuasive charms. No matter how rigid the muscles, or how rapid and hard the breath be drawn, a hypodermic injection of one-fifth of a grain of apomorphine will brush aside our cobwebs of doubt in diagnosis and place a pedestal under us in the estimation of the anxious family.

In those cases of epilepsy in which the convulsion is produced immediately by deleterious matters in the stomach, apomorphine goes hand-in-hand with the stomach tube; sometimes one should be chosen, sometimes the other. When hysteria is an element, the tube is a veritable *bête noir*.

Let us give an example in speaking of the malingerer. A cowboy from the West had come East for his neighbor's health, and, finding here different conditions of life—that wishes no longer made saddle horses, only nightmares ready to hand—he conceived the bold idea of becoming epileptic and being somewhat "buggy" afterward. Once too often did he tempt fate, and caught a Tartar in the shape of one-fourth of a grain of apomorphine. To-day he breaks stone on the public road.

To the Matteawan State Hospital, by natural gravitation, in 1896 there came an Antigua negro, six feet two inches, weighing two hundred pounds, a typical bully, who began at once to exercise his choice amusement upon the weaker ones about him. One day two one-fifth-grain doses of apomorphine entered his pachyderm; and now he obeys willingly any one who carries the symbol of authority.

The utility of this drug is but little known, the gentleman from South Carolina to the contrary.

The gentleman from Oregon should have saved his dose till the next day, as he had already allowed more than an hour to pass before giving it.

Edgar J. Spratling, M.D.,
First Assistant Physician, Massachusetts Hospital for Epileptics.

ZOLA A NEUROPATH.

To the Editor of the Medical Record.

Sir: In the article "Zola a Neuropath," published in the Medical Record of September 17th, a statement is attributed to Max Nordau, which is completely contrary to the entire spirit and letter of his masterly work, "Degeneration." The sentence to which I refer is this: "Max Nordau's startling theory that genius is only a form of degeneration, although not accepted in its entirety, is yet regarded by many as worthy of some consideration." This happens to be just exactly what Nordau does not say. He says that a degenerate may be a genius or an imbecile, but distinctly asserts that a genius is not necessarily a degenerate.

In comparing the same genius with the gifted degenerate he uses these words: "Take from the former the special capacity through which he becomes a genius, and there still remains a capable, often conspicuously intelligent, clever, moral, and judicious man, who will hold his ground with propriety in our social mechanism. Let the same be tried in the case of a degenerate, and there remains only a criminal or madman, for whom healthy humanity can find no use." He proceeds to contrast the healthy genius Goethe with the degenerate Schopenhauer, and, farther on in the book, the sane Tennyson with the mystics Swinburne and Dante Gabriel Rossetti. Pray let me refer you for reperusal page 23, from which I have quoted the above sentence. A hearty admirer of both the Medical Record and Max Nordau, I am content to leave to you the decision of my case, and trust that you will pardon a criticism ventured with all modesty.

T. E. Nott, Jr., M.D.

[Perhaps the statement to which our correspondent objects, that Nordau's theory is that "genius is only a form of degeneration," was a somewhat too emphatic assertion, and not altogether in accord with the spirit of Nordau's work. The word "often" in the place of "only" would possibly better express his meaning. Still it cannot be denied that Nordau implies that there is a decided affinity between degeneration and genius.—Ed.]

DIPHTHERIA PREVENTIVE OR DIPHTHERIA ANTITOXIN?

To the Editor of the Medical Record.

Sir: It is becoming very clear that diphtheria antitoxin is in no sense an antidote for the poison of diphtheria, its only effect being to inhibit the activity of the bacillus producing the poison. Like vaccination in small-pox, it is a preventive and not an antidote, the only difference being that in the case of diphtheria infection is usually present before inoculation is made, so that it becomes a question of lessening the dose of the toxic material instead of preventing its formation enirely. In other words, the toxins once formed cannot be neutralized or their effects modified by the injection of the serum; only their quantity is lessened by controlling the activity of the bacillus producing them. This being the case, the use of the word antitoxin, which, unexplained, seems to imply, to the general public particularly, the possession of antidotal attributes, is unfortunate. If instead of using this term the physician will say that he pro-

poses to use a preventive, he will get his cases under observation and treatment much more readily and at a very much earlier stage, and people of average intelligence will be very much better satisfied, whatever the results. So plainly is this the fact that the writer has quite fallen into the habit of calling the serum the diphtheria preventive when talking to patients, instead of using the much more formidable and confusing term antitoxin. In short, just as soon as it is explained that it is a preventive and not an antidote the thing goes very much better.

M. A. VEEDER, M.D.

LYONS, N. Y.

HAWAII FROM A HEALTH POINT OF VIEW.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The editorial in your issue of October 15, 1898, entitled "Hawaii from a Health Point of View," is based upon such erroneous information that it is calculated to mislead opinion regarding the salubrity of our recent acquisition, the Hawaiian Islands. As a fact, no more delightful or wholesome climate exists in any other part of the world. Owing to the insular position of the territory and the peculiar circuit of the currents throughout the Pacific Ocean, the extremes of heat and cold are unknown, and the hurricanes and typhoons that devastate the West and East Indies never occur. Prior to the wars of conquest a century ago, the native population was redundant. Since the advent of Captain Cook that population has steadily diminished, not in consequence of insalubrity of natural environment, but by reason of certain infectious diseases to which the aborigines were utter strangers before their contact with foreigners. Chief among these were syphilis and tuberculosis, which were propagated among the people with fearful rapidity as a consequence of their promiscuously affectionate habits. The introduction of measles from California in 1848 is usually cited as having decimated the population. This statement is not exactly correct. The disease spread so rapidly that nearly every one sickened at the same time, but it was not unusually severe. The natives, however, knew nothing of the proper treatment of the uncomfortable fever, and sought relief in frequent baths in the waters of their mountain streams and alluring surf. Almost immediately they were attacked with inflammations of the respiratory tract and alimentary canal. While thus struggling, a world-epidemic of influenza reached the islands, and attacked every person there resident. Before this infliction had passed away, the Californians sent them some choice specimens of whooping-cough, which started a third epidemic that raged with great severity among the children. Scarlatina was also imported, but did not prevail extensively.

The result of this fourfold incidenee within the space of a few months was, of course, disastrous to the native people. Foreigners, their children, and the aborigines under the personal care of the foreign residents, suffered no more severely than Americans and Europeans in their own countries. But the native Hawaiians paid the penalty of inexperience, and one-tenth of the population perished.

Small-pox was introduced from California into Honolulu in the year 1853. It spread just as far as it could till arrested by vaccination. Owing to the difficulty of procuring vaccine virus, the disease prevailed for a number of months here and there throughout the islands. But it produced no such mortality as you have quoted from Dr. Morrow's ill-informed statement. The total number of cases was 6,405, and the number of deaths was 2,485. Scarcely any of the foreign residents contracted the disease, being protected by previous vaccination. As for "burying half the population of Honolulu," nobody has ever done that, unless in his dreams over an empty wine bottle.

The ravages of tuberculosis and syphilis have been already mentioned. Of these diseases Americans and Europeans in Hawaii have little experience, unless they adopt the habits and mode of life of the aborigines.

Leprosy, also, has furnished a similar history. While its propagation has been provoked and stimulated by the childish innocence of the primitive people, very few foreigners of continental birth have ever been infected; and then only when their own habits have been dangerously assimilated to those of the aborigines. The inside history of these experiences has never been fully published. As a result of the ruthless system of inspection and segregation in vogue, the disease is now rarely seen outside of the leper prison; and as the progress of civilization elevates the community the prevalence of leprosy diminishes.

I have said nothing of the tolerance of infection that is growing among the islanders as a consequence of continued incidence of infectious diseases. That forms an interesting chapter in their medical history.

I quite agree with you in the desire that our wealthy nation may be induced to make a thorough investigation of the diseases that exist in salubrious Hawaii. No more interesting biological station for such research can be found in any part of the world.

HENRY M. LYMAN, M.D.

CHICAGO, October 20, 1898.

Society Reports.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, October 17, 1898.

GEORGE TUCKER HARRISON, M.D., PRESIDENT.

Abdominal Hysterectomy; Resection of Ileum by a Modification of Maunsell's Method; Appendectomy; Recovery.—DR. FREDERICK HOLME WIGGIN reported the following case: A girl of eighteen years came under his care last July, suffering from pyosalpinx. There was also a history of specific infection, and at the time of operation she exhibited certain secondary symptoms. She was suffering a great deal. The usual abdominal incision was made through the right rectus muscle, and further examination showed that a portion of the ileum was adherent to the fundus of the uterus. During the separation of the adhesions a large portion of the peritoneal coat of the bowel was injured. The appendix was included in the mass. After amputation of the uterus the appendix was removed, and then the damaged portion of the ileum was resected. The ends were joined together by a modification of the Maunsell operation. The speaker said that for a long time it had seemed to him that the chief value of the Maunsell method was the demonstration of the possibility of passing the sutures through all the coats of the bowel without causing septic infection. Working upon this theory, he had found that the invagination and slit employed by Maunsell were unnecessary. In the modified method, which he now employed, the first suture was passed through the mesentery, the second directly opposite, and then one suture on either side. The others were inserted in a similar manner, with the exception of the last two. Here Lembert sutures were substituted. Before they were tied, one or two ounces of saturated solution of sulphate of magnesium was injected into the bowel to

secure an early movement. In his case, the patient rallied well from the operation, and felt so comfortable on the third day that she cried because she was not allowed to get up. Dr. Wiggin said that in several other abdominal cases he had employed this modified method, with equally good success. If the sutures were properly inserted and were tied sufficiently tightly, they would be hidden from view.

Two Large Abdominal Tumors.—Dr. Wiggin also presented two large abdominal tumors. The first one had been removed from a woman, about fifty-nine years of age. She was in a very feeble condition at the time, and operation had been declined by several surgeons. An exploratory laparotomy had been done by one surgeon, but as the incision had been made low down and the intestines found adherent, it had been deemed impracticable to remove the tumor. The woman accepted the risk of the operation, and accordingly, after she had been stimulated freely for several days, the operation was done on July 14th. An incision was made from the ensiform cartilage to the pubes. It was found that there were no adhesions whatever above. The pedicle was quite broad, and seemed to spring from the fascia of the pelvic muscles on the right side. From the time of making the first incision to turning the tumor out of the abdomen, about fifteen minutes elapsed. The large abdominal wound healed by primary union, and the patient did well for a considerable time. About three weeks after operation the speaker had gone off duty at the hospital, but he had learned that after five or six weeks the vomiting had returned and the woman had died. The autopsy showed that death was due to kidney disease. The pathological report by Dr. Leon T. Le Wald, of the Carnegie Laboratory, showed that the tumor weighed twenty pounds and measured thirty-two inches in its greatest circumference. The general surface was irregular, with a few small round elevations. The pedicle was situated in the depression between the two main masses of the tumor, and contained a large artery with greatly thickened walls. The tumor had a thin but distinct capsule. On section, the mass presented a nearly homogeneous smooth surface. Microscopical examination showed it to be made up for the most part of smooth muscular fibres and connective tissue, the former predominating. There were areas of infiltration with fat, and others of infiltration with lime. The anatomical diagnosis was myofibroma, probably arising from the intestinal tract.

The second specimen had been removed two weeks previously from a woman, forty-one years of age, who gave a history of an abdominal growth having existed for many years. The tumor grew from the anterior wall of the uterus, and when it was taken out there was free venous hemorrhage. In the efforts to control this, a large portion of the base of the bladder was accidentally cut across, and it was also wounded low down on the right side. The bladder was carefully sutured from the inside with catgut, and a peritoneal flap from the tumor dissected up and used to cover over the sutured portion of the bladder. A catheter was fastened into the bladder and left there for the first twenty-four hours. It was then removed, but the patient was catheterized every two hours. Four days ago the lower angle of the wound had opened, and some urine had escaped therefrom. A self-retaining catheter was then inserted. To-day she had passed fifty ounces through the catheter, and she was now making a very excellent recovery. The pathological report from Dr. Le Wald showed that the tumor weighed seventeen pounds, and measured nine and one-half inches vertically, seven inches antero-posteriorly, and nine inches laterally. Its surface was slightly irregular, with rounded elevations. It had a distinct capsule, which was continuous with the outer surface of the anterior uterine wall. The tumor was very hard, owing to extensive calcification. The posterior wall of the uterus was greatly thickened, owing to a myomatous growth. The ovary was fibro-cystic.

Dr. J. A. Wyeth asked what kind of a needle Dr. Wiggin used in making the end-to-end anastomosis, and whether he had observed any sepsis in these cases.

Dr. Wiggin replied that he preferred to use a straight, round milliner's needle, about No. 7 or 8. He had not observed any sepsis in the cases in which the modified method had been used, and he was of the opinion that it considerably shortened the time of operation. He had done the operation in ten or twelve minutes.

Rapid Formation of Plastic Exudate.—Dr. Wyeth said that this was much more rapid than suture by the Lembert-Czerny method. He had used the latter for the mucous membrane and the Lembert for the outer sutures. Working as rapidly as possible, it had taken him from half an hour to one hour. Although he had never had the courage to undertake it, he had often thought that, as certain perforating wounds of the bowel were not necessarily fatal, it might be safe to use a suture passing through all the coats. Experience had shown him that plastic exudate was thrown out very soon after suture of the intestine. For instance, in one case, in which a patient had died three hours after operation, the autopsy showed that the sutures were entirely concealed in plastic exudate. This was remarkable, considering that the patient was practically moribund at the time of the operation.

Dr. Wiggin said that passing the sutures entirely through the bowel seemed to him to give firmer suturing than the Lembert method. In one case that he had had, the peritoneal coat had been entirely regenerated in sixty hours. Three days ago he had undertaken to close a fæcal fistula by means of the through-and-through suture. Finding at the time of the operation that there was involvement of the stomach, he had operated upon this organ with the same through-and-through sutures. The day previous the patient's temperature had been 100° F. and the pulse 110, and this evening the temperature was 98.6° F. and the pulse 98.

Dr. Thomas H. Manley said that, while theoretically operation was the proper treatment in uterine fibroids, the necessary risks of the treatment and the sequelæ made it proper to defer operation unless very troublesome symptoms were present. It seemed to him perhaps better to treat these cases electrically by the Apostoli method. He had noticed that insanity was not a very infrequent sequel of the removal of fibroids; he had had one such case in his own experience.

The Large Tumor a Rare One.—Dr. Leon T. Le Wald said that the very large tumor presented by Dr. Wiggin must be a very rare one, for in two thousand specimens in the Carnegie Laboratory he had been unable to find anything exactly similar. As there was no connection with the uterus or bladder, it was reasonable to suppose that the growth sprang from some portion of the intestinal tract.

The President said that from his own experience he felt inclined to believe that the tumor had really originated from the uterus, as a subserous tumor with a long pedicle, and that it had become detached from the uterus subsequently and attached elsewhere. He had had such a case, and had followed it during life and to the autopsy table.

The Medical Side of the Alcohol Problem.—Dr. T. D. Crothers, of Hartford, read a paper with this title. He said that one of the inexplicable things in life was the fact that the study of alcohol and its effects on the human race had been left to the laity, and particularly to philanthropists. The injuries from

the use of alcohol had always been a dark, unexplained shadow.

Baneful Effects of Moderate Use of Alcohol.—The ingestion of alcohol accelerated the heart's action ten or fifteen beats a minute at first, but after a while the circulation became slower, so that the pulse rate dropped at least as much as fifteen or twenty beats below the normal. Vision was always diminished and rendered unreliable by the ingestion of alcohol. The acuteness of the sense of hearing was likewise impaired. The increase in the pitch of the voice of persons under the influence of alcohol was due to impaired hearing. Hallucinations of hearing were frequent under such circumstances. The senses of taste and smell were also influenced by alcohol. The sense of touch was always exaggerated or diminished, and careful measurements of muscular force showed that the muscular system did not escape the deleterious action of this poison. If the temperate man suffered from the use of one or two ounces of alcohol in this appreciable way, then the continual or frequent drinking of alcohol must exert a distinctly deleterious influence. All experimenters agreed that when alcohol was taken in excess the result was a profound tissue and cell degeneration and general starvation of the tissues. Alcohol, by its anæsthetic action, soothed the irritable nerve centres, and the effects were so pleasing that the individual desired to repeat the experience. Often this desire to seek relief by its anæsthetic effect was really an indication of a diseased condition, which perhaps was disclosed only by a post-mortem examination. A century ago the anæsthetic action of alcohol created dementia and idiocy, but to-day it was more apt to cause delirium and paralysis. Heredity seemed to be one of the most prominent causes of inebrity.

Treatment.—The removal of all spirits at the beginning of treatment was always followed by the very best results, and unpleasant effects could be neutralized by the use of strychnine in doses of one-twentieth of a grain every three hours, together with the bromides to produce sleep. A calomel purge and a hot bath were useful adjuvants, and coffee was sometimes very beneficial. There was no danger of delirium being produced by this abrupt withdrawal of alcohol. In many cases dementia, well-marked paresis, or tuberculosis appeared when spirits were withdrawn. The special exciting causes should be discovered, if possible, and removed. In some of the periodical cases the attacks were preceded by certain premonitory symptoms which enabled the physician to use preventive measures, such as the use of calomel or saline cathartics, rest or exercise as the case might be, along with acids and vegetable tonics. Apomorphine and mixtures of atropine and hydrastine were always dangerous, on account of their narcotic properties and depressant action on the organism. Cases which had been subjected to active so-called specific treatment always displayed a very marked enfeeblement. Practically strychnine should never be given alone, except immediately after the withdrawal of spirits. At other times it should be combined with cinchona or similar preparations. The coal-tar preparations were of very uncertain value. The various mineral and vegetable acids were exceedingly valuable, and it was often necessary to alternate these tonics at short intervals.

Best Remedy for the Drink Craze.—The most effective remedies for the drink craze were strong solutions of cinchona or quassia bark, given in doses of one or two ounces every hour. It quickly produced a disgust for drink. The action of such remedies was, of course, temporary, unless followed by a regular course of treatment. Hot baths and massage were exceedingly useful. Many cases were curable in the early stages, and the family physician should qualify himself for this important task.

Dr. Wickes Washburn said that the reader of the paper had not told when these cases were beyond the reach of treatment. Personally he believed that the pathological condition which obtained late in the disease was caused by the tortuous and hardened state of the arteries impinging upon the brain tissue, and the consequent interference with the nutrition of this organ, and when this condition existed one could hardly expect much improvement from medical treatment.

Dr. Manley said that it was a noteworthy fact that the victims of alcoholism were now sent to hospitals for medical treatment, instead of being looked upon as criminals and punished therefor. Alcoholism was certainly a disease which came within the province of the physician, and was amenable to medical treatment.

"Wine for the Stomach's Sake."—Dr. Henry Illoway said that the statement had been made in the paper that constipation was one of the causes of the drink habit. He had had a large personal experience with constipation, but had never been able to observe any direct connection between the two. It was rather an antecedent dyspepsia. The drink craze was not infrequently brought about by the medical adviser recommending the use of alcoholics "for the stomach's sake."

Dr. Crothers, in closing, said that there was no time in which the alcoholic disease could be considered curable or incurable. The drink craze was simply a symptom or sign, and its suppression did not mean a cure of the underlying disease. In a rough way it was proper to say that in a certain number of cases constipation was closely associated with the drink craze, and that when the constipation was relieved the drink craze was removed or benefited. Nearly all the periodical cases were practically epileptics—they were storm centres—and their causation was most interesting. The mistake was constantly made of considering these causes as moral rather than physical.

Foreign Body in Uterus.—Dr. A. E. Gallant exhibited a uterus which had been removed post mortem, and which presented certain unusual features. The subject was a colored woman, who had been referred to him by Dr. Avac Cutujian. On September 18th she had had a temperature of 103.5° F. The highest temperature on each day was in the morning, and the pulse constantly remained above 130, notwithstanding the temperature. Intra-uterine curettage and packing had no effect. There were no symptoms or signs of peritonitis. Hysterectomy was advised, but was not consented to. If it had been, it would almost certainly have saved her life. At the autopsy, in the very much softened and gangrenous fundus uteri a foreign body was found, which proved to be vegetable fibre, but further than this nothing had been learned regarding its nature. There was no history of any foreign body having been introduced, but the speaker thought it not improbable that the mass discovered at the post-mortem examination was the remains of a tupelo tent.

False Labor Pains.—As soon as false labor pains are suspected a four-quart enema should be given at once and then a quarter of a grain of morphine hypodermatically. The morphine may be repeated by the mouth in an hour or two if the pain lessens but does not disappear. Nothing stops the pain so rapidly as an enema. Do not think of cathartics. They take too much time and may increase the irritation. In some cases it is impossible to stop the colic until after hot drinks, as ginger and peppermint, or inhalations of chloroform, and even hot fomentations and flaxseed-meal poultices have been used.—Dr. T. Mitchel Burns, *Journal of the American Medical Association*, September 17th.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 20, 1898.

EDWARD JANEWAY, M.D., PRESIDENT.

The Wesley M. Carpenter Lecture: "Modern Views of Certain Symptoms and Causes of Renal Diseases."—DR. CHRISTIAN A. HERTER delivered the lecture. Regarding dropsy, the lecturer said that it was necessary to account for the entire absence of dropsy in some cases of nephritis in which there was suppression of urine for several days, if we were to accept the hydræmic theory of dropsy, propounded by Bartels. He believed that the view first advanced by Cohnheim, which attributed renal dropsy to alterations in the walls of the smallest blood-vessels, would ultimately be proved to be the correct one. In support of this theory was the fact that a very large proportion of cases of acute and subacute renal dropsy were associated with well-defined glomerulous lesions in the kidneys. The glomerulous lesions were of two kinds, viz.: (1) a variety distinguished chiefly by proliferation of the endothelial cells; and (2) a variety characterized by an accumulation of cells in the capsular spaces. The first was the more common. The albumin found in the urine in cases of renal calculus could be proved to have had its source, in part at least, in the glomeruli. While the vascular hypothesis of dropsy was the most satisfactory for the œdemas of acute and subacute nephritis, it was not so generally applicable in its simple form to chronic nephritis. Another element in the production of dropsy in many cases of nephritis was the high arterial and low venous pressure which often existed. From a study of a large number of autopsy records he had discovered that dropsy was almost twice as frequent with kidneys of large size than among patients with contracted kidneys, and that renal dropsy was much greater in cases having large kidneys than those with medium-sized kidneys.

Delayed Excretion.—Delayed excretion might be defined as the postponement of the work of the kidney in ridding the blood of its excretory solids, owing to renal disease. Methylene blue was the substance employed in making the test for this condition. Urea formed within the body in a definite period, and was excreted in a given time under normal conditions. In cases of chronic nephritis it was important to know the percentage of urea in the blood, and this information might be gained from the examination of an ounce of blood. When one grain of methylene blue dissolved in ten minims of water was injected into a muscle, it appeared in the urine in a period varying from ten minutes to half an hour, and it continued to color the urine for a period varying from fifteen to forty-eight hours. When injected into the muscle of a patient suffering from nephritis it appeared usually as promptly as in health, but the time required for its disappearance varied greatly in different cases of nephritis. It had been claimed by some writers that in interstitial nephritis the permeability of the kidneys to methylene blue was diminished—in other words, that excretion was delayed; whereas in parenchymatous nephritis the permeability to methylene blue was increased, or excretion was accelerated. However, his own experiments with methylene blue in ninety-eight cases in the City Hospital did not bear out this view. It was also noticed that in the same individual at different times the period required for excretion of the methylene blue varied. The following deductions regarding the methylene-blue test seemed to be warranted: (1) A distinct delay in excretion was evidence of the inability of the kidney to do its work on time; (2) such delay, when prolonged (four days or more, and repeated), was probably associated with an increase in the urea in the blood, and was to be taken as a sign of latent uræmia; (3) periods of delay in excretion might alternate with periods of normal excretion; (4) the prompt disappearance of the color (within thirty-six hours) was a tolerably accurate indication that the kidneys were excreting the ordinary urinary solids in a normal manner, although the urine might contain albumin and casts. Well-defined uræmic symptoms should be considered a contraindication to the employment of the methylene-blue test. When it was not desired to give the methylene blue hypodermically, it might be safely administered by the mouth in the dose of one grain, but it should be remembered that it was excreted more rapidly than when given subcutaneously—eighteen to forty-eight hours.

Bacteriuria.—The presence of bacteria in the urine was, of course, no proof that they had reached the urine by way of the kidneys, but frequently renal lesions were set up during the passage of micro-organisms through the kidneys. It was now conceded that bacteria might pass through the kidneys in considerable number, without leaving any evidence behind. The manner of their passage was probably comparable to the diapedesis of the blood cells. The kidneys were capable of removing from the blood only a limited number of bacteria. The acute degenerative nephritis of typhoid fever probably depended more upon the action of bacterial products than on the organisms themselves, but it was doubtful if such a nephritis was ever absent when the bacilli were found in the urine. A peculiar variety of bacteriuria was characterized by the presence of a large number of colon bacilli. The urine in such cases was turbid when first voided, and did not clear up on standing. It was acid in reaction and often had an indescribable odor. Albumin was absent unless there was some associated pathological state. Short rod-shaped bacteria were found in large numbers, and they developed the cultural characters of colon bacilli. It was probable that the bacteria reached the blood through some breech in the intestinal tract, and the fact that the bacteriuria was often associated with more or less diarrhœa or other gastro-intestinal disturbance would seem to bear out this view. This form of bacteriuria often proved most obstinate to treatment, but the best results were obtained from the internal administration of salol and the free ingestion of water. Many of the lesions of acute nephritis were the result of combined infections. A large proportion of all cases of acute nephritis were due to infection with the pneumococci, pathogenic streptococci, or staphylococci, the bacilli of typhoid fever, or the plasmodia of malaria.

Amyloid Kidney.—The amyloid kidney had long been a highly interesting enigma, but clinical observation had associated with this disease three conditions, viz.: (1) prolonged suppuration; (2) tuberculosis; and (3) syphilis. Recent experimental studies made it clear that the filtrate of cultures of the staphylococcus aureus were capable of producing amyloid degeneration, especially in the spleen and liver, but also in the kidneys. The long-continued action of the toxins of the staphylococcus seemed to have the power of setting up amyloid degeneration.

Alcoholism and Kidney Disease.—As a result of a study of four hundred and sixty-eight autopsies, Dr. Herter said that he had arrived at the conclusion that there was no special relation between alcoholism and the small granular kidney, and that alcohol was influential in the production of nephritis with the large rather than with the small kidney. This was in accordance with the findings in autopsies on drunkards, *i.e.*, that the kidneys were usually large and congested. Modern investigation had taught us, the speaker said, that kidney disease was not a local process, but was intimately connected with various diseased conditions of the system as a whole.

SECTION ON GENERAL MEDICINE.

Stated Meeting, October 18, 1898.

LOUIS FAUGÈRES BISHOP, M.D., CHAIRMAN.

The Evolution of Scientific Medicine.—The chairman, DR. LOUIS FAUGÈRES BISHOP, read a paper with this title, as follows:

"The fact cannot longer be ignored that great changes have taken place in the economic relations between physicians and the public. It has long been apparent that as a means of earning a livelihood and of winning a desirable position in a community the profession of medicine does not offer the inducements to us that it offered to our forefathers. It would seem that the work of the average man has become more definite and clearly defined. We have come to do, each of us, some particular branch of our art better than in former times. In other words, the physician and surgeon has become more of an artisan and less of an artist. The artist constructs from his imagination—he idealizes. The artisan performs a definite defined work from carefully drawn plans. Even in departments of medicine that it would seem impossible to render scientific, such as mental diseases, the classification has advanced and recorded experience been accumulated, until even the alienist can work according to rule.

"But the evolution of the profession has also been affected by forces from without. The relation of the physician to the community has been profoundly modified by the general progress of knowledge and the extension of science and learning to so many fields of human activity. The number of professions, in the true sense of the word, has been enormously extended. The management of special commercial enterprises, such as railroads, electric systems, great financial corporations, and manufacturing companies, is no longer intrusted to chance employees, who have acquired skill merely through experience, but is conducted by persons especially trained in engineering and technical science. Professional training has become so diversified that the physician finds himself only one of a great many who are set apart to do a particular work because of special education. In the beginning the trades and business were far removed from science and the systematic improvement which comes through development along the lines of exact observation and inductive reasoning. Medicine also was involved in superstition and supported by authority rather than reason. As time has gone on the conduct of all human affairs—commercial, social, and even religious—has come under the dominion of the scientific tendency of the age which leads to simplification of method and organization of effort. At the same time medicine has thrown off mysticism, secrecy, and reliance upon authority. So the public at large and physicians as a class have come near together, and the physician finds himself one of a large number of specialists and subservient to much the same laws as the others. As a laborer, he must find a market like his friends, the electric engineer, and the rest, and must be governed by the same laws of fitness, supply, and demand. Pressure of circumstances will compel him more and more to conduct the business side of his work in conformity with scientific business methods. In fact, to be unbusiness-like is to controvert the order of the just relations of man to man. Business in its best development is more highly moral than many a system of theology.

"A great disturbing element in the business relations of physicians is philanthropy. The physician has more opportunity than others to exercise this faculty, and he also must be acknowledged as having more chances as an individual for gain by the wrongful exercise of the privilege of gratuitous service. He benefits himself but injures the business possibilities of other members of his profession. The same selfish principle is seen in the commercial world when large department stores sell without profit a class of merchandise which they do not care to handle except to induce crowds to come to their bazaar, but which represent the means of livelihood of a large number of small shopkeepers. In this way, for the sake of prestige and experience, the older physician may injure the younger man, as witness the hospital and dispensary abuse. But fortunately philanthropy has not escaped the modern scientific fact that charity must be controlled by fixed principles, and not left solely to the impulse of the emotions. Organization cannot long be deferred. Philanthropy is seeking more and more the guidance of principles and facts developed by scientific method in observation and experiment.

"A suggestion was made by General Sternberg in his address as president of the American Medical Association, that physicians should educate the intelligent public up to the point where it can discriminate between science and charlatanism. His words are so apropos that I cannot do better than to quote them. He says: 'The old saying is that the pen is mightier than the sword. This is, no doubt, true in politics, but in science the pen is a feeble instrument compared with the test tube, the microscope, the chemical balance, etc. Nevertheless I am about to advise well-informed physicians to make greater use of the pen, not for the elucidation of those problems which remain to be solved, but for the purpose of calling the attention of the non-medical portion of the community to the recent achievements of scientific medicine. It is a remarkable and lamentable fact that many persons, belonging to the so-called educated classes, are grossly ignorant as regards the present status of medical science. They not only speak of us as "old-school doctors," but intrust their lives and those of their children to pseudo-scientists, who, taking advantage of popular interest or the great discoveries of the day, make extravagant claims as to the curative power of electricity, the *x*-ray, oxygen, ozone, or some wonderful microscopic destroyer.'

"It is certainly true that a physician can no longer even practise without taking his more intelligent patients into his confidence. A smattering of medical knowledge has become a part of a general education, just as a certain amount of mathematics, astronomy, geography, etc., is a part of the mental furniture of the average thinking and reading man. The dignity of the profession is well maintained when patients are taught that a knowledge of medical facts is common property, that there is some difference in the power of men to observe symptoms, but that the great difference between physicians and between the physician and the layman is in the trained judgment which determines the relative importance of facts and the quantity, time, and character of treatment.

"The tendency in America is to give up all sects in medicine and allow physicians to choose their professional associates purely on the ground of integrity and personal preference. This liberal and scientific spirit has found its chief growth in New York State, with the result that the controversial side of medicine has been abandoned for the scientific. New York may well be regarded as the centre of influence of a modern school of scientific medicine, and a monument has already been raised to it, in the amount of good work in investigation and analysis which has been done. The modern school of scientific medicine relies for its recognition and support upon a public educated in modern philosophy, a public dominated by the scientific spirit of a scientific age. It claims as an advantage that medical knowledge should be open to any curi-

ous seeker, and that many medical facts should be of the common knowledge of the people. The public has already acquired that little knowledge which is so dangerous. It will not give it up. Our only salvation is to go boldly forward and educate the masses to a point where they themselves can discriminate between knowledge and imposition. The enemies of medicine have already entered upon a flank movement, and the newspapers are blackened with advertisements of serums, extracts of organs, and germ killers, some of which assume the names of great discoverers. This movement of charlatanism was only to be expected, and must be met by training the people to distinguish between science and fraud.

"The Academy of Medicine has played its part in justifying medical knowledge and disseminating medical truth, but it cannot rest on its oars. The conclusions of the discussions of yesterday have become the actual practice of to-day, and it must move on constantly to new fields, or must recultivate old fields which have for a time lain fallow. Medical truth can never be attained, but must be constantly sought. It would seem that unconsciously and with many forebodings of evil the profession has worked up to a more scientific plane in the broadest meaning of that term. In the process—as has ever been the case in progress—many old idols have been shattered and the discipline of newly recognized laws has had to be learned."

The Relation of Chemistry to Practical Medicine and Some of the Methods Available in the Daily Work of Physicians.—Prof. R. H. Chittenden, professor of physiological chemistry in Yale University, read this paper. Twenty years ago physiological chemistry had only commenced to occupy a proper place in the scheme of medical studies, when the first independent laboratory had been established in the Strasbourg University under German *régime*. Every new fact that had been brought to light in the laboratory had contributed something to that fund of knowledge which had been of practical value to the general practitioner. A widespread advance in the application of chemistry, physiology, and pathology had been noted in the past twenty years, and the speaker believed that the most important advances in scientific medicine for the next twenty years would be along chemical lines. The micro-organisms were not directly responsible for the ills which they produce; the characteristic symptoms were but the outward manifestations of the physiological action of the specific substances produced by the growth and multiplication of these micro-organisms within the tissues of the body. We now knew that the Loeffler bacillus produced a soluble poisonous substance of a proteid nature, which, when injected, gave rise to the characteristic symptoms of diphtheria, followed by death. Combined chemical and physiological study had made possible the production of an antitoxin which owed its antidotal action to chemical substances. On the strength of Ehrlich's researches it was assumed that the diphtheria toxin was a single definite compound with definite physiological and antitoxic properties only at its origin; in reality it was an unstable substance and there were great variations in the neutralizing power of a fatal dose in different toxins. Toxins readily underwent deterioration. Chemical study had shown that the growth of micro-organisms, both pathogenic and non-pathogenic, was attended by the development of proteolytic enzymes, which were responsible for the soluble proteid products resulting. It was now known that wherever micro-organisms grew the most prominent products which resulted were albumoses or proteoses, akin to those formed by the proteolytic enzymes of the digestive juices. These latter products were quite toxic when introduced into the blood current. Further, when the soluble products of digestion were introduced into the blood current they were rapidly eliminated through the kidneys, just as other poisons were. The point which the speaker wished to emphasize was that in the decomposition of proteids by an ordinary digestive fluid enzyme we had to deal with a progressive hydrolytic cleavage, in which the first-formed products (primary proteoses) were transformed into secondary products (secondary proteoses) and these finally into true peptones. The primary products were much more active than the secondary products, as a rule. The speaker then proceeded to call attention to the many arguments which supported the view that in the zymolysis produced by many pathogenic micro-organisms we had to do with a corresponding hydrolytic cleavage with consequent formation of a now more or less toxic substance, the one formed from the other by successive hydration and accompanied by corresponding changes in toxicity or physiological power. He made the statement that all pathogenic bacteria produced a row of chemical substances endowed with more or less toxic power, and these were chiefly responsible for the characteristic symptoms of a disease. There was clear evidence of the existence of a row of chemical substances elaborated by the several ductless glands, which exercised, as the secretions from the thyroid, a controlling influence over the nutritional processes of the body, either counteracting, or, more likely preventing the formation of toxic substances of great power. To-day we obtained from the thyroidal tissue a specific substance, the iodothyrin, characterized by its containing iodine and being marked with certain physiological properties. In the suprarenals, chemical work had given evidence of the presence of a basic substance, a pyridin base or alkaloid, upon which well-known blood-pressure-raising powers depended. Internal secretions from the hypophysis cerebri, ovaries, testicles, etc., contained chemical substances of undoubted physiological power.

The speaker then referred to the practical value to the physician of the chemical study of food, urine, and fæces, and its bearing upon the general problem of nutrition. He spoke also of the quantitative analysis of the urine and fæces, as well as of the food, with a view to ascertaining the true nutritive value of the latter and the extent of proteid and other forms of metabolism; the data thus obtained would, he said, prove of inestimable value in many questionable cases and afford a basis for accurate diagnosis. The fact that our markets were flooded with food preparations showed how little thought was given to the exact nature and composition of food. He believed that the time would soon come when as much care would be given to this matter as was now given to the remedies prescribed. The chief problem in the determination of the nutritive value of food centred around the proteid or albuminous foods; this required only a determination of the amount of nitrogen. The method of Kjeldahl was readily applicable and yielded accurate results. These matters must, sooner or later, demand the attention of the conscientious practitioner.

Much could be learned in studying the different forms in which nitrogen was eliminated through the urine. To determine with any accuracy whether uric acid was being excreted in large or small quantities, the quantitative method of Hopkins was sufficient for clinical purposes. Uric acid had an origin quite independent of urea. Kossel had pointed out that true nuclein was characterized by yielding on decomposition a row of xanthin bases, all of which contained an alloxin group and a urea group. Uric acid was an alloxin body. The feeding of nuclein-containing foods tended to increase very markedly the output of uric acid. The continued excretion of uric acid during prolonged fasting was mainly due to katabolism of the nuclein-holding cells of the organism. In leu-

kæmia the great increase in the excretion of uric acid was undoubtedly due to the destruction of leucocytes rich in nuclein. For the determination of urea, one should remember that the sodium hypobromite decomposed not only urea but also the other nitrogenous constituents; for clinical purposes, however, this error was not prohibitive, since the object was to obtain the nitrogenous waste.

Very little was known about creatinin aside from the fact that it was increased with a meat diet and decreased with a milk diet and one rich in vegetable matter.

Leucin and tyrosin appeared in the urine as purely pathological constituents. These were the normal products of pancreatic digestion. In the urine they were supposed to be pathognomonic of acute yellow atrophy of the liver; to prove this to be fallacious the speaker cited an instance occurring in his own family in which these substances appeared without being dependent upon this disease. He did not believe the presence of leucin and tyrosin in the urine to be a proof, or indication even, of this disease. He saw no reason why leucin and tyrosin could not appear in the urine whenever the functional activity of the liver cells was interfered with, especially when it was noted that leucin and perhaps tyrosin were antecedent stages in the formation of urea. He recommended a careful examination of the urine for these substances in severe cases of jaundice.

The detection of melanin in the urine was no positive proof of the existence of a melanotic tumor. Melanins were the products of the transformation of proteids. Urines which tended to become dark or black on standing were always open to the suspicion of containing melanogen, which on oxidation gave rise to the dark pigment, melanin.

Ehrlich's or the diazo reaction was originally thought to be pathognomonic of typhoid fever. The speaker believed that when properly tried and with sufficient experience, it had considerable clinical value. The chemogen, which was the cause of the reaction, was met with in other febrile diseases, notably in pulmonary tuberculosis. Simon was quoted as stating: "While the reaction may be observed in other diseases as well as in typhoid fever, it is usually not difficult to distinguish between these and the latter condition except in certain cases of acute miliary tuberculosis. As the reaction, however, is obtained not later than the twenty-second day of the disease, and is usually present as early as the fifth or sixth day in typhoid fever, and while it generally does not appear earlier than the beginning of the third week and then persists almost to the end in acute tuberculosis, its occurrence may be of decided value in diagnosis in many instances."

Indican took first rank, the speaker said, among the normal chemogens of the urine. It was the product of oxidation of the indol formed in intestinal putrefaction. He believed that micro-organisms in the intestinal tract were solely responsible for the formation of indol and its ultimate appearance in the urine as indican. Therefore, the amount of indican to be detected in the urine might be taken as an indication of the extent of intestinal putrefaction, and indirectly as to the acidity of the gastric juice. Indicanuria was almost invariably observed in all cases in which there was hyperacidity of the gastric juice. Skatotyl, coming from the oxidation of skatol, phenol, and paracresol, might also be used as a measure of the extent of intestinal putrefaction.

Of special significance to the clinician was the presence of acetone and diacetic acid in the urine; these owed their origin to the breaking down of the proteid matter of the tissues, and hence were most conspicuous in those conditions in which inanition was pronounced. In the testing for sugar, *i.e.*, glucose, the speaker laid emphasis upon the advantage of using the Böttger-Almen-Nylander test as well as the Fehling's solution. He thought all physicians should be familiar with the phenyl-hydrazin test for sugar; the test was free from all fallacies and was absolutely reliable. He also referred to the chemical tests for the detection of albumin in the urine. The tests usually applied merely testified to the presence of albuminous matter, without indicating the character of the proteid. He briefly outlined the tests for serum-albumin, serum-globulin, albumoses or proteoses, etc. True peptone was never present in the urine, so-called peptonuria being in reality albumosuria. Gastric digestion was next referred to. This might depend upon increased or decreased secretion of hydrochloric acid, more generally the latter, and sometimes upon decreased secretion of pepsinogen or pepsin. Ewald's test meal furnished another illustration of the intimate relation between chemistry and practical medicine. The determination of total acidity, of the relative proportion of free and combined hydrochloric acid, of the presence of lactic or other organic salts, etc., was now carried out by proper chemical tests; the methods at present available were numerous, but were by no means perfect.

Physiological chemistry and pathological chemistry stood in close touch with physiology and pathology. A full understanding of the normal must be had in order fully to appreciate the significance of the abnormal; the line of demarcation between the two was exceedingly thin and wavy. Chemistry could make clear many of the deviations from the normal, which were the forerunners of disease and death. The speaker hoped for a fuller appreciation of the intimate relation which chemistry bore to scientific medicine and for a more extended usé of the many practical methods which chemistry offered as an aid to diagnosis.

Dr. Beverley Robinson said it was his wish to further scientific research. Laboratories should be established in this city as well as throughout the country. Although he recognized that the best possible work was to be done in laboratories, yet there were limits to the amount of work that could be done. At the College of Physicians and Surgeons the student, unless he had had previous training, must acquire a knowledge of chemistry in the first two years. The speaker recognized the importance of this subject, but thought that there were other things in college that should receive more attention; exercise, for instance. The general practitioner of to-day was too busy in his efforts to provide for his family to undertake the tests mentioned by Dr. Chittenden. There was a limit to the amount of baggage that the practising physician could carry; unless a man was an anchorite or a hermit he could not learn all these things. He believed the solution rested in the endowment of laboratories in hospitals; this was the best possible way to provide for the learning of these sciences, which were so important and most essential for the advancement and practice of our art. Great credit was due to the man who gave money enough to equip hospitals so that young men could carry on laboratory research. He did not believe there was any direction in which money could be more profitably expended than in the acquisition of a thorough knowledge of chemistry.

Dr. William H. Thomson said that the great subject of infection had become a chemical one. He referred to the problems that had confronted the profession in regard to the contagium vivum, and its effect when introduced into the system. As soon as it was thought that the symptoms were due to the growth of germ life with the development of toxins, then the subject fell into the domain of chemistry almost exclusively. Vital

chemistry was to organic chemistry as complex as organic chemistry was to inorganic chemistry. Dr. Chittenden had entered upon the subject of urine analysis and the methods of discovering certain ingredients in the urine; the speaker asked if the doctor could promise that chemistry would come to our aid in answering questions connected with uræmia. He had failed to receive a single point on this subject. There was nothing that so frenzied him as that vicious organ, the kidney. We might remove from two-thirds to three-fourths of that organ and the remainder would pass more urine and more urea than before; but we were apt to have rapid emaciation and death from solution of muscular tissues. How was it explained? Again, he asked how one could explain cases in which there was a disorganization of the kidneys and yet not a drop of urine was sent into the bladder. A patient had had a previous impaction of calculus in one kidney; he had a calculus impacted in his remaining kidney; how was he going to die? The speaker had been called into consultation and informed his questioners that the patient would die with symptoms of uræmia. There was no coma and the patient died from pure asthenia. If the ureters of animals were tied they did not die with symptoms of uræmia. These were no small questions, and it was to be hoped that chemistry would render aid in solving them. Pale urine occurred in subjects of nervous disorders, such as hysteria, neurasthenia, etc.; yet cases had occurred in which there was marked textural change in the kidney and here there was pale urine with low specific gravity. He had seen this day a patient with pale urine, of good specific gravity, whom he had watched for several years for uræmic symptoms; there was no albumin and the last specimen showed a specific gravity of 1.025. In diabetes, pale urine he regarded as a danger signal. He asked how we could explain intermittent functional disease, with the sudden nervous explosions and convulsive attacks. In epilepsy and migraine no one could predict when an attack was going to occur. There was no neurologist who could go into company in the evening, and predict that the vivacious lady talking to him would soon be seized with one of these attacks. There were many men going about with kidney disease, carrying on their business, who did not know when convulsions might seize them, because there was no warning. All this, the speaker thought, pointed to toxic origin. To chemistry we must look for an explanation. The speaker had found hydrochloric acid in ulcer of the stomach, occurring in a young woman. He had found it present at times and absent at other times in this disease. In typhoid fever the absence of pepsin was almost invariable if it had run for twenty days. He was much gratified at the emphasis made by Dr. Chittenden in regard to indicanuria. Indican in the urine he considered a danger signal.

Dr. Morris Manges spoke of the diseases of the stomach in relation to chemistry. There was no organ in the body more indebted to chemistry than the stomach. He thought the ordinary analysis of the stomach contents was within the grasp of every one, and that such analyses should be more frequently made, not so much to learn about the acids present, but to learn more about the ferment, pepsin. In typhoid fever he had found pepsin present. If pepsin was to be given he advised giving it in large doses by itself, or in combination with sugar. If it be given with hydrochloric acid, it showed that we had forgotten our chemistry, since hydrochloric acid rendered pepsin absolutely inert. Elixirs of pepsin were also inert. There was no such thing as a specialty in diseases of the stomach any more than there was in diseases of the heart, lungs, or kidneys. He thought that if, in schools, the student should devote as much time to test-tube reactions as he did to the relations of arteries and the course of nerves, we would have more practical physicians and better practitioners.

Dr. A. Rose thought the chemistry of respiration should be studied more. It was well known that the inhalation of CO_2 gas would relieve most of the symptoms of phthisis. There was less cough, the fever was reduced, and the patient's condition was bettered. How was that to be explained? If one inflated the rectum with CO_2 gas, this gas was eliminated through the lungs according to the law of diffusion of gases; more CO_2 was eliminated, more O was introduced. This interchange of gases took place in the alveoli in the lungs, being independent of respiration but governed according to the law already referred to. The final result of introducing CO_2 gas was to improve the nourishment of the body. The speaker had experimented with CO_2 gas in a young girl, sixteen years of age, who was a sufferer from chlorosis. Knowing the effect of CO_2 gas, he induced her to use it by inflation of the rectum. For years she had suffered greatly from insomnia, but under this treatment she recovered.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Abstract of the Proceedings of the Twenty-Fourth Annual Meeting, Held at Nashville, Tenn., October 11, 12, 13, and 14, 1898.

(Concluded from page 639.)

Second Day—Wednesday, October 12th.

The Importance of Early Diagnosis in Surgical Cases.—Dr. J. C. Morfit, of St. Louis, Mo., read a paper on this subject. The diagnosis of a disease ought to be the most attractive feature in the practice of medicine or surgery. It was the foundation on which any plan of treatment was applied. The physician should promptly and exhaustively weigh every indication of cause and effect and apply his therapy accordingly. The speaker had recently seen two cases of pyosalpinx which were cured by surgical interference. Each case had been treated by a good practitioner, yet in neither had there been a complete physical examination, and consequently the real trouble was not detected. One was treated for indefinite inflammation of the bowels, the other for malaria. He cited these cases to emphasize the duty of the physician to himself and his patients of utilizing every available means to arrive at an early and positive decision as to what he was treating.

Gonangiectomy and Orchidectomy for Hypertrophied Prostate in the Aged.—An excellent paper on this subject was read by Dr. George W. Johnson, of Dunning, Ill., in which he reported five cases, and made a second report on twenty-eight cases previously recorded. After referring at length to the literature of the subject and reporting his cases in detail, Dr. Johnson arrived at the following conclusions: (1) All cases of prostatic hypertrophy should be given at least two weeks of palliative treatment, with rest in bed. This treatment should be regulated according to the conditions. (2) If no relief was had from this line of treatment, a thorough and systematic examination should be made for vesical calculi and polypi, as well as structural and malignant disease of the prostate and bladder. Cystitis, acute prostatitis, and prostatic abscess should always be borne in mind. The urine should be frequently examined. In cases of cystitis the ureters should be catheterized to determine the condition of the kidneys. This could now be easily done by the Harris instrument. If by digital examination per rectum the prostate was found to be en-

larged, its approximate dimensions should be noted and urethral measurements taken. The patient should then be as well prepared as possible for operation. Having decided upon operative interference, the operator alone must decide upon what operation he will do. Gonangiectomy or orchidectomy offered less risk to life. (3) Chloroform should be used, as it required less time and was not so irritating to the kidneys. The operation should consume as little time as possible. Gonangiectomy or orchidectomy could be done quicker and with less shock than any other operation. Strict attention should be given to the after-treatment. (4) The time for relief after operation was irregular. In the speaker's experience the relief had not been so clearly defined as to hours and days, or so immediate as in most cases reported. In but two cases had the catheter been required after operation. Enuresis was constantly present in his cases for from one to six weeks after operation. (5) More immediate relief was given to cases of orchidectomy, and the prostate grew softer and diminished more rapidly in such cases than when gonangiectomy was done. (6) The kidneys should be carefully watched and supported after operation. Mental symptoms appeared in three of his cases, two of which were due to renal disease. (7) Long-standing and troublesome herniæ could be successfully treated in the aged. He had successfully treated eighty-four such cases, in none of which had a recurrence taken place up to this time. Of this number he had encountered the condition of congenital with acquired hernia in six cases. In five of the cases the acquired sac was outside of the congenital one. In one case it was within it. (8) Bassini's operation was resorted to in all but five cases, and in these Fowler's method was used. (9) Cystic degeneration of the testicles was met with in twenty-five cases. These usually had chronic hydrocele also, and were always cases with hernia of long duration. (10) When the intestines occupied the scrotum in a large mass, they were returned to the abdominal cavity three or four days before the operation. In many cases there were adhesions preventing reduction. (11) Examinations were always made for vesical calculus, but none was found. (12) The somatic condition was greatly improved, and when bilateral orchidectomy was done the patients became obese. (13) A thorough line of palliative treatment of from two to six weeks' duration, with rest in bed, was given each patient. (14) In cases of herniotomy the patient was kept in bed from three to five weeks, unless very asthenic, with the hope of getting better organic union and thereby minimizing liability to recurrence.

Third Day—Thursday, October 13th.

Address on Surgery.—Dr. George Ben Johnston, of Richmond, Va., delivered the address on surgery. His subject was "The Progress of Renal Surgery." Renal surgery was altogether a matter of the past three decades, it having had its commencement with the successful nephrectomy performed by Simon in 1869. Dr. Johnston dealt with nephrotomy; floating and movable kidney; renal and ureteral calculi; neoplasms of the kidney; tuberculosis of the kidney, when not a part of a general miliary tuberculosis, which he said might either have its origin in the kidney or be an ascending affection from the bladder. Hydronephrosis also received attention. He made no attempt to arrive with anything approaching completeness at the progress or present status of surgery of the kidney. He had endeavored merely to point out some of the advances which had been made in this field of surgery, and to indicate the present views of surgeons upon some of the most important points. Especially did he emphasize the conservatism which had developed along this line, and which now marked the attitude of the surgeon in this as in other branches—a conservatism which realized that the glory of surgery was not in amputation and in mutilation, but in saving important organs.

"Why I Perform Vaginal Ablation in Pelvic Inflammatory Cases."—Dr. William R. Pryor, of New York City, stated that when he performed hysterectomy in pus cases, he preferred the vaginal route, and gave his reasons. He dealt with the subject under the heads: Incision, separation of adhesions, direction of effort in the enucleation, hemostasis, drainage, hernia, accidents, instruments, narcosis, and time, convalescence, and results. Up to October 1st of this year he had performed vaginal hysterectomy for pelvic inflammatory lesions, exclusive of fibroids and cancer, in eighty cases. Since then he had done the operation a number of times. No patient had died, either from the operation or from complications. He had no fæcal fistulæ to report, no sinuses, no vesico-vaginal fistulæ, and no hernias. There had been no cases of phlebitis and no intestinal obstructions. The vagina had in no case been shortened. (For the technique of the operation he referred the reader to the *American Journal of Obstetrics*, vol. xxxviii., No. 6, 1898.)

A Consideration of the Limit to Operative Gynæcology.—Dr. Shelby C. Carson, of Greensboro, Ala., read this paper. The purpose of the speaker was to emphasize the importance of medical gynæcology; to show that surgery could not advance a legitimate claim even to the larger portion of this great field. A beautiful tribute was paid to this branch of medicine by applying to it the eloquent eulogy of Daniel Webster upon justice. Surgery as a science was pronounced as practically without limit, but as an art it had probably reached the summit. What constituted true surgery was then discussed, the author quoting not only from text-books, but from the latest utterances of such men as Wyeth and Annandale, to prove that surgery, of all other branches, was based upon principles and hedged in by fixed laws; that when these were disregarded there was no true surgery. The folly of the ablation of the ovaries and tubes in many cases was made manifest. The nerve element in woman was closely considered, the anatomical connection between the nervous system and the genitalia being defined. As a consequence of this connection, neurasthenia was frequent, for which surgery afforded no relief.

The Therapeutic Value of Leaving Large Quantities of Decinormal Salt Solution in the Abdomen.—The author of this paper was Dr. J. Wesley Bovee, of Washington, D. C. He reported six cases to illustrate the usefulness of this procedure. In a number of cases the effect was not so marked, and in a few but little benefit was apparent. The first case was one of papillomatous broad-ligament cyst; with fifteen litres of decinormal salt solution left in the abdomen there was marked increase of urine. In Case 2, large multiple uterine fibroma and large ventral hernia, a secondary operation, three litres of decinormal salt solution in the abdominal cavity and one litre under the breast produced a marked urinary increase. In Case 3, papillomatous fibro-adeno-cystoma of the right broad ligament, eight litres of decinormal salt solution was left in the abdomen; there was considerable urinary increase. In Case 4, multilocular ovarian cyst, five thousand cubic centimetres of decinormal salt solution was left in the abdomen; there was increased excretion of urine. In Case 5, multiple fibroma of the uterus and pelvic adhesions, with great shock, two litres of decinormal salt solution left in the abdomen increased the urinary excretion. In Case 6, multilocular chondro-cystoma of the left ovary, seven litres of decinormal salt solution was left in the abdomen, and the urinary excretion nearly doubled during

the following six days. The marked stimulating effect of the solution on the kidneys was noticeable in all these cases. Penrose had found that the average amount of urine excreted during the first twenty-four hours after operation in one hundred cases was 13.4 oz.; for the second, 14.6 oz.; and for the third, 19.8 oz. He also found that for the first day the maximum amount of urine was 27 oz. In many of the cases of the essayist this maximum was much more than doubled. While the number of cases in which he had used these large quantities of decinormal salt solution was small, the effect should encourage a further application of the remedy in proper cases. Not one evil effect of the solution was observed in any of the cases.

A Plea for Pelvic Cellulitis and Peritonitis.—Dr. F. F. Bryan, of Georgetown, Ky., read a paper with this title. He reported twenty cases, and drew the following conclusions: (1) Cellulitis and peritonitis were important manifestations, leading to the greatest amount of suffering that woman was heir to. (2) Their recognition and the retention of their nomenclature should keep physicians constantly on the watch for them. (3) Their proper treatment in the early stages would obviate these latter evils to a great extent, as cellulitis and peritonitis were easily curable in the early acute stages. (4) Should opportunity for an early cure not be offered, then the chronic cases should have the medical and minor gynæcological treatment mentioned, under which many would be cured and others obtain relief. A respectable quota would of necessity have to turn to surgery for their cure.

Surgical Treatment of Paralysis in Children.—Dr. Alex. C. Wiener, of Chicago, read this paper. A clear distinction should be made in diagnosis as well as treatment between cerebral and spinal paralyses. A common symptom in both diseases was muscular paralysis, and yet there was a great difference between the two affections. In spastic paralysis one group of muscles became rigid and overpowered its opponents, rendering them overstretched and useless, but still their innervation was by no means disturbed. In spinal paralysis there was a true degeneration of the lower neuron and the dependent muscular groups. This being borne in mind, the treatment was to equalize the balance between the spastic and the overstretched muscular groups by lengthening the rigid muscles. This was accomplished either by tenotomy, resection of tendons, or loosening the attachments of the muscles from the bone, as was done in a spastic condition of the adductor muscles of the pelvis. The after-treatment consisted mainly in not allowing the extremity to leave its overcorrected position too soon, and in strengthening the functionally weakened opponents by massage, baths, and electricity. Apparatus in these cases was utterly useless and should be entirely discarded. Any other peripheral cause of reflex irritation, as phimosis, occlusion of the prepuce, or of the clitoris, of course was to be removed. In anterior poliomyelitis we had to deal with a true paralysis of certain muscular groups. This might be overcome by apparatus which supplanted the paralyzed muscles, or by operative procedures. These consisted in dividing the belly of an active muscle up to the place of its insertion, and sewing the corresponding part of the tendon into the cleft of the tendon belonging to the paralyzed muscle. The inactive muscle was thus supplied with the vigor of the innervated muscle. Care should be taken, as Milliken had pointed out, that the sheath of the tendon was preserved. By this artificial change in the arrangment of muscles the function of one muscle was transmitted to another. There took place an alteration of the reflex activity in the nerve centres of the muscles; hence the importance of the function of the extremity was by no means in its merely mechanical action.

The Diagnosis of Gonorrhœa in Women.—Dr. Joseph Rilus Eastman, of Indianapolis, read this paper. The diagnosis of this affection in women was comparatively easy, even without the microscope. With a history of impure coitus, free purulent secretion from the vulva, vagina, and urethra, intertrigo, burning on micturition, and vesical tenesmus, the diagnosis was not far to seek. Upon inspection one usually detected a discharge of tenacious pus, or greenish or yellowish streaks upon the linen might alone be in evidence. The symptoms of gonorrhœa in women were dwelt upon at great length. The gonococcus grew fat upon flat epithelium. A comprehensive examination of the discharge was not complete until the secretions of the urethra, Skene's lacunæ, the glands of Bartholin, the vagina and cervix had been searched through; and in chronic cases several preparations should be made from each of these. To secure unmixed gonorrhœal pus from the cervix uteri, care should be taken that the platinum wire did not come in contact with the vagina. It was best first to rinse and then dry the vagina with cotton, to free it from mucus. It would be concluded after many examinations for gonococci that the urethra was the seat of predilection of gonorrhœa in women, and that the vulvitis and vaginitis were secondary, being caused by the bathing of these parts with the discharge from the urethra and cervix. The diagnosis of acute gonorrhœa might be made by contemplation of the clinical phenomena alone. For example, if acute urethritis was present, it was almost certain that the gonococcus was to blame. Observation for a few days would establish the diagnosis beyond conjecture, since the symptoms of non-specific urethritis would disappear rapidly. In chronic gonorrhœa too much dependence upon clinical manifestations was hazardous. Condylomata were often present, but appeared also often independently of gonorrhœa. Débris-laden discharge from the vulvo-vaginal glands was usually an expression of old gonorrhœa, but other germs, as the staphylococcus aureus and saprophytic forms, might occasion just such a discharge. Among the more common indications of chronic gonorrhœa were the maculæ gonorrhoicæ of Sänger, red papules about the openings of the vulvo-vaginal glands, sclerotic inflammation of these glands (in which the glands were felt as hard, non-sensitive nodules, under the examining finger), cysts of these glands, and scars and erosions in the vulva. All of these conditions might be caused by other germs than gonococci. Here, as in acute gonorrhœa, the most reliable indication was the urethritis.

Posterior Displacements of the Uterus.—Dr. A. M. Cartledge, of Louisville, read this paper, in which he dealt with the subject from a clinical standpoint. He discussed the causes, symptoms, and diagnosis of these displacements. Treatment should be divided into measures which corrected the cause and methods of support by suturing and shortening the round ligaments. Sometimes it was necessary to employ both methods in the same individual, in order to make the result durable. In the first category were to be included thorough curettage, repair of cervical lacerations if present, perineorrhaphy and restoration of the pelvic floor, with the use of tonics, laxatives, and rest. These methods, if carried out persistently, would ultimately relieve the vast majority of posterior displacements. They were not so dramatic or sudden in their relief as ventro-fixation and the Alexander operation, but were more in accord with rational ideas. In order to succeed they required time—six to eight months—for the structures to resume their normal tone. They also usually required to be supplemented during some weeks or months following their performance by anterior and posterior tamponade, or a well-fitting pessary should be employed to hold the uterus in position

until the repaired parts regained their strength. It was irrational surgery to use any form of support until existing causes had been as far as possible removed. As between ventro-fixation, vagino-fixation, and the Alexander operation, preference should be given the latter, if no accompanying disease was suspected. When such disease existed the operation of ventro-fixation should be practised, as it gave opportunity for inspection and correction of the pelvic disease. It was the best operation in all cases of adherent uteri.

Some Phases of Intestinal Obstruction.—Dr. A. H. Cordier, of Kansas City, Mo., followed with this paper. The causes of this condition were many and varied. Modern methods of diagnosis in skilled hands had led to the saving of many lives, which, heretofore, would have been lost by delay in resorting to the proper treatment. While the diagnosis of intestinal obstruction could usually be made early, there were some cases in which the pathological manifestations were so insidious or vague that their detection required time and much careful clinical analysis. The symptoms of intestinal obstruction were thoroughly outlined. The speaker said that the falsehoods uttered by pain and the truths left untold by opium had been very expensive to human life in the management of intestinal obstruction. Surgical treatment for the relief of this condition should be resorted to early. It should be thorough and quick. No protracted delays or chronic surgery should enter into the management of an acute intestinal strangulation, as these cases stood prolonged anæsthesia and slow surgery badly.

Dr. F. F. Lawrence, of Columbus, Ohio, followed with a contribution entitled "Essentials to Success in Abdominal Surgery."

The Surgical Treatment of Exophthalmic Goitre.—Dr. Bayard Holmes, of Chicago, read a very interesting paper with this title. He said the surgical treatment was based on the theory that in this disease the direct morbid factor was an increase in the normal excretion of the thyroid gland. He gave a synopsis of the physiology and pathology and an outline of the embryology of the thyroid, and also reported a case in which he had operated, the results in which were a very powerful argument in favor of surgery in dealing with this affection.

Some Forms of Gangrene and their Treatment.—Dr. J. S. Nowlin, of Shelbyville, Tenn., read this paper. The term gangrene meant death of a part, and was applied to the soft tissues. The blood was always involved in this disease. If the blood was performing its functions, there could be no local death. The blood channels being destroyed, gangrene necessarily followed. Gangrene appeared sometimes suddenly after injuries to the spinal cord. A normal functional activity in the blood prevented the first step in the process of inflammation. Simple endarteritis might be the cause of gangrene; an inflamed artery was then surcharged with blood, stasis resulted, coagulation took place, the lumen was destroyed to a certain extent, and gangrene resulted. Sepsis was doubtless a most frequent cause of gangrene in the extremities. In traumatic gangrene the surgeon should look out for sepsis. If there was a simple endarteritis with tissue formation, amputation should be performed at the first evidence of failing vitality.

Fourth Day—Friday, October 14th.

Diphtheria and its Logical Treatment.—Dr. A. M. Osness, of Dayton, Ohio, contributed a paper on this subject. He said that the pathological process in diphtheria was caused by the serum albumin at the point of infection becoming modified from incorporation with the specific virus. It was then repudiated by the blood stream and exuded into the neighboring tissues, where it, plus necrotic cells and fibrin, formed the pseudo-membrane, a congenial nidus for the Klebs-Loeffler bacillus. The intoxication of the system depended upon the energy of the lymphatics, upon which devolved the removal of the exudate. In the treatment the use of antitoxin serum offered the risk of over-toxicity, from additional toxin or systemic impairment, and from invalidation of the centres; monosulphide of calcium had been given in three-quarter grain doses every half-hour for a period of thirty-six hours to children, with the best of results. Water should be taken internally quite freely to help elimination of the toxin, local swabbing being resorted to as well, with a mixture such as the physician should deem necessary.

The Early Diagnosis of Diphtheria.—Dr. William K. Jaques, of Chicago, followed with an excellent contribution on this topic. He said that outside of laryngeal complications the mortality from diphtheria was due to the toxin produced by the Klebs-Loeffler bacillus. No physician could successfully treat diphtheria unless he understood the nature of this toxin, how it was produced, and how the cells might be fortified against its destructive action. He must understand that the Klebs-Loeffler bacillus was a distinct living entity or vegetable organism; that one of the products of its existence was diphtheria toxin, just as the result of the life of the yeast plant was alcohol. To appreciate the danger of his patient, a physician must understand the rapidity with which these bacilli multiply under favorable conditions. The clinical symptoms manifesting their residence might give no indication as to the rapidity with which the fatal amount of toxin was being produced. It being understood that toxin was a product of these germs, their multiplication meant an increased amount of toxin, which soon reached the fatal point unless checked by the use of antitoxin. This demonstrated the importance of a physician knowing at the earliest possible moment what germs were present in an angina. In order to ascertain the value of direct diagnosis, by which was meant the examination of material taken directly from the infected area without waiting for incubation, the Chicago health department had introduced the following culture outfit for the use of physicians: A sterilized swab was placed in a glass tube; a slide carefully wrapped in paper was placed with this in an envelope, together with a culture box and directions for using the same. Physicians were requested to inoculate the swab from the inflamed site, spread a little of the mucus upon the slide and allow it to dry. The culture medium was inoculated from the same swab and it was returned to the glass tube. The whole outfit was then to be sent to the nearest incubator station or laboratory. When no antiseptic treatment had been administered before the culture was taken, and the disease manifested malignancy by stupor, hoarseness, or swelling of the cervical glands, it had been possible in about fifty per cent. of the cases to find sufficient bacilli to warrant a diagnosis of diphtheria, even before any trace of membrane was visible. When it had been possible to get a small portion of membrane to spread on the slide, there had been no difficulty whatever in about seventy-five per cent. of the cases in making a direct diagnosis. In the malignant form of diphtheria nearly fifty per cent. of the cases were fatal unless proper treatment was administered. Any physician who neglected to make a correct diagnosis during the time when the remedy was efficacious, *i.e.*, during the first two or three days, was responsible for the result. The technique of bacterial diagnosis of diphtheria was simple. The entire outfit for this work might be obtained for less than $100. The essentials might be acquired at home by any physician who was willing to devote no more than his leisure moments to it. To demonstrate the protective value of antitoxin, the following experiment had been

conducted: On October 10th, in the presence of Dr. F. W. Reilly, assistant health commissioner of Chicago, Dr. Wynekoop, assistant bacteriologist, the essayist, and Dr. Adolph Gehrmann injected nine guinea-pigs with four times the fatal doses of diphtheria toxin. The first three animals had been immunized two days previously by the injection in each of one-tenth of a cubic centimetre of antitoxin. The next three received two-tenths of a cubic centimetre of the same antitoxin each, following the injection of toxin. The third three had no treatment whatever after the injection of the toxin. The pigs were correctly labelled as to condition. They presented decided effects upon the fourth day. All pigs that received antitoxin were alive and apparently well. Of the three not protected, two were dead. The third three being still alive would indicate the possession of natural immunity against the toxin.

Pichi.—Dr. H. W. Whittaker, of Columbus, Ohio, read a paper on the therapeutic uses of pichi. In Chile, South America, pichi, he said, was found growing in abundance as a shrub. No doubt the active principle of the drug resided in the balsamic resin, but chemical examinations had so far been unsatisfactory in determining its chemical composition. The annoying symptoms of chronic cystitis with enlarged prostate yielded to the action of pichi, as was illustrated by the citation of a case. Cystitis complicating specific urethral infection, involving the prostatic urethra, was a combination which under favoring circumstances did not readily respond to treatment, and yet under the influence of this drug the conditions became more tolerable. This remedy was indicated in all of the various forms of diseases of the liver. In gallstones, pichi had proven a valuable remedy in assisting the secretion of bile and theoretically aiding the discharge of the stones. Uric-acid formations rapidly disappeared from the urine under the corrective influence of this remedy and the general condition of the patient improved.

Dr. J. H. Carstens, of Detroit, reported a case of rupture of the body of the uterus during confinement.

A Few Practical Points in the Treatment of Posterior Urethritis.—This paper was read by Dr. A. Ravogli, of Cincinnati, Ohio. The author recapitulated the principles of the treatment for this disease. (1) Irrigations with the Janet method in a recent case of gonorrhœa would in many cases prevent posterior urethritis. (2) Irrigation with the recurrent catheter with permanganate of potassium, followed by injections of protargol, would cure in a relatively short time a case of subacute posterior urethritis without complications. (3) When chronic posterior urethritis had lasted for a long time, and had caused infiltration of the submucous tissues, then the application of a sound with ichthyol salve gave the best results.

Dr. F. E. Kelly, of Lamoille, Ill., read a paper on varicocele. The author outlined the operation for radical cure and the indications for its performance. He considered Bennett's operation of resection of the veins and shortening of the spermatic cord the ideal radical procedure, which he described in detail.

Dr. R. A. Bate, of Louisville, read a paper entitled "The Arthritic Diathesis." The term diathesis was applied to an inherited predisposition to altered nutrition. He assumed in diathesis an inability on the part of the cells to produce oxidation. He mentioned the diseases generally conceded to be dependent upon the arthritic diathesis. He stated that he had experienced favorable results from antilithæmic remedies in glycosuria, nasal and bronchial asthma, lithiasis, albuminuria, obesity, eczema, paresis, rheumatism, angina pectoris, recurrent typhlitis, vertigo, biliousness, dyspepsia, neuralgia, and migraine.

A Trilogy of Diseases: Acute Articular Rheumatism, Endocarditis, and Chorea.—Dr. Albert E. Sterne, of Indianapolis, contributed this paper. He advanced considerations concerning the nature of these three affections and of the connection of chorea with manifestly infectious disease, namely, acute articular rheumatism. A case in point was reported. While he could report several instances of chorea associated with both arthritis and heart lesions, this was the only case known to him in which the sequence of this trilogy seemed distinctly connected with a suppurating injury, following a fairly incontestable portal for the invasion of the system by the ordinary pus microbes. If it was admitted that valvular disease was mainly rheumatic, or at least infectious in character, then the list of cases of chorea connected with the diathesis became much greater, inasmuch as from twenty-five to fifty per cent. (Osler) of cardiac patients gave a history of chorea. Looking at the question impartially, it seemed almost imperative to assume an intimate relationship between the three diseases.

Condemnation of Behring's Conduct.—The following preamble and resolutions were offered and unanimously adopted:

"*Whereas*, The general public, the medical profession, and the drug trade of the United States have long suffered extortion at the hands of foreign manufacturers of synthetic remedies; and

"*Whereas*, Our lax and indulgent patent laws bestow a triple monopoly upon the process, the composition, and the name of chemical products for medicinal use, thus excluding every possibility of a healthy competition; and

"*Whereas*, The same evil has been recently disclosed in the domain of biological medicine by the patent granted Prof. Emil Behring and the Hoechst Farbwerke on antidiphtheritic serum—a patent which could not be obtained in Germany, France, England, or Canada; therefore be it

"*Resolved*, By the Mississippi Valley Medical Association, that the seal of its condemnation be placed upon the unethical and unprofessional conduct of Professor Behring; that it is the duty of every member to renounce the use of the Behring serum; and that the American manufacturers who purpose contesting the patent in the courts are entitled to the moral and substantial support of every American practitioner;

"*Resolved*, That an earnest appeal be made to the members of the commission on the revision of our patent and trade-mark laws, appointed by President McKinley, and their assistance invoked for the modification of existing laws and the suppression of prevailing abuses;

"*Resolved*, That a copy of these resolutions be sent to every medical journal in the United States and to the members of said commission, as follows: Hon. Arthur P. Greeley, assistant commissioner of patents, Washington, D. C.; Hon. Peter Grosscup, Chicago; and Mr. Francis Forbes, New York City;

"*Resolved*, That the members of this society be urged to write their congressional representatives at Washington, and bespeak their support of any measures of relief ultimately proposed by the commission."

Officers.—The following officers were elected for the ensuing year: *President*, Dr. Duncan Eve, Nashville; *First Vice-President*, Dr. A. J. Ochsner, Chicago; *Second Vice-President*, Dr. J. C. Morfit, St. Louis; *Secretary*, Dr. Henry E. Tuley, Louisville, re-elected; *Treasurer*, Dr. Dudley S. Reynolds, Louisville, re-elected.

Chicago was selected as the place for holding the next meeting, the time of which is to be fixed by the committee of arrangements and the executive officers.

Toothache, arising from catching cold, sodium salicylate, gr. xv. every four hours.—Frederick C. Coley.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 29, 1898:

	Cases.	Deaths.
Tuberculosis	217	154
Typhoid fever	73	23
Scarlet fever	108	6
Measles	57	1
Diphtheria	132	18
Laryngeal diphtheria (croup)	8	9
Cerebro-spinal meningitis	0	6
Yellow fever	1	0

In the Klondike.—American physicians, it is said, are being debarred from practice in Dawson, and one is reported to have been arrested. There would seem, however, to be plenty of work for medical men, since typhoid is quite prevalent and the two hospitals are overcrowded.

Heredity and Disease.—Dr. Harry Campbell (London *Lancet*, September 10th), in an essay on the "Marriage of the Unfit," says: "I maintain that all diseases are hereditary; you cannot eliminate the influence of heredity from any disease, and I will prove it. What is disease? It is abnormal life. And what is life? It consists of an interaction between the individual and his environment. Therefore disease is an abnormal interaction between the two. It follows that you cannot possibly eliminate the part played by the individual from the causation of any disease, since it is his structure which determines whether he shall or shall not react abnormally to a given environment Now his structure is essentially determined by heredity. I have therefore proved my point. This is no mere logical quibbling, but a practical fact. I will test my position by taking a disease with which most people will probably say heredity has nothing at all to do—the wheal caused by flea bite. This affection depends upon the morbid interaction of the host and the specific environment constituted by the poison with which the parasite inoculates him. As every one knows, the liability to be flea bitten and the tendency to suffer from wheals when thus bitten differ greatly in different individuals. Some suffer little or not at all in this way; others grievously. Upon what does this difference depend? It depends upon differences in the organization or structure of the host, and these differences are essentially determined by heredity. Hence all parasitic diseases, from a flea bite to pulmonary consumption, from typhoid to malignant tumor, are hereditary. Such diseases depend upon defect in the organism as regards some specific environment; but others, such as chronic Bright's disease, diabetes, ovarian cyst, strangulated hernia, may occur independently of any specific environment, and it is obvious that these are, *a fortiori*, hereditary.

Aphasia in Relation to Testamentary Psychology.—Dr. William Elder (*British Medical Journal*, September 3d), in a discussion on this subject at the sixty-sixth annual meeting of the British Medical Association, drew the following conclusions: (1) That organic diseases of the brain may render a patient incapable of making a will, and that some form of aphasia may be produced also as one of the symptoms of the organic disease. (2) That some forms of aphasia may render a patient incapable of will making. (3) That auditory aphasia, if at all well marked, incapacitates a patient from will making. (4) That some other forms of aphasia, such as pictorial word blindness, pictorial motor aphasia, and graphic aphasia, may render a patient incapable of making a will, not necessarily from his being mentally incapable, but from the difficulty of carrying out the legal formalities. (5) That these difficulties in carrying out the legal formalities necessarily vary according to the law of the particular country. (6) That in simple uncomplicated cases of infrapictorial auditory, infrapictorial visual, and infrapictorial motor aphasia, the subjects are capable of valid will making.

Suicides, which have been rather frequent of late among returned soldiers, are attributed in some quarters to overdosing with quinine and other drugs. Perhaps a quack remedy, which is being widely advertised as recommended by Miss Clara Barton, may have something to do with it. We trust her published letter in relation to her use of this nostrum among the soldiers is a forgery.

Long-Distance Diagnosis.—Brilliant as is the accomplishment of making a diagnosis across the room or at first glance, the process is not always a safe one. According to the *Lyon Médicale*, Professor Renaut recently had occasion to pay a visit to a pharmacist, on a matter of substitution in a prescription the professor had written and said he would like to see him privately. The druggist invited his visitor, who was unknown to him, to enter his private office, and when closetted said to him with a smile: "I know why you have come to consult me; it is because of a *chaudepisse* which has gone down into the testicle. I saw it at once by the way you got out of your carriage."

Dreams.—Dr. A. Pilcz, in a very interesting psychological article, concludes as follows: (1) A periodicity in the intensity of dreams cannot be demonstrated. (2) There exists a relation between the subject of the dream and the intensity of the sleep, in this sense, that the deepest sleep is dreamless, or brings up only such groups of association as took place in the psychical life of the patient at some time long ago, and which in the waking state are more or less forgotten. Memory pictures of recent date, which belong to the actualities of life, are reproduced in dreams in only a minimum of deep sleeps—that is, in restless sleep. (3) This rule also appears to apply to the insane. (4) Chronic insane patients do not dream, as a rule, of the "diseased ideas" which in the waking state are uppermost in their minds.—*Wiener klinische Rundschau*, August 7th.

Embalming Crushed Members.—*Health*, July 30th, is responsible for the following: "A woman, eight and one-half months' pregnant, had her hand crushed in machinery. For several days the hand was plunged for hours at a time in phenicated and disinfected hot water. Then a few whiffs of chloroform were given and the toilet of the hand was accomplished with quantities of very hot water and solutions of sublimate and potassium permanganate, removing the loose projecting fragments of bone. Small squares of soft gauze impregnated with a polyantiseptic salve were carefully fitted into every crevice, covering the hand entirely, and the dressing was completed with a thick layer of cotton and a tight compressing bandage outside of all, to secure anastomosis of the vessels. She then left for a maternity, where she underwent a normal confinement. The embalming dressings were not touched for three weeks, and, when removed, under a thick layer of fœtid, chocolate-colored fluid the wounded surface was found covered with healthy granulations, with the necrosed parts entirely eliminated. An autoplastic operation was performed a week later, which healed rapidly."

TECHNIQUE AND USE OF SALINE INFUSIONS.*

BY THOMAS F. REILLY, M.D.,

NEW YORK.

SINCE the physiology and pathology of the organism have become better understood there have been frequent attempts to influence its morbid conditions by direct medication of the blood.

In the earlier efforts blood itself was used, and successfully, to combat the anæmia of hemorrhage; but the difficulties attending its use were so many and the dangers so great that it could never come into general use. Milk was tried, but the results were not satisfactory. Although the use of the saline solution by intravenous injection is recorded as early as 1832, it is only since 1878–81 that its value in hemorrhage has been generally recognized. Even now, despite the fact that its wide range of usefulness has been so thoroughly established, it is very seldom employed by the general practitioner. In some quarters the fear is expressed that there will be difficulty in getting the solution to flow into the vein; in others, that some dire evil will result, should even a single bubble of air find its way into the circulation; and, like other remedies thought to be difficult of administration or dangerous in use, it is often delayed until all hope of success is futile.

Methods.—The methods by which the solution is introduced are: (1) the direct (intravascular); (2) the subcutaneous (hypodermoclysis). Under the direct may be included: (1) intra-arterial; (2) intravenous. The technique in the intra-arterial method is practically the same as in the intravenous, except that the solution is injected toward the periphery.

Dawbarn has successfully used a modification of this method, which consists of the injection of the solution into a large artery through an aspiration needle that is thrust directly into the vessel. On account of the danger of sloughing the intra-arterial method is seldom employed. Of the other two methods the intravenous injection has the wider range of usefulness. For direct results, for speed and painlessness of the procedure, it is easily pre-eminent. Furthermore, in toxic conditions when a depurative action is desired, the subcutaneous method is unsatisfactory, owing to the fact that after the tissues have taken up a certain quantity of the solution absorption ceases, for a time at least, and this cessation cannot occur when the solution is introduced directly into the vein.

In advanced cardiac disease, when the additional strain on the heart would be too great, or whenever a sudden rise in the blood pressure is likely to be attended by serious results, the intravenous method is contraindicated, and resort must be had to the other method.

However, if any prejudice exists against a skin incision and when haste is not a factor, the average physician will still prefer the subcutaneous method. For subcutaneous use an aspirating needle, attached to a Davidson syringe filled with the solution, is plunged into the loose connective tissue of the abdominal wall, the axilla, or, in females, under the breast, and the solution pumped in. In lieu of a Davidson syringe, an ordinary fountain syringe, elevated about six feet, will answer. Another valuable appliance, suggested by Dr. H. A. Kelly, is the reversed aspirator, for the use of which the solution is placed in the jar of an ordinary aspirator and air is forced in, displacing the solution. In whichever way the solution is administered subcutaneously, not more than from six to ten ounces can be introduced in one place, and for that reason many punctures are necessary. The pain is not so severe if glycerin or carbolic acid be added to the solution (Mathieu). No accidents appear to have followed this method, as not even an attack of cellulitis is recorded against it.

Inasmuch as the intravenous method is generally regarded by the majority of physicians as a formidable operation, more attention will be given to its details. The apparatus commonly employed in the hospitals of New York for this purpose consists of a glass funnel connected by a piece of rubber tubing, three feet or more in length, to a cannula, about four inches long by one-eighth of an inch in diameter, curved for about an inch at its point, to facilitate its introduction into the vein, and is generally provided with a stopcock.

The method commonly employed is as follows: The forearm is placed in a position of supination. After thorough cleansing of the part, a bandage is tied about the middle of the arm, so as to distend the veins. An incision, an inch long, is made at the bend of the elbow, over the median basilic or cephalic vein, whichever is the more prominent. The incision is carried through the skin and fascia. With a grooved director the fat overlying the vein is torn away and the vein raised from its bed. Two catgut ligatures are next passed beneath the vessel. The distal ligature may now be tied in the lower angle of the wound, but it is better to wait until the vein has been opened, on account of the uncertainty sometimes arising as to whether the vein is really opened. The vessel is opened by a clean-cut longitudinal incision, about three-eighths of an inch in length, and the cannula is inserted about one-half an inch, in the direction of the venous flow. The other ligature is tied closely about the vein and cannula, thereby securing the latter in position; then the bandage is taken off.

When the cannula is removed this last ligature is tightened, and the skin may be united with proper sutures or left to heal by granulation. When it is probable that a second injection will be needed, the tube may be clamped and the cannula allowed to remain, although it would seem that under such conditions clots might form and be forced into the circulation by a subsequent injection. Yet this method has the approval of many eminent surgeons.

A modification of the above method, devised by the writer and practised in a considerable number of cases, certainly has some slight advantage in simplicity and rapidity. It is as follows: The forearm being in posi-

* Read before the New York State Medical Association, October 20, 1898.

tion, cleansed, and a bandage applied above, (1) a short superficial incision is made over the vein; (2) an ordinary uterine tenaculum is quickly worked down alongside of the vein, then turned upward, and after being brought out on the other side of the vessel is left hanging, thereby raising the vein and controlling any excessive hemorrhage during the operation. The vein is immediately incised, and the cannula, through which the solution is dropping, is inserted. When enough of the solution has been injected and the cannula withdrawn, in case a ligature is not to be had, the tenaculum is removed and a compress will control any hemorrhage. By this method it is possible to have the solution entering the vein within thirty seconds. The only instruments requisite are a scalpel and tenaculum (Sims) and a transfusion apparatus.

For the latter purpose a piece of rubber tubing, three feet long, with a douche bag at one end and a cannula, will answer as well as the more elaborate apparatus. In lieu of a cannula an aspirating needle, a goose quill, or, better still, a medicine dropper will answer the purpose. If the action of a stopcock be desired, it may be imitated by allowing the solution to flow for a few seconds, and then clamping the tube with a pair of artery forceps, or by pinching it up with the fingers until the cannula is in the vein. During the infusion the funnel is held about an arm's length above the point of injection; whenever possible, the entire apparatus should be sterilized. At any rate, the cannula should be clean.

The outline of the vein can be made more prominent after the bandage has been applied by alternate flexion and extension of the wrist or elbow. The right arm is preferable, because the veins are a trifle more prominent. When both of the veins mentioned above are too small for the cannula, although such a condition must be very rare indeed, the dissection should be carried an inch or so up along the inner side of the arm, to get the basilic vein, at the same time avoiding any injury to the internal cutaneous nerve, as it crosses at this point. Some surgeons prefer the saphenous vein where it crosses the malleolus. In extreme cases, when the superficial veins cannot be made prominent, the suggestion has been advanced that a transverse incision be made across the forearm and the open vein picked up.

One of the common causes of failure in this simple operation is the neglect to remove the bandage tied about the arm for the purpose of distending the vein. I have known this to happen in several instances and all sorts of reasons, concerning blood pressure, etc., given as the cause of the failure to get the solution to enter the circulation. Another fault is the pushing of the cannula between the coats of the vein. This can best be avoided by a clean incision, about three-eighths of an inch long. A sharp-pointed cannula is very much more likely to cause this result than a blunt-pointed one; and, furthermore, even when such an instrument has entered the lumen, it is apt to make a second puncture. Force should be avoided in the introduction of the cannula, for when the point of the cannula has once entered the lumen of the vessel, unless great disproportion exists between the size of the cannula and the vein, no force is necessary to accomplish its complete introduction. If force appears to be needed, it is more than likely that the point has caught in the tissues of the vessel wall, and that the force exerted, instead of pushing the cannula farther along the lumen of the vein, is tearing the vessel wall and doing damage to the surrounding tissues. In the ordinary method so much time is often spent in adjusting ligatures, etc., after the vein has been raised from its bed and before the cannula is inserted, that the vessel has become partially collapsed and reduced to a mere ribbon. Especially is this result likely to happen if the distal ligature be tied before the venous incision is made.

When this occurs' it is better to cut the vein directly across, tying the distal end. A clamp is next put on, about an inch above, and the vein raised out of its bed for this distance. The proximal end is then lifted up, and after the orifice is distended with a probe the cannula is inserted and the clamp removed. When the superficial incision has once been made, it is advisable that the position of the arm should not change, as there may be trouble in locating the vein again.

Fallacies as to Air, etc.—Contrary to the general opinion, there is very little danger to be feared from the introduction of small quantities of air into the circulation. In several instances I have seen a cannula full of air accidentally introduced, with no evil results. The experiments of Hare, Senn, and others prove the harmlessness of air, beyond the slightest shadow of a doubt. In one instance Hare[2] injected forty cubic centimetres of air into the vein of a dog, so that most of it went directly to the heart, without any evident effect upon the blood pressure. More recently, McClintock[3] has shown that from twelve hundred to fourteen hundred cubic centimetres of air may be introduced into the jugular of a horse and no harm be done. Although, unquestionably, all solutions should be filtered, in at least two instances personally observed small particles of dust, etc., did not occasion any disturbance. A little absorbent cotton in the bottom of the funnel will answer as a filter in an emergency.

Preparation of Solutions.—In the preparation of the solution various additions have been made to the simple salt solution. Some formulæ, as that of Hayem, contain an alkali, with the intention of more nearly approximating the chemical constitution of the blood serum. Others, as that of Ringer, contain in addition a salt of calcium, which is said to have a direct coagulating effect upon the blood.

But Bosc and Vedel,[4] as a result of a series of elaborate experiments with the various solutions used, came to the following conclusions: Distilled water is noxious, even in small quantities. Ordinary water, nontoxic, not very destructive to the red corpuscles, and might be used in an emergency. Simple salt solution, quite innocuous, so long as the quantity of salt does not exceed three times the quantity of sodium chloride normally contained in the blood; artificial serum, not superior to salt solution of seven-tenths per cent. The strength of the solution in general use varies from six-tenths to eight-tenths per cent.

In the preparation of a solution of six-tenths per cent., ninety-two grains of ordinary table salt are added to a quart of water. For ordinary purposes two small teaspoonfuls, not heaped up, will approximate the requisite amount (a small teaspoonful of salt, brushed off with a straight edge, weighs from forty to forty-five grains). The solution, after the addition of the salt, should be boiled and filtered. If it is to be kept for any length of time, it should be protected by cotton plugs, to keep out dust, etc. In hospitals double or quadruple strength solutions are constantly kept on hand, so that the decinormal solution may be quickly prepared by the addition of simple hot water. The temperature of the solution should be about 100° F. It is better that it be a degree or so warmer when put into the funnel, as it will lose about one degree in passing through the tube. An increase of a few degrees is not a matter of consequence, and many surgeons now advocate the use of solutions of 105°–110° F., on account of their stimulating effect. The experiments of Athansin[5] prove that, in animals at least, solutions having a very high temperature, 165°–175° F., can be safely used.

I have found that a solution of approximately the proper strength and temperature may be obtained by

adding a pint of boiling water to a quart of solution containing one hundred and thirty-eight grains, or two large teaspoonfuls of salt, the latter solution being kept at the room temperature, 60°–70° F.

When no account has been kept of the amount of solution injected, it may be useful to remember that under ordinary circumstances it requires about five minutes for a quart of solution to run in.

The quantity requisite ranges from a few ounces to several quarts. The chief guides in any case will be: (1) The return of the pulse with increase in volume and diminution in rate; (2) return of color and facial expression or perhaps consciousness. Rarely more than two pints are needed at one injection, but the injection may be repeated many times on the same patient. Enormous quantities have often been used, and generally with the happiest results. In one case recorded, twelve pints were injected during an operation, and Lejars mentions a case in which twenty-six litres were given in five days. There is very little danger of putting too much of the solution into the circulation, especially so in the anæmia following severe hemorrhage. Derske and Faye showed that an amount of solution equal to four times the quantity of blood that an animal possessed could be safely injected. Wiggin, however, mentions the case of a patient with a weak heart, in which an injection of three quarts, rapidly given, so overburdened the circulation as to cause death. When large quantities have been used and the patient does not regain consciousness within a few hours, it is well to see that the bladder is not distended, as sometimes the amount of urine excreted is marvellous.

Use.—The most widely known field for the employment of the saline solution is in the anæmia due to hemorrhage. Inflet and Leffort, in 1878, were the first to suggest its use in this condition. Since then it has been the resource of surgeons the world over in the treatment of this form of anæmia, and with uniformly satisfactory results.

The immediate source of danger from sudden loss of blood is the fall in blood pressure to a point where the circulation cannot be maintained. The first indication, therefore, is to raise the pressure in the vessels. This the saline solution does, supplying from a mechanical standpoint a liquid capable of taking the place of the blood lost, and also acting as a stimulus to the vasomotor system. As an ultimate cause of death, the loss of enough of the oxygen-bearing red corpuscles to arrest the respiratory function might be feared; but this need not cause us any concern, for it has become an established fact[6] that in animals blood may be withdrawn until the heart and respiratory functions have ceased for some time, yet if one-third of the blood remains in the system and a sufficient quantity of saline solution be introduced, cardiac and lung action is at once restored and the animal recovers. Furthermore, in pernicious anæmia the loss of red corpuscles sometimes amounts to as much as ninety per cent., yet respiration is not seriously impaired. But it does more than restore the circulation; it has a decided hæmostatic action.

Pierre Delbert, in 1889, observed the blood clotting directly as it was flowing from the vessels, following an intravenous injection of saline solution, and his observations have since been confirmed. As an example of this hæmostatic action, the following is cited:

Rosie M—— was operated upon for pyosalpinx. Owing to dense adhesions, considerable hemorrhage followed, which for various reasons could not be controlled. On account of the precarious condition of the patient the wound was packed and she was put to bed. Two hours later she was still bleeding and was in a condition of collapse. The face was pale and covered with a cold sweat, the eyes were half open and glassy, the pulse was thready and rapid (160 or more), and the blood still continued to well out of the wound. I gave her an intravenous injection of two pints. The first result noticed was an increase in the tension of the pulse and a marked diminution in rate (80–90). The color began to appear in the face; the eyes regained their lustre and consciousness returned; but, more important still, the bleeding ceased. About half an hour later the patient had a short, sharp chill, and fully recovered some time later.

The theory has been advanced[7] that it produces this hæmostasis by exciting the contraction of the arterioles and a migration of the hæmatoblasts from the hæmatoformative centre. These are destined primarily to replace the blood lost by hemorrhage, but, arriving in a serum yet rich in fibrin, they are precipitated and form the nucleus of a clot. Its twofold function becomes especially apparent in internal hemorrhages, such as hæmoptysis and the hemorrhage of typhoid fever. It is advisable in these two conditions, unless there is immediate danger of death, to allow the fluid to run very slowly, on account of the increase in blood pressure.

Shock.—In the condition of shock with its attendant vasomotor paralysis the vessels are flaccid; the blood for the most part is accumulating in the large abdominal veins. The ventricles of the heart are practically empty and deprived of a sufficient blood supply and its normal stimulus, and the heart is beating only occasionally. Drugs, given either by the mouth or hypodermatically, are of no avail, because they cannot be absorbed. Something must be done to cause more fluid to enter the heart and thus keep up the flagging circulation, or death will shortly ensue. Nothing surpasses the saline solution for this purpose. Stimson[8] reports a number of cases of shock treated successfully in this manner. Three of his cases were accident cases, and when admitted to the hospital they were in a condition of extreme shock.

Spencer[9] reports several cases of shock, occurring during cerebral operations, treated successfully in a similar manner. Many other cases are reported by good observers, and their reports all seem to have this in common, *i.e.*, that they are all enthusiastic in its praises as a life-saving measure.

In the treatment of shock during an operation, Dr. Wiggin[10] advises that as soon as the pulse increases twenty or thirty beats a minute strychnine shall be given hypodermatically until one-twelfth of a grain is reached, and supplemented with glonoin. In case this does not control it, intravenous saline infusion should be resorted to at once. In his service at the City Hospital it is resorted to upon the slightest indication, with the happiest results.

Its good effects are visible on the day following the operation, inasmuch as these patients do not complain of the unbearable thirst that so commonly follows severe operations, nor do they have the drawn, pinched expression so often observed under similar conditions. Whenever a patient to be operated upon is in a weak condition, it is a good plan to give the injection as soon as the patient is anæsthetized. In conditions of electric shock it is advisable to employ it, even though life seems extinct.

Uræmia.—Whatever our belief may be as to the exact causative agent in uræmic conditions, it has long been admitted that some toxic agent does accumulate and circulate in the blood. Bouchard found that, while it required ten cubic centimetres of normal human blood to kill a guinea-pig, from three to six cubic centimetres of blood from a uræmic patient would accomplish the same result.

Now, as this agent is contained largely in the blood serum, the most logical sequence would be to get rid of as much of the blood containing the poisonous agent

as possible, without directly endangering life, and then to dilute the remainder with some harmless agent. Such an agent we have in the decinormal salt solution. Furthermore, the saline solution has a powerful osmotic action on the kidney cells themselves, and thus increases the eliminative processes (the researches of Bosc would indicate that its action is mostly manifest upon the cells of the convoluted tubules). In addition, clinical experience has proved that as a result of its introduction into the circulation diaphoresis and purgation occur, so that it fulfils all indications for treatment in a case of uræmia.

In one case of this kind when I had the opportunity to employ it the effect was certainly remarkable. The history is as follows: Ellen K——, aged forty years, with a record of uræmic symptoms extending over five months, complained of a sudden blindness. A few hours later she had a uræmic convulsion lasting ten minutes. The urine contained albumin and casts. Hot packs, diuretics, and purgatives were employed, and the next day she was feeling better. Two days later, as a result of a nervous shock, she began to toss about in bed in a delirious manner. Convulsion being feared, glonoin, one-seventy-fifth of a grain, was given at once hypodermatically, and chloral and bromide were administered per rectum; five minutes later she had a convulsion. She was put in a hot pack and one-sixth of a grain of pilocarpine was given hypodermatically. Fifteen minutes later another convulsion occurred, followed in a few minutes by a third, when the convulsions ceased. The patient was now in coma. There were profuse salivation and œdema of the lungs, probably due to pilocarpine. An hour later her condition was rapidly becoming worse; the face was cyanotic, respiration stertorous, skin dry, and pulse very weak and irregular. Ten ounces of blood were withdrawn and two pints of salt solution were introduced directly into the vein. The pulse now improved in tension and became slower, and her general condition was much better. Three hours later the pulse began to weaken and became rapid, reaching 140 for the second time. Another pint of the saline solution was given, and the patient began to rally. She soon regained consciousness, and from that time on she progressed favorably. The case is especially interesting, in that it shows that œdema of the lungs is not a contraindication to the use of the saline infusion.

Proben reports a case of eclampsia with total suppression of urine. Two quarts of the solution were injected, and within twenty-four hours the woman passed one hundred and nine ounces of urine.

Merlin[11] reports a similar case.

Porak has treated fourteen cases of uræmia with these injections, with one death.

Suppression of Urine.—McBurney[12] reports a case of acute suppression of urine, following removal of a large calculus from the kidney, that successfully responded to these injections.

Diabetes.—It is very probable that the good results obtained by Lépine in diabetic coma by the use of intravenous injections of salt and sodium bicarbonate are due more to their depurative and eliminative action than to any chemical change that may be supposed to take place, and so far the decinormal salt solution will answer as well. Garnier and Lambert[13] have succeeded in at least temporarily arresting the glycogenic function of the liver by decinormal salt injections, so that we may hope for more permanent results in the future in an otherwise hopeless class of cases.

Sepsis.—Within the past two years it has been heralded by the French writers as almost a specific in septic conditions, and their results would seem to justify the claims. The *rationale* of this treatment, according to Pozzi, who is a strong advocate, is that in the first place by raising the intravascular pressure it increases the patient's power of resistance, enabling him to carry on the struggle against disease. In cases of septicæmia the blood-making organs thus get time to produce new blood corpuscles for phagocytosis, and the kidneys, the excretion of which is increased, eliminate the toxin.

Lejars and Michaux[14] report its successful use in seven cases of peritonitis.

Berrin[15] reports a case of septic peritonitis as cured by its use. Monod has had seven cases with three recoveries. Michaud has had fifteen cases with five recoveries. Duret[16] has had four cases with three recoveries.

Ange[17] and Buchanen each report instances of its use in septic conditions. The latter in a puerperal case used six quarts at one injection, and believes it was instrumental in saving life.

Tuffier makes a favorable report of fifty cases of septic conditions and hemorrhage, including two cases of tetanus.

Duret[18] reviews the history of twelve personal cases, of which eight were cases of septicæmia (four post-operative, four puerperal), one case of severe shock, two of collapse from hemorrhage, and one of urinary infection. Of the twelve patients so treated, ten recovered.

Bertin'[18] reports the case of a woman septic for three days; the abdomen was distended and painful with frequent vomiting. On the fourth day she seemed to be dying; two pints were injected. This was followed by marked cyanosis, and shortly after there was a decided improvement and the patient recovered. In a discussion of Bertin's report, Segond, Pozzi, Bouilly, and others heartily indorsed the use of salt solution in such cases, and spoke of it as being constantly employed by them in all cases of grave septicæmia, with the happiest results.

Claisse,[19] in describing the phenomena observed in these cases, says: "We find the patient suffering from a severe infection, all the organs working badly; temperature about 104° F. In ten minutes twelve hundred to fourteen hundred cubic centimetres of solution is injected. At once the patient feels better and reaction begins; usually the patient now enters on what is known as the critical stage, which comes on four or five minutes later. There are a violent chilly sensation of extreme cold, strong rapid pulse, and a rapidly rising temperature, 104° to 106° F. in an hour. About six or eight minutes after the chill there are a feeling of heat, flushed face, and labored respiration, pulse and temperature being unchanged Water now makes its appearance in quantity through the pores of the skin and the kidneys. In three or four hours later the real improvement becomes manifest. The temperature sinks to normal and convalescence is established. In severe cases improvement is only temporary and the injection must be repeated."

One successful case of osteomyelitis with multiple abscesses is reported by Lejars.[20]

Rau[21] reports a somewhat similar case.

Cholera.—The first application of salt solution in general medicine was to counteract the lowered blood pressure of the algid stage of cholera. It was used with great success in the Paris epidemic of 1884, and later in Hamburg in 1892. Dr. McLeod tells me that it was largely employed in a similar epidemic in this city in 1833. Its twofold action, *i.e.*, washing out the poisons and supplying liquid, together with keeping up blood pressure, rendered it a most useful agent.

Sahli[6] reports its successful use in cases of typhoid fever, uræmia, and diabetes.

Bosc[6] has collected a number of cases of its successful employment in typhoid fever. In this disease the indications for its use are the same as in cholera.

Pneumonia.—Bassi[22] reports its use in eight cases

of severe double lobar pneumonia, with seven recoveries. He says that the best time to use it is about a day or so before the expected crisis, or whenever the pulse becomes intermittent, or, in fact, upon any grave change in the patient's condition.

Legnaini [23] reports three successful cases of a similar character.

Galvagin, Pellegrine,[24] and Lejars[20] also have had decided success from its use in this condition.

Purpura Hæmorrhagica.—Feltz and Pigot [25] report a case of purpura hæmorrhagica cured by its use.

Rau[21] has used it successfully in a similar case.

Ulcerative Endocarditis.—Dalchi reports its successful use in two cases of ulcerative endocarditis. In one case a litre a day was employed for five days.

Pyelitis.—Delbert has had good success from its use in pyelitis, and he believes that the increased amount of urine washes out the pelvis of the kidney and also eliminates the toxins.

Carbon-Monoxide Poisoning.—Brodier[26] reports the case of a man suffering from carbon-monoxide poisoning (coal gas). He was in a comatose condition; the autopsy nearly all the organs were found in such a condition of extensive degeneration as to preclude any possible chance of ultimate recovery.

Toxæmia Due to Colon Bacillus.—Vedel [28] has been able by the use of saline infusion to neutralize in rabbits the toxæmia due to intravenous injection of the toxins of bacilli coli communis.

Painter's Colic.—Delearde reports five cases of painter's colic treated by subcutaneous injection of the saline solution. The pains soon ceased. Diarrhœa set in, lasting for two or three days, followed by rapid recovery.

Carbolic-Acid Poisoning.—Landouzy in severe cases of carbolic-acid poisoning advises bleeding followed by infusion of saline solution. Several unreported cases, treated in the hospitals of this city, tend to confirm this statement.

Tetanus.—Tuffier has had two successful cases of its use in traumatic tetanus.

Epilepsy.—Monet and Viret,[29] as a result of extensive investigation of the urine in epileptics, believe that epileptic attacks are due to a critical accumula-

reflexes were lost; the respirations varied from 44 to 52 per minute. Nystagmus was present. The pulse was feeble and rapid. Oxygen inhalations and injections of ether were useless. As a last resort an intravenous injection of saline solution was given. This was followed by a chill, vomiting, and profuse diaphoresis. Improvement began at once. The injection was repeated in an hour, and his rapid recovery followed. Hueily, Bergmann, and Fräntzel have reported similar cases.

Mushroom Poisoning.—The editor of *La Presse Médicale*, June 12, 1896, after giving the history of several cases of mushroom poisoning, advocates venesection followed by saline infusion as the logical treatment for this condition.

A temporary amelioration was afforded in a few cases of grave jaundice, mentioned by Delamare.[7]

Burns.—Tomalisoni [27] has obtained very good results from its use in extensive burns. In the course of his experiments on dogs suffering from such injuries, he found that if the saline solution was introduced they almost always lived; otherwise treated they all died.

Alcoholism.—In the only case of acute alcoholism in which I have had an opportunity to employ it as a depurative agent, the patient, a chronic alcoholic, had been delirious for two days, with a weak, rapid pulse, ranging from 140 to 150. A few ounces of blood were withdrawn and a pint of the solution was injected. The pulse fell to 90, increased in volume, and the patient was restored to consciousness for a short time. Although previous to the injection death seemed imminent, the patient lived for thirty-six hours. At the tion of toxins in the blood, and recommend the use of saline infusion as a depurative agent, at intervals to be determined by the relative toxicity of the urine.

Arsenic Poisoning.—In view of the fact that arsenical poisoning is always followed by great drop in blood pressure, and inasmuch as the arsenic circulates in the blood, it occurred to the writer that a saline infusion would act as a diluent for the poison and keep up the blood pressure at the same time. A number of experiments were performed on cats, and, while they are not sufficient in number or conclusive in result, they make it certain at least that life can be greatly prolonged by this means.

In every case characteristic symptoms of arsenical poisoning, such as vomiting, diarrhœa, prostration, etc., were all manifest within twenty minutes. In two cases there was considerable blood in the stools. In every case a large amount of urine was passed within a few hours after the infusion. From a review of these cases it would appear that it is better to wait until the poison has all entered the circulation, in order that the full effect of the solution can be obtained.

Many competent observers believe that the rôle of increased temperature is a conservative factor in diseased conditions, and they assert that it stimulates the production of antitoxins. The experience of Elfström in the use of heated blood in the treatment of pneumonia makes it probable that the action of heat does more than simply attenuate the bacilli. The universal rise in temperature following the saline injections, the chill and crisis, the marked improvement that follows, all seem to indicate that antitoxins in

sufficient quantity have been produced to neutralize, temporarily at least, the toxins; surely the salt solution *per se* could not do this. It seems to me that we can account for part of this beneficial action by the fact that the solution is usually introduced at a temperature several degrees higher than that of the blood, and that probably the increased heat stimulates the production of the antagonistic principles.

Finally, in summarizing we may say that in general its indications are:

1. In all cases of severe hemorrhage, whether external or internal.

2. In shock, both simple and post-operative, it fulfils all indications.

3. In all toxæmic conditions, and here it should follow venesection. Indeed, no agent thus far compared with it in efficacy in uræmic and septic conditions.

4. In cases of poisoning due to vegetable or mineral substances.

5. In any pathologic state attended with feeble pulse, due to diminished arterial pressure.

6. As a last resort in cases of imminent death from any cause of an accidental nature.

SUBNORMAL TEMPERATURE.[1]

BY LE ROY J. BROOKS, M.D.,

CHENANGO COUNTY, N. Y.

So little is said in a collective way concerning subnormal temperature that one may be forgiven if in such a study he repeats many well-known facts, in order more satisfactorily to analyze the conditions that produce it.

Flint states that the subnormal temperature is exceedingly rare, and, except in extreme variations, of less consequence than the supranormal. Vierordt tells us that a continued subnormal temperature—that is, continued for several weeks—is very rare, and Starr[2] that a temperature of 97° F. in children continued for several weeks is a very serious condition, whatever its cause. My own observations lead me to think that it exists more often than we suspect. Doubtless it is overlooked from the fact that clinicians devote but little attention to temperature disturbances, unless above the average normal. We infer that if there are no manifestations of fever further observations are unnecessary.

I am impressed with the fact that we overlook in this neglect important early indications of disease. A single temperature register, taken at intervals of twelve or twenty-four hours, is rarely a good index. As a matter of diagnosis of diseases, not of themselves febrile, as great an amount of knowledge can be gained by following the temperature curve at short intervals, for one or two or a dozen days, as we get from examinations of urine taken separately from each quantity voided.

Another point worthy of suggestion is the difference between fever and pyrexia. It is the distinction between heat and temperature. There may be pyrexia without fever. The body heat is the form of energy produced in and lost from the body, and is estimated by the calorimeter. The body temperature is the relationship between production of heat and loss of heat, and is estimated by the thermometer.

Again, a temperature may be normal for health, yet subnormal for disease. I imagine that something of this kind occurs in yellow fever and in cholera and perhaps in acute atrophy of the liver, the combination being far more rapidly destructive and exhausting than either heat production or heat elimination alone.

Fever, in our common acceptance of the term, is a condition due to a specific infection, unless we except the temperature variations from structural changes in the nerve centres. It is characterized by a train of symptoms, such as exhaustion, emaciation, disturbed functions, pain, mental unbalance, temperature acting only a single part. The specific causative toxæmic results may produce either an elevation or a depression of temperature, and the latter generally indicates a greater intensity of the poison. An afebrile pneumonia is more disastrous than the febrile. A diphtheria, with or without extensive exudation, with rapid gland invasion, is often characterized by a subnormal temperature and is notoriously fatal. A "typhoid condition," as we term it, without the typical typhoid temperature, is more serious than its prototype. The "malignant" cases of appendicitis with subnormal temperatures are the unresisting, overwhelming, gangrenous ones that never recover. What we ordinarily fail to measure fully is that morbid temperature is a creation of impressions upon a specific nerve centre by toxins, and that the peculiar power of one may be reversed or modified in its combinations with others, and that the strength of the union produces unexpected results.

I have questioned whether we might not get more valuable suggestions from some other method than the usual one in obtaining the internal body temperature. The rectum approaches accuracy more closely than under the tongue, but this is so frequently influenced by local conditions that we are liable to be deceived. This was manifested in an observation that gave the temperature under the tongue at 98.7° F., and in the rectum at 101.5° F. A local rectal congestion explained the differences. To consider the question systematically, let me classify it in a somewhat arbitrary way, yet sufficient for the purpose: (1) Subnormal temperatures as normal for the individual. (2) As a prodrome. (3) During the progress of disease. (4) As a sequel.

My friend, Dr. Phelps, reports a case of a fellow-student in which the temperature was habitually 97° F. under the tongue. He states that the patient was apparently vigorous, active, and capable of as much work as other students. He possessed a healthy color and felt himself to be in perfect health. Dr. Phelps knows nothing of the history of this man for the past three

[1] Read before the New York State Medical Association, October 18, 1898.

[2] "Disease in Children."

years, and I doubt if he still retains his full vigor, for as a continuous increase indicates serious functional or organic changes, so a continuous decrease will result the same. We recognize the normal physiological variations of from two-tenths to three-tenths of a degree.

The second class seems to me to possess exceptional importance, because the temperature depressions not only present indications of subsequent developments, but suggestions for treatment that may prove abortive of serious conditions, if correctly interpreted.

Mrs. D——, aged thirty-nine years, well-nourished, and as fine a specimen of physical development in a woman as could be found, weighing one hundred and sixty pounds, and five feet ten inches tall, came to my office in 1894, with the complaint that while eating and sleeping normally, with no unusual care or responsibility and no recognizable disease, she had been constantly languid for some weeks. This was contrary to her usual feeling, for ordinarily she possessed rather unusual physical activity and vigor and a large amount of executive ability. I examined her carefully and was forced to declare that I could not find the slightest disease. The heart was perhaps small for her size, but she had sound lungs, perfect digestion, normal menses, normal pelvic organs, and was free from evidences of disease or injury. Urine abundant, elimination sufficient, constituents normal. The family history showed several cases of insanity. I prescribed strychnine and rest, and awaited developments. I saw her again a few weeks later. She had taken to the bed, complained of extreme lassitude, but was placid and intelligent, and with every function perfectly carried on. Heart's action not strong but regular. Surface cool, slightly congested, but not livid. The temperature under the tongue registered 96.8° F. She had absolutely lost her interest in her household affairs and ignored them, under the impression that in her previous activity she had exhausted her nerve force and was paying the legitimate penalty to nature. I ordered complete mental and physical rest, systematic feeding, and massage, and more generous doses of the strychnine. After a few weeks of such treatment she gradually improved; the average temperature reached 98° to 98.5° F., and she resumed her usual responsibilities. She removed to Norwich soon, and I did not see her again until 1896, when I was called to the southern part of the State, to see her in consultation. She presented a repetition of the earlier history, except that the surface presented a passive capillary congestion, the heart's action was weak and irregular, without organic lesion, and the pulse was correspondingly weak. The functions of respiration and digestion were perfectly performed. The temperature was 96.5° F., not exceeding 97° F. at any time in a given twenty-four hours. Her mental condition had undergone a decided change. She was suspicious, emotional, apprehensive of impending death, and had a marked suicidal tendency. The physical conditions were like those of a vasomotor paralysis. I suggested again strychnine and phosphorus, special feeding, and light massage, and in a few weeks she recovered; and with the recovery the temperature became normal. She remained well about a year. I was called again in the latter part of 1897, to find a repetition of the same history, and the same processes brought a gradual recovery. In January, 1898, her husband came to me with a statement that he had discovered that her temperature was again subnormal, and that he could see indications of increasing lassitude. The strychnine was given, and evidently checked the advance and averted the attack.

Now, in this family was a history of seven suicides. I was familiar with two of the persons, both of whom were committed to asylums. All of them hung themselves. I do not insist that the mental condition of my patient was the result of the depressed temperature, but suggest that the subnormal temperature preceded the other manifestations, that it was sufficient to give an early and definite warning, and that its recognition and proper treatment prevented the more serious attack.

The following case is an anomaly, because of the variations of temperature without discernible causes. I have been the patient's attendant for the past ten or more years, and have had many occasions to be assured that before the present disturbance her average temperature was normally 98.5° F. She is from a family without hereditary taint, except a remote tuberculosis. In 1895, a few months after the birth of her second child, she began complaining of exhaustion, and I found that the temperature from early morning until 2 or 3 P.M. did not exceed 97° F., and much of the time varied from 95° to 97° F. It then began gradually to increase, until in the evening it reached from 95° to 101° F. We instituted a careful search for the cause. Her bodily weight varied but little. The appetite was good. The lungs, heart, abdomen, and pelvic organs were perfectly healthy. The urine was frequently analyzed and the proportion of solids estimated, with negative results. We searched for evidences of malaria and examined the blood, without results. Her sanitary surroundings were perfect. This condition continued month after month without change in symptoms except a mental depression during the hours of the low temperature, until the early part of 1897. I referred her to Dr. Janeway, who after his usual exhaustive search failed to find a sufficient cause, beyond a theory of some central irritation, and wrote me that he had had for three years under his care a professional gentleman who presented a similar history, which he could not account for. He suggested treatment for a possible malaria, which availed nothing. Dr. Herter also saw her, without any more definite conclusion. Dr. Ford, of Utica, was consulted and suggested a possible autotoxis, and thought he could detect some variation of the respiratory sound in a small section of the right lung. A most exhaustive search for a source of toxæmia failed to reveal anything; there has been no advance of pulmonary disease, and the respiratory change was evidently due to a temporary bronchial catarrh. She became pregnant the last time in 1897. After the beginning of her pregnancy the temperature became normal, she was relieved from the lassitude, gained several pounds in flesh, and regained her natural brightness. This continued until the eighth month, when she became nervous and apprehensive about her approaching accouchement, which was contrary to her usual reception of that event, and was irritable, depressed, and emotional. I found her temperature again from 96° to 97° F., continuing so during the full twenty-four hours. There was not a sign of uræmia or the other complications of pregnancy. She passed through her confinement easily and quickly, without complications, except a little excess of flowing. Within an hour after its completion she passed into a condition of lethargy, was utterly indifferent to surroundings, paid little attention to the child, talked incoherently, or, if aroused, was exceedingly depressed and apprehensive. She remained in this condition a week, the temperature never exceeding 98° and generally nearer 96° F. She rallied slowly, and up to the present time, while able to be about and perform her household duties, still has the temperature variations of a depressed morning and an elevated afternoon, and possesses the mental depression and constant sense of weariness.

One condition existed in these two cases in common —hearts normal in structure but weak in force for the demand upon them.

My friend, Dr. Williams, of Greene, N. Y., has been for two or three years investigating cardiac areas,

and believes that in nearly all cases of laziness or chronic weariness without disease he has found a marked relative disproportion between the size of the heart and the body. The heart is too small for its work, and the "fellow can't help it." We are, doubtless, all familiar with the picture so graphically drawn by Hammond twenty-five years ago, of the influences of excess of mental toil upon the cerebral circulation—the undue distention of the vessels, the subsequent reaction and passive congestion, and the ultimate nerve weakening, functional irregularity, inability for mental application, delusions, etc., later described as neurasthenia. A small heart or a weak heart, too small for its requirements, can easily produce the same results. The defective pump, sluggish circulation in the terminal arteries, insufficient blood supply to nerve centres, irregular thermogenesis or thermotaxis, depressed temperature, mental depression, melancholia, suicide, produce a familiar picture. The overworked business man often presents a record as follows: After perhaps an unusual business strain he becomes weary, listless, nervous, irritable, despondent, sleepless, unable to apply himself, and with a lack of judgment in his business affairs. These cases frequently present for days preceding the going out and during the time a subnormal temperature, varying from one-half to two degrees. Dr. George Williams, of Greene, has made many observations in this direction, and has recently presented a paper before the Broome County Medical Society, giving the results of his studies. He has kindly consented to permit me to cite some of the cases and opinions given by him.

W. L. S——, aged sixty years; good habits and in excellent health for a man of his age. Has large business interests, to which he has devoted himself assiduously. He came to my office with a complaint of general nervous distress, which he could not define clearly. An observation of his temperature gave it as 97° F. His business at this time was in a crisis, which taxed him to the utmost. I advised rest, but he could not take it. In ten days I was called to his home, to find his condition so much like that just described that I need not repeat it. A month's rest and he returned to business, with vigor and ability restored and temperature normal. He has repeated this history several times during my knowledge of him, each time with the premonitory subnormal temperature, followed by insomnia, nervousness, etc., until a complete rest restored him. I suspect a time will come when his recuperative powers will be unequal and his mental powers permanently enfeebled.

O. M——,[1] merchant, aged fifty-eight years, good physique, and a tremendous worker. He has periodical "giving out times," as he describes them, and the history of the preceding case is repeated. His temperature for days registers 96° to 98° F. Absolute rest in bed, freedom from all business cares, and strychnine restore the exhausted forces, and in two or three weeks he returns to his business. These cases justify me in the belief that the fall of temperature is the earlier manifestation of the condition, and that if this is recognized and appropriate measures are resorted to the later disease may be averted.

Periodical alcoholics present a depression of temperature for a period of from one to five days preceding the outbreak of extravagant indulgence. As a matter of fact, it is a consciousness of physical subnormality that induces the resort to stimulants. Alcoholic excesses, especially in the solitary drinker, seem to be a sequence, the result of an attempt by artificial means to re-establish a normal bodily balance. An illustrative case is that of G. B——, a man, aged thirty-five years, good physique, who has a periodical drunk at intervals of from four to six weeks, and it does not seem to be associated with "pay-day" excesses. In the interval he abstains entirely. The period lasts a week or so, during which he drinks excessively. His complaint is, as the period approaches, "I do not know what to do with myself." The sense of uneasiness, of inability to apply himself to his work, to concentrate his thoughts, is almost overpowering, and leads to resort to the stimulants if not averted. His temperature for several days preceding his resorts to drink is 96.5° or 97° F., and if then proper treatment is resorted to the desire for stimulants passes off, the temperature regains normal, and the storm is prevented.

Dr. Williams has recorded a number of cases, presenting the same temperature depression. He has made further observations that lead him to think that there is a class of cases that present the same periodical storms, resembling closely the alcoholic storm, and have exactly the same symptomatic history, but in which surroundings or restraining qualities prevent the use of stimulants. He believes that in the majority of such cases there is a history of some early violence or injury implicating the nerve centres. He cites me the following cases, which I have condensed from his notes:

First patient, aged sixty years, business man, has recurring attacks at intervals of two to six months, in which for from one to two weeks at a time the temperature registers from 95° to 97° F., and with it is a physical condition that either partially or completely (according to severity) disables him from attending to his business. He is despondent, weary, irritable, etc., and has during the attack a dull irregular pain along the spine. He had a fall from the barn loft to the floor several years ago, injuring his head (concussion).

Second patient, aged forty-five years, capable, active farmer; he fell from a tree at the age of ten, striking upon his head and shoulders. He has had for several years reccurring waves of physical and mental depression, preceding and during which his temperature is about 95° F.

Third patient, aged twenty-seven years, mechanic; fell from a high window during infancy. Gives a history similar to last, of low temperature and depression, which occasionally results in alcoholic excess.

Fourth patient, aged forty-six years, farmer, ordinarily energetic; fell from a load of hay to the ground, striking on his neck and head. At intervals of from six months to a year he had attacks of exhaustion, with physical and mental depression without definite cause. These would last two to four weeks, and preceding them by a few days and during the attack his rectal temperature does not exceed 95° and is often at 94° F. During the intervals the temperature is normal.

The subnormal temperature in the "progress of disease" is an interesting study, worthy of a more prolonged and able consideration than I can give it. A glance at the cases characterized by constant or irregularly occurring subnormal temperature will show the following: Myxœdema, exophthalmic goitre, uræmia, chronic alcoholism, syphilis, chronic nephritis, constipation, influenza, diabetes, yellow fever, insolation, cholera, spinal sclerosis, melancholia, cerebral traumatism, surgical shock. There are two distinct classes, and possibly a third. The first class involves primarily the nerve centres in organic changes, such as syphilis, spinal sclerosis, chronic alcoholism; the second class those that produce specific symptoms through the process of acute intoxication, as in uræmia, chronic nephritis, constipation, yellow fever, influenza, chronic jaundice. The third class may have a measure of autotoxis, combined with some specific influences upon the sympathetic or glandular systems, as myxœdema and exophthalmic goitre. It is probable that while various theories, which it is not the object

[1] Reported by Dr. Williams.

of this paper to discuss, exist concerning the origin of the two latter diseases, the essential element of the resulting cachexia of both is an autotoxæmia, and that the diseases are closely allied.

Chervalier suggests that under the influence of certain pathological conditions the thyroid gland secretes a toxic matter, and this by action directly on the nervous system produces the secondary nervous phenomena in the patient. There seems to be a relation between the two. Myxœdema often follows an exophthalmic goitre. The heart is the seat of morbid phenomena in both. In Graves' disease there is a tachycardia, in myxœdema slowness of heart action, and attacks of exophthalmos are met with at the commencement of myxœdema. But whether the thyroid be a poison eliminator or a poison producer, the ultimate result is a toxic condition of the system. There are many cases reported of continuous subnormal temperature in myxœdema, the temperature continuing from one to three or four degrees below normal. As these have been published, I need not cite them. The temperature of exophthalmos is quite as often normal or elevated, but occasionally subnormal.

Just which toxins produce a subnormal and which the supranormal it is difficult to determine. It is probable that the same toxins will produce opposite results in different conditions of the system; just as in uræmia, while urea remains unchanged we get a normal (or supranormal) temperature, when a decomposition takes place we get an ammonæmia with a powerful temperature depression; or when the renal organs are irritated, a nephritis with tissue necrosis and fever. A case just under my observation demonstrated this clearly. When the condition was discovered, there had been no change from the normal; then followed several days of depression to 97° or 96° F., and then a crisis with convulsions, followed by a temperature ranging from 100° to 103° F., and as convalescence progressed a recurrence of the subnormal.

In carcinoma, particularly of the liver and stomach, there are many cases reported of long-continued subnormal temperatures. Dr. Blair, of McDonough, reports to me a case of carcinoma of the stomach, in which for months the temperature did not exceed 97° and at times was 96° F. Two months preceding death the temperature gradually increased to 101° or 102° F. Here the combination of destruction, infection, and sepsis doubtless was the cause of the change. The same may be said of the intestinal toxins, many of which produce a subnormal temperature, but when combined with foreign sources of infection, systemic poisoning, and structural changes act oppositely. The depressed temperature of cholera is, doubtless, also the result of varied conditions, such as the specific poison, the excessive drain, and the rapid and destructive nephritis and tissue changes.

We occasionally find a case of diphtheria in which the poison overwhelms the system rapidly, and in which the temperature never reaches the normal. These cases are fatal from their inception; and the same may be said of the diffuse or rapidly spreading pneumonias, due to influenza, that most of us have seen during the last five years. Death marks them as its own from the moment of the seizure. The latter cases of pneumonia are certainly more abundant than in former years, and exceedingly fatal. Tessur reports a case of this character, in which the highest temperature record was 97.4° F. In February, 1895, there occurred three cases in one family, evidently due to infection from each other, characterized by temperature that (except in the later stage in one of them) did not exceed 99.5° F. Many similar cases are on record.

The class that involves the nerve centres primarily, such as spinal sclerosis, syphilis, chronic alcoholism, undoubtedly depress the temperature by their direct effect upon the heat-producing or heat-regulating centres, aided by their influence on functional activity. I need not report cases.

A class of cases presenting periodical subnormal temperatures, not commonly recognized, deserves a brief mention.[1] Hemiplegics after apparent recovery are continually, at short intervals exhibiting depressed temperatures for several days at a time; and with this appears also a train of symptoms analogous to those described as occurring in alcoholics. These depressions are warnings that recovery is never complete, and that some degree of physical impairment has attended the lesion. Epileptics often present a temperature of 97° and 98° F., and particularly preceding an attack it may be found at 95° to 96.5° F.

I fear I have already burdened you, and I hasten to mention one other class of cases, which perhaps is out of order in this part of the discussion—cases with a history of chronic or subacute rheumatism, involving the joints irregularly, the thermometer indicating 96.8° F. or 97.6° F. This phenomenon is usually of short duration, may last three or four days, and is subdued by guaiacum. The same condition is occasionally observed in grown people, and attributed to either intense cutaneous evaporation or the retention in the system of some toxic substance.

The last class, occurring as a sequela of disease, includes the subnormal temperature resulting from surgical shock, the depression following continued fever and hemorrhage. These are familiar to us, and I will not further discuss them. Cases of excessive venery are reported, in which as a result occurs prolonged subnormal temperature with general depression of the nervous system. Dr. Gibson, of Utica, states that he has frequently found, in examining pensioners in the winter who had ridden several miles in the cold, a subnormal temperature lasting two or three hours. This result he attributed to heat abstraction.

In conclusion let me summarize: (1) Subnormal temperature is not so uncommon as we are led to suppose by writers. (2) The subnormal temperature is a frequent prodrome of disease, and an important indication for abortive treatment. (3) A continued subnormal temperature (whether cause or effect) is disastrous, and especially to the nerve centres. (4) The subnormal temperature in diseases usually characterized by elevated temperature is a very grave symptom. (5) The causes producing a subnormal temperature can probably be covered by two pathological conditions: (*a*) a primary disease or injury to nerve centres; (*b*) an autotoxæmia.

SENILITY.[2]

By F. W. HIGGINS, M.D.,
CORTLAND COUNTY, N. Y.

"To old people, dyspnœa, catarrhs accompanied with coughs, dysuria, pains of the joints, nephritis, vertigo, apoplexy, cachexia, pruritus of the whole body, insomnolency, defluxions of the bowels, of the eyes, and of the nose, dimness of sight, cataract, and dulness of hearing." This is Hippocrates' catalogue of the ailments of old age.

Aside from the morbid conditions of which it may be considered the cause, senility is an important factor in every case in which it is present. In any surgical operation, it is a matter for consideration. As physicians we meet with its effects daily; it is endemic everywhere. Charcot calls it the normal disease.

What is old age? To the physician it is not a mat-

[1] Reported by Dr. Williams.

[2] Read before the New York-State Medical Association, October 20, 1898.

ter of dates, but of physical condition. Some are physiologically older at sixty than are others at eighty. How many of us have seen a white-haired woman, almost toothless, face wrinkled and pallid, with form bent, step short and uncertain, and trembling hands—and been astonished to find her less than sixty years old!

Old age is not a question of years; it is not determined by the grayness of the hair alone, nor will it do to measure it by the feel of the temporal artery. Cazali's statement that "a man is as old as his arteries" is too short a phrase to contain the whole truth of so large a theme.

We cannot properly define old age until we have formed for ourselves some adequate concept of life itself. This is confessedly most difficult. According to Herbert Spencer, life is continuous adjustment of internal relations to external relations. Senility from this point of view would be a lessening of this capacity for continuous adjustment.

Or life may be defined as a constant balance between assimilation and disassimilation. Old age, then, is characterized by diminished assimilation. In growth assimilation exceeds its opposite. An organ in which assimilation is retarded is senile. That there is lessened metabolism may be shown by an examination of the urine. In middle life the amount of urea to one kilogram of body weight may be stated to be 0.41 gm. In old age it falls to 0.13 gm. If we accept these definitions we find that a failure in ability continuously to adjust itself to environment is one factor in senility; the other is diminished assimilation.

But old age is a process taking place in each individual cell. If we would learn the secret of senility, it must be done by the aid of the microscope. "A cell is not nourished; it nourishes itself." When the ability to absorb and utilize the pabulum presented to it flags, then that cell has passed its meridian. In the struggle for existence going on among the somatic cells, such an ill-nourished cell must sooner or later go to the wall. Diminished vital resistance and diminished assimilation are both signs of obsolescence in cells.

Of the cells entering into the composition of the body, some can reproduce themselves indefinitely. Of these the connective-tissue cell is the type. The most highy specialized cells can reproduce themselves scarcely at all. So when a nerve or muscle cell dies, its place is taken by one of connective tissue. As traumatic lesions are replaced by scar tissue, so the traumatisms of disease, during the course of life, destroy muscle cells or gland cells that are never restored, but are replaced only by the lowly organized connective-tissue cell.

Tillmanns states that in the liver after a contusion a traumatic growth of connective tissue occurs, so that in a case observed by him only two months after such an injury there was in many places no longer any normal liver parenchyma to be seen. The repeated shocks that come during a long life may be considered the equivalent of a severe traumatism by an accumulation of their minute traumatisms. There may be more than a fanciful analogy to the crystalline changes occurring in the inanimate iron of a car wheel, which is rendered useless after being on the road a certain period.

Old age, then, begins in primary cell elements. After a long continuance of the replacement of the parenchymatous cells by adipose and fibrous tissue, the result becomes manifest in a microscopic section and we call it fibrosis of the organ. This is the essential of old age. The liver is called cirrhotic; the kidney, gouty; the joints are said to be affected with nodular rheumatism; in the lungs Sydenham called the process peripneumonia notha—in these days it is termed senile asthma; at the neck of the bladder occurs hypertrophy of the prostate; in the brain there is an increase of the neuroglia; in the heart there is fatty degeneration; in the middle ear there are deafness from thickening of the tympanum and anchylosis of the ossicles. Yet it is in the walls of the blood-vessels that the most important though the less striking changes take place. De Menge examined five hundred senile cases microscopically, and found endarteritis in all. At first these changes are occult; but soon in the cells of the intima of the minute blood-vessels, apparently from the irritation of some peccant material in the blood circulating through them, a degeneration of the normal serous to fibrous and fatty cells takes place. An extension of the same process to the muscular coat follows, with the resulting thickening of the wall, diminution of the calibre, and hindrance to the normal blood supply. If these minute blood-vessels are vasa vasorum, then senile degeneration of the walls of the larger arteries nourished by them takes place, and atheroma or its equivalent is found. A rich train of the manifestations of senility originates from this factor. Atrophy and softening of the brain from lessened blood supply, apoplexy from a broken weak vessel, and gangrene of the extremities arise in this way.

There are also breaking down of the alveolar partitions in the lungs and senile emphysema; thickening of Glisson's capsule; and amyloid, fatty, and calcareous changes everywhere. Another sequel is weakness of muscle, which gives rise to such diverse symptoms as presbyopia; dilatation of the cardiac ventricles and the arch of the aorta; dilatation of the hollow organs, as the stomach and bladder; torpidity of the bowels, with constipation and all its chain of evils.

It will be noticed at once that the pathology of chronic alcoholism presents an almost identical chain of lesions. There is the same fibrosis—the same tendency to atheroma. The acute observation that "for the alcoholic the years count double and triple" would indicate that the effects of old age and of alcohol on the system were the same, and each intensified the other.

Infective diseases lower the coefficient of vitality and so cause premature old age. We have seen this markedly illustrated during the past few years by the grippe. Syphilis and slow metallic poisoning also have a similar pathology. Indeed, the analogy is so close as to lead to the inquiry whether old age also may not be due to an intoxication.

One is certainly justified in asking this apparently absurd question, if it be true that the microscopic changes found in old age are identical with those produced by alcohol, the toxin of syphilis, or the products of defective metabolism in the gouty or rheumatic subject. The term toxin of old age sounds ridiculous, but, after reading Bouchard's monograph on autointoxication, it appears slightly less so. If in the normal organism sufficient toxins are daily elaborated to cause death if not eliminated by the kidneys and liver and lungs and skin, it becomes comprehensible how the system may become clogged by the ashes of its own fires.

The analogy to some of the lower organisms is very striking. Yeast plant is immortal; it buds and grows as long as the alcohol produced by it is removed. But fermentation stops when the product of its own growth reaches twenty per cent.; that is, senility of the cell occurs. In the same way the product of vital activity in every cell in the body is toxic to that cell, and acts slowly only when elimination is comparatively perfect.

A striking example of the changes taking place in a tissue from deficient elimination, and one open to daily inspection, is the various catarrhs. The loss of

function, fibrosis, and final atrophies in nasal catarrh are all senile changes.

Does the study of the pathology of old age give rise to any indications for treatment? For general senility, No. We cannot by any general or local treatment get rid of the cicatrix of a burn. No more can we by treatment replace the fibrous cells of a worn-out tissue with new parenchymatous cells. Mercuric chloride has been thought capable of discussing atheroma and fibrosis by its alterative action, but the claim is doubtful. Arsenic, in popular writings, is said to be capable of temporarily rejuvenating an old man, but physicians do not find that its rather mysterious powers extend so far. Brown-Séquard's testicular juice was much talked of from the fame of its propounder, but no one seems to have taken its recommendation seriously.

But there is a practical side of the question to physicians. If senility cannot be treated, senescence can be. If general senility is not, in the strictest sense, a disease, partial senility is so. If normal senility is not frequently brought to the attention of the physician, he is to combat and prevent premature senility.

If we are to avert partial senilities, it is necessary that we shall early recognize the organ that is breaking down. If this is done, by regulating the habits of life, by decreasing the amount of work required of that organ, by increasing nutrition, the balance may be partially regained. If we cannot bring the organ up to the level of the rest of the organism, then we must follow Fothergill's advice and level the other organs down to it.

Oliver Wendell Holmes, the poet, must have been also a good physician to have portrayed so accurately the idea of old age by the chaise in which "every part was made as strong as the rest," and at last—

> ". . . it went to pieces all at once—
> All at once and nothing first,
> Just as bubbles do when they burst."

But if we are to recognize which organ is most likely first to fail in our patient, we must go back to the old study of diathesis, which the French alone now consider worth attention. There are the laxus, which grows fat in old age, and the strictus, which withers up. One would expect to find sluggish liver more frequently in the former class, a cirrhotic kidney in the latter. The scrofulous and the arthritic are to be differently defended against the dangers of premature senility.

In the scrofulous, cells are ill adapted to resist the invasion of disease from outside. The lymph stream is sluggish, antitoxins are not quickly developed, the soil is favorable for the growth of germs. These are more liable to the accidents of disease. One feels more anxiety with a surgical patient of this class.

The arthritic is more subject to vicious influences from within. Such a patient has developed antitoxins against tuberculosis, typhoid, and diphtheria, but dies of auto-intoxication. Here you may expect chronic rheumatism and persistent eczema. Here the fibroid changes are sure to occur. Our hope is that important and vital organs may be spared. The various cachexias, which have been defined as acquired diatheses, are equally important to notice.

We are taught that in the treatment of acute disease we must know in which direction lies the danger of death, and conserve that organ. In our middle-aged patients we should also know whether premature senility is attacking the heart, the lungs, the kidneys, the stomach, or the brain, and prolong their lives in accordance with that knowledge. The treatment is largely hygienic, and follows naturally from a clear conception of the condition. Our patient must not eat too much, and proper elimination must be constantly maintained. They need less meat, but are to eat more milk and cereals, as befits second childhood. Alcohol is more apt to do harm than good. There must be fresh air and exercise. There must not be sudden changes in temperature or altitude or habits. Medicines must not be too strong. Many old people have come to their death by a dose of morphine that would be moderate in middle life. A compound aloin pill may be required daily.

We must not look for the reaction symptoms in the old that we are accustomed to see in the same disease in earlier life. A pneumonia in a child is ushered in by a convulsion, in an adult by a chill, in an aged person by no symptom at all. Old persons do not have so much pain with biliary calculi, so much vomiting with cancer of the stomach, so much variation in the tendon and pupillary reflexes, so much systemic disturbance from diabetes, or so much elevation of temperature in fevers.

In our surgical cases a study of senility is equally valuable. We operate on the very old with good results, but on the prematurely or partially senile we must observe great caution. In the old we are especially careful to have the operating-room well warmed and to avoid excessive loss of blood. In a fractured hip we attend to the general condition of our patient more than to the position of the limb.

Summary.—The essential of old age is the replacement of parenchymatous cells by connective-tissue cells. This is caused by the destruction of the higher cells by accident, or, which is more usual, by toxins produced by the organism itself. Premature or partial senility should be recognized and treated.

A CASE OF APPARENT ABSENCE OF THE SPLEEN, WITH GENERAL COMPENSATORY LYMPHATIC HYPERPLASIA.*

By EUGENE HODENPYL, M.D.,

INSTRUCTOR IN PATHOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY; PATHOLOGIST TO ROOSEVELT AND ST. FRANCIS' HOSPITALS, NEW YORK.

In looking over the literature for records of cases of absence of the spleen in persons whose viscera showed no other abnormality, one finds, as might be expected, the number to be small. That such cases have occurred seems to have been accepted as a fact by some pathologists. Rokitansky[1] states that the spleen may be entirely wanting. Ziegler[2] states that the spleen may be absent in very rare cases in otherwise healthy people, but neither of these authors enters into details of actual cases.

I find records of nine cases of alleged absence of the spleen. Of these nine cases, two were found in very young children, and the absence of the spleen was associated in both with various other abnormalities. In one of these latter cases (G. Martin[3]), a child, one and one-half months old, who died in convulsions, was found to have no trace of a spleen, but there were so many other structural defects about the child that it could not be said to have been in an otherwise healthy condition. In the other case, likewise (F. D. Birch-Hirschfeld[4]), a child who died an hour after birth was found to be without a spleen; the liver was enormously enlarged. While this case cannot be accepted as an example of the occurrence of absence of the spleen without detriment to health, yet so carefully was the autopsy conducted, and by so competent a pathologist, that it would seem certain that this case demonstrated at least the possibility of entire absence of the spleen. In passing, it may be remarked that

* Read before the New York Pathological Society, October 12, 1898.

absence of the spleen occurring in monsters and associated with absence of other important organs, like the liver, stomach, and kidneys, need not here be considered. As long ago as 1820 Hensinger[5] related several such cases, some having been observed as far back as 1564.

Coming now to the remaining seven cases of absence of the spleen in the adult, Jelenski[6] states that Meinhand, in St. Petersburg, autopsied a woman, aged fifty-seven, who had no trace of a spleen. He also states that J. J. Sachs, on February 8, 1845, performed an autopsy on an adult and found a similar condition of affairs to exist. Unfortunately, Jelenski gives no more details than are here mentioned. R. Libby,[7] in an article published in 1846, relates a case of a negro slave who was executed for murder in 1834, in whom no trace of the spleen could be found at the autopsy. This man during his life was subject to periods of melancholy, and was of a surly and irritable disposition. I am loath to accept this case without reserve, since it is stated that there was present in the abdomen, contiguous to the tail of the pancreas, an abscess (size not given) which was oblong in form. It seems not improbable that this abscess was the remains of the spleen. H. A. Ramsay[8] describes a case of a man, aged twenty-eight, who probably, judging from the description, died of general tuberculosis, in which the spleen could not be found. I am forced to believe from a perusal of the account of this case that the presence of the spleen was overlooked, and that it can therefore not be accepted as a case of true absence of the spleen. Koch and Wachsmuth[9] describe very briefly a case of a man, aged forty-nine, who was very large and very muscular, and who died of typhoid fever. The spleen is said to have been absent, and the splenic artery was wanting in this case. E. Moroni[10] and Gonzalez M. Olaechea[11] have each reported a case of complete absence of the spleen. I have been unable to obtain access to either of these two publications, neither have I been able to find abstracts of them.

The history of the case which I have to report is as follows:

N. W——, aged thirty-two, male, colored, native of United States, was admitted into Roosevelt Hospital, New York, May 4, 1898. Died, May 7, 1898. Family history negative, personal history unimportant.

Present illness. The patient felt perfectly well up to four days ago, when he was seized with severe headache and pains throughout the body. The pain was especially severe over the lumbar region, and was made even worse by stooping. On the following day pain over the left side of the chest became especially marked, and this was made worse on deep inspiration. There were no chills. A slight cough developed. For the past two days there has been pain all over the abdomen, which became somewhat distended. There has been some constipation for the past few days.

On admission. The patient was muscular and well nourished. Mucous membranes jaundiced. Pulse regular, but rapid. Tongue coated. The patient was apparently in great pain. Temperature, 105° F.; pulse, 134; respiration, 34. Urine negative. Examination of the blood showed a marked leucocytosis, but no malarial parasites were found. Physical examination negative.

On the morning of the third day of his stay in the hospital, or on the seventh day of his disease, the patient suddenly went into collapse and died. While he was in the hospital, the severe pain and gradually increasing jaundice were marked features. The temperature ran an irregular course, ranging from 99° to 105° F. The pulse was more nearly stationary at about 134.

Autopsy, seven hours after death. The body was that of a large, well-developed, muscular negro. The conjunctivæ were moderately jaundiced. There were several old scars on the anterior surfaces of the legs. In the peritoneum were several old peritoneal adhesions. Mesenteric lymph nodes were markedly enlarged. They were hard, and on section contained cheesy and calcareous material. The retroperitoneal lymph nodes, more especially in the region of the promontory of the sacrum, were also enlarged, cheesy, and calcareous. Some of these were one inch in diameter. The appendix was normal. The gall bladder contained no gall stones. All the viscera, as well as the fat and subcutaneous connective tissue, were moderately jaundiced. There were old adhesions over both lungs. Both right and left pulmonary arteries were filled with a firm red branching clot. The bronchial lymph nodes contained old fibrous and cheesy tubercles. Both lungs were considerably œdematous. The left pulmonary pleura was studded with many fibrous (healed) tubercles. Both lungs contained dense fibrous and cheesy tubercles, sometimes isolated, and at times occurring in conglomerate fibrous masses. They were rather more numerous in the right lung than in the left. In the heart several tiny, fresh (?) vegetations were found on the mitral valve. It was without appreciable stenosis. The heart muscle looked normal. The liver was large, weighing seven and one-half pounds. It was of a dark purple color. The organ was friable, and the cut section looked rather coarsely granular. The gall bladder contained one drachm of orange-colored bile. The common duct was occluded by a mass of enlarged lymph nodes pressing on it. The stomach was bile stained, and its mucous membrane was digested. The pancreas was atrophied. Notwithstanding careful search, no trace of the spleen was discovered. In the small intestine Peyer's patches presented a "shaven-beard" appearance, and occasionally the solitary lymph nodules were swollen. The large intestine was normal. Both suprarenals were larger than usual. The kidneys were large. They showed no macroscopic lesion. The brain and cord were not examined.

Anatomical diagnosis. Obstructive jaundice; chronic general tuberculosis; œdema of the lungs; absence of the spleen.

Microscopical Examination.—The more important microscopic features of this case were confined to the lungs, lymph nodes, the suprarenal capsules, and more especially to the liver.

Lungs. The nodules in the lungs were evidently tuberculous in character, although efforts to demonstrate tubercle bacilli were unsuccessful. The larger ones were mostly composed of a dense, cheesy material, oftentimes containing calcareous masses, and were surrounded by zones of dense fibrous tissue. Most of them were more or less pigmented, and in some of the smaller nodules giant and epithelioid cells were seen. The smaller blood-vessels commonly showed a fairly marked arteritis, with thickening of the media.

Lymph nodes. The bronchial lymph nodes showed the usual characteristics of chronic tuberculosis. The mesenteric and retroperitoneal lymph nodes presented several interesting features. First, both seemed uniformly involved. Second, on section each contained more or less in the centre of the nodule a dense mass of dry, cheesy material, often comprising calcareous matter, and making up from one-half to two-thirds the bulk of the node. The appearance of the cheesy material was quite uniform. No cell outline could be made out in it, and but very rarely could even nuclear fragments be detected. Tubercle bacilli were not found. Surrounding the cheesy masses were fairly thick zones of dense fibrous tissue, almost wholly devoid of nuclei. There seems to be little doubt that the process was of a tuberculous character and in a quiescent or arrested stage, although the nodules presented appearances not unlike those seen in medium-size

gummata. Third, surrounding the nodules just described there was a considerable lymphoid hyperplasia of the nodes. In this portion of the nodes there was no especial increase in the connective-tissue stroma. There had been but slight proliferation of the endothelium normally lining the reticulum, and the lymph nodules and perinodular lymph spaces as well as the capsule of the node were still fairly normal in appearance. It is evident to me from this examination that there had been in the mesenteric as well as the retroperitoneal lymph nodes an actual and considerable increase in the normal elements, *i.e.*, a compensating hyperplasia.

The suprarenals. The lymphatic hyperplasia, which was noticeable in some of the other organs, was particularly so in the suprarenals. In the medullary portion of the gland were numerous aggregations of lymphoid cells, some of considerable size. There was also some diffuse infiltration, and to a less marked degree there were smaller accumulations of spheroidal cells in the cortical portion. Apparently the increase in size of the suprarenals was due to the presence of the lymphatic new growth.

Liver. The liver was increased to twice its normal size. This increase in size and the dark purple color of the organ noted at the autopsy were due almost entirely to a dilatation of the liver capillaries between the liver cells. The dilated and distended capillaries occupied almost as much space as the parenchyma. The gall ducts were empty and collapsed. The branches of the portal vein were commonly dilated. The central vein was normal. The branches of the hepatic artery showed no change. Glisson's capsule throughout the liver contained a large number of cellular elements. The cells were here sometimes packed together in little compact masses, although throughout the whole of the capsule they were abnormally abundant. They were contained in a scanty, fibrillar stroma. The character of the cells varied. The most abundant resembled leucocytes or lymphocytes, and of these the small spheroidal mononuclear cell was the most numerous. Some of them were polynuclear, having from two to four nuclei, and some contained a single, large, finely granular nucleus (eosinophile cells). In addition to these forms, there were many larger and flat cells, resembling endothelium or epithelioid cells.

It is difficult to interpret this cellular proliferation of Glisson's capsule. It would seem possible that it was an early stage of biliary cirrhosis dependent upon compression of the common bile duct from adjacent enlarged lymph nodes. It seems also even more probable that this cellular proliferation was of the nature of a lymphoid hyperplasia of the pre-existing Arnold's lymph nodules, similar in character to the hyperplasia of the lymph nodes of the mesentery and retroperitoneum and suprarenals, and similar to the same increase in size of the solitary lymph nodules of the intestine which was noted at the autopsy. If the latter assumption is the correct one, we are justified in the belief that the process is a physiological one tending to compensate for the absence of the spleen.

Remarks.—This case furnishes several interesting features: (1) The occurrence of widespread tuberculosis exhibiting marked healing phases in an individual who failed to experience the usual symptoms therefrom. (2) The occurrence of sudden and fatal jaundice caused by obstruction of the common gall duct from an adjacent mass of enlarged lymph nodes. (3) The absence of the spleen in the adult without detriment to health. (4) The occurrence of physiological compensatory lymphoid hyperplasia of other parts of the lymphatic apparatus.

Regarding the question of the absence of the spleen in this case—namely, the possibility of this organ having been overlooked at the autopsy—I am firmly of the belief that this mistake did not occur. I am, however, prepared to admit that had the condition of the splenic artery been carefully determined with reference to possible anomalies of its terminal or splenic branches, and had these branches been found wanting, my case would thereby have received additional confirmation. I am also mindful, as I was at the time of the autopsy, that the spleen under certain conditions becomes greatly diminished in size and might therefore be more easily overlooked. Thus Stengel [12] quotes Savill as having seen a spleen in an adult which weighed but 3.63 gm., whose dimensions were but $1\frac{3}{8}$ by $\frac{1}{8}$ by $\frac{1}{5}$ in. Kuhn [13] has seen in a woman, aged sixty-four, a spleen of even smaller dimensions. Therefore, had each of the hundred or more enlarged mesenteric and retroperitoneal nodes been examined microscopically, with negative results so far as finding in them spleen tissue, my case would still have additional support.

Whether or not there regularly follows after extirpation of the spleen a compensatory hyperplasia of other lymphatic organs has not as yet been definitely settled. In none of the recorded cases of absence of the spleen, unless it be those of Moroni and Olaechea, was there any mention made of the condition of the lymph nodes. In my own case the lymphatic hyperplasia was well marked in the lymph nodes, liver, suprarenals, and intestines.

In the "American Text-Book of Physiology," page 272, I find this statement: "An increase in the size of the lymph nodes and bone marrow is said to occur after extirpation of the spleen, but this is denied by others." I have found no recorded case of extirpation of the spleen which was followed by autopsy, but in animals, as shown by the experiments of Winogradow,[14] K. Foa Pio,[15] and Mosler,[16] there follows in most cases after extirpation of the spleen a very considerable increase in size of the lymph nodes and bone marrow. In one of Mosler's dogs, however, which was killed eleven months after extirpation of the spleen, there was not the slightest trace of any alteration having taken place in the remaining lymphatic structures as a result of the operation.

Several cases in the human subject have been reported, in which the condition of the lymph nodes, thyroid, and blood have been noted after successful splenectomies. O. Riegner[17] reports a case of a boy, aged fourteen, seven months after splenectomy was done for rupture of the spleen. Four weeks after the operation gangrene of the left leg developed, which required amputation. In the amputated leg several enlarged (bohnengrosse) lymph nodes were found. Later the axillary, cervical, and inguinal lymph nodes became enlarged, and reached the size of hazelnuts. Considerable increase in size of the thyroid also followed. The swelling of these organs gradually subsided in this case, so that seven months after operation those in the axilla were alone palpable. Ceci [18] has observed a temporary increase in size of the tonsils and thyroid after splenectomy. On the other hand, Czerny, Billroth, Albert, and Trendelenburg, quoted by Riegner, have failed to observe any enlargement of the lymph nodes, tonsils, or thyroid, after successful splenectomies.

Progress of Medical Science.

Treatment of Ectopic Gestation.—Dr. H. W. Longyear (*Annals of Gynæcology and Pediatrics*) summarizes as follows: (1) In all cases of intraperitoneal rupture, operate as soon as the diagnosis is made; do not wait for reaction to occur. Support such patients before and during the operation by application of heat to the extremities and back, transfusion of decinormal saline solution, rectal use of beef tea and saline solution, and strychnine, nitroglycerin, and digitalin by hypodermic injection. (2) If the hemorrhagic blood cannot be quickly removed, let it alone and use drainage. Do not flush the abdominal cavity to remove blood. The peritoneum will absorb the blood with much less danger than is caused by such manipulation. (3) Use silkworm gut *en masse* to close the abdominal wound, in case there has been great loss of blood, as the buried animal suture is not readily absorbed when such depletion has occurred. (4) Extraperitoneal hæmatocele is usually self-limiting and will almost always result in the death of the fœtus and the recovery of the patient. (5) In cases that go on to full term, operate at the end of pregnancy to save the child. Operate through the abdomen, drain through the vagina, and leave the placenta to come away by disintegration. (6) Electricity should be used only in cases so situated as to preclude the possibility of securing proper surgical treatment.

Hot Air in Hepatic and Renal Hemorrhages.—In Dr. Czerny's clinic Dr. Schneider has experimented on animals with steam and hot air in controlling hepatic and renal hemorrhages. He finds that steam does not control profuse bleeding, and is therefore not indicated in renal or liver hemorrhages. On the other hand, hot air is of value and deserves a trial on the human subject. Hollander's apparatus was employed in these experiments, but is not suitable for the purpose suggested.—*Beiträge zur klinischen Chirurgie*, Bd. 2, H. 3.

Nose and Throat Affections and their Relation to General Medicine.—Dr. Walter F. Chappell (*Medical Review of Reviews*, April) says: "Several innocent rashes, resembling in appearance the rash of scarlet fever and measles, are accompanied by throat symptoms, which may readily lead to a mistake in diagnosis. For instance, some persons are very susceptible to certain fish poisons, and may develop a pyrexia and pharyngeal redness, with a rash closely resembling that of scarlet fever. Again, certain persons subject to recurrent follicular pharyngeal tonsillitis develop a bright scarlet rash over the chest and back, as one of the initial symptoms of approaching tonsillitis. A member of my family had this peculiarity, and it so happened that a number of physicians saw her, during numerous attacks, and all at first thought they had a case of scarlet fever with which to deal. The rash in such cases has not lasted, in my experience, more than twenty-four hours, and often a much shorter period, and does not spread beyond the parts stated."

The Study of Hysteria in Childhood.—Dr. Herman B. Sheffield (*New York Medical Journal*, September 24th) summarizes the contents of a paper as follows: (1) Hysteria is a neuro-psychosis, manifesting itself in an array of functional disturbances of one or all of the higher centres (intellect, feeling, and will), with secondary changes in the lower ones, underlaid by a morbid condition of the nerve substance. Whether this defect lies in the neuron, in the nerve cell, in the nerve fibre, or in all of them, is a question as yet awaiting correct solution. (2) The etiology of hysteria in childhood is, like that in the adult, very obscure. Anything that lowers the vitality of the patient serves as a predisposing cause. The rôle played by heredity as an etiological factor of hysteria is overestimated. Much more weight must be laid upon the acquired causes, among many of which imitation, faulty methods of education and discipline, alcoholism in the young, and trauma are deserving of special mention. (3) Hysteria attacks boys as well as girls, the ratio being as one to two. It is comparatively rare in children under eight years of age, although youths eighteen years old are not exempt from it. (4) The symptomatology of hysteria is characteristic for its changeability and multiplicity. In the United States it is observed, as a rule, in the following order of frequency: (*a*) Spasmodic affections (convulsions, spasm of the laryngeal muscles—croup—contractures, catalepsy); (*b*) sensory symptoms (painful sensations, anæsthesia, blindness, contracture of visual field, hemianopsia, deafness); (*c*) motor disturbances (paralysis of the extremities, paralysis of the laryngeal muscles—aphonia); (*d*) visceral and vasomotor disturbances (affections of the alimentary canal, dyspnœa, tachypnœa, hyperpyrexia). (5) The treatment consists in removal of the causes, attention to general hygiene, isolation and rest, suggestion and hypnotism. The duration of this disease depends greatly upon the skill in treatment; the prognosis is, at all events, favorable.

Visceral Anæsthesia in Tabes.—Dr. Pitres (Fr. Congress for internal Med., 1898) calls attention to a new form of visceral anæsthesia in locomotor ataxia. The extreme sensitiveness of the epigastrium to pressure or blows in the healthy individual is well known. In the examination of fifty tabetic subjects, the writer found this sensitiveness normal in twenty instances only, in thirteen cases it was lessened, and in nine entirely absent. In such patients there is neither skin anæsthesia of the abdomen nor increased abdominal-wall reflex. On the other hand, in many of them the feeling of hunger and of appeased appetite is lost.

Poisoning by Opium and its Alkaloids.—Dr. Paul Schenk, in an original article in the *Deutsche Medizinal-Zeitung*, August, draws the following conclusions: (1) Opium simulates morphine poisoning in its essential points. (2) Death following poisoning by opium and its alkaloids is due to poisoning of the central nervous system. (3) Of all the alkaloids, codeine stands next to morphine in its poisonous effects. (4) All the other alkaloids have either no poisonous properties or are very mildly poisonous to the human system. (5) From the post-mortem examination alone in a case of poisoning by opium or morphine, it is not possible to decide whether death was due to acute or chronic poisoning. (6) In a doubtful case the most

important point is the history, and next in importance is the chemical analysis. (7) Chemical examination should be made even in cases in which a positive history is obtained.

Hypnotism in the Treatment of Alcoholics.—Dr. Rybakow, in an article in *Wratsch* for August, draws the following conclusions from cases under his own observation as well as from the literature on the subject: (1) Alcoholics are very susceptible to hypnotism, and subject themselves to the hypnotic influence much more readily than many other patients. (2) Hypnotism is a very good remedy in the treatment of alcoholism. (3) The favorable effect of the treatment shows itself in the improvement of the subjective symptoms, the disappearance of the depression, of the apathy, and, finally, in the complete loss of the thirst for alcohol. Sometimes one sitting suffices not only to overcome the desire for the habitual potion, but also to break off an acute attack. (4) By repeating the sittings one may at times delay the patient's cravings; the intervals, however, vary, depending entirely upon individual characteristics. (5) Complete cure by hypnotism, according to the experience of the author, is seldom obtained; relapses also are proportionally frequent. However, other authors report instances of complete cure by hypnotism. The duration of the treatment depends especially upon the degree of degeneration; the milder the degeneration the more positive and lasting the cure. (6) Relapses are most frequently noticed in patients under this treatment when the sittings are discontinued too early. (7) In the treatment of the craving for alcohol by hypnotism, the utmost care should be taken in reference to the promptness of the sittings. (8) The hypnotic treatment may be instituted at any time; it is, however, better that the sitting take place during the state of sobriety. At all events, it should be delayed until the agitation and hallucinations have subsided.

Small-Pox and Phthisis.—That variola predisposed the subject to tuberculous affections was long since advanced by Landouzy. In confirmation of the theory, Dr. Lop (*Bul. de l'Acad. de Méd.*, September 6th) now brings forward a series of sixty-four observations, to which are added seventy-six by other observers, all going to show that the form of tuberculous disease is more severe and runs a more rapid course.

Enlarged Cervical Glands.—When a patient comes to you with enlarged lymph nodes of the neck, be sure to examine the throat most carefully. If the patient is a child, remember that a very common cause of lymph-node inflammation is the presence of hypertrophied tonsils or of adenoid vegetations. In an individual of middle age, examine any hypertrophy critically, bearing in mind the possibility of neoplasm.—*International Journal of Surgery.*

Cholelithiasis.—Dr. Naunyn, of Strasbourg, draws the following conclusions: (1) In biliary colic the gall-bladder tumor depends upon a cholecystitis. (2) The pains in the so-called biliary colic are in many cases due to the existing cholecystitis. (3) The icterus which is seen in biliary colic frequently depends upon the cholecystitis, or more so upon the accompanying cholangitis; it is often an inflammatory icterus, in contradistinction to the "lithogenous" icterus which may occur when the stone exists in the common bile duct and prevents the outflow of bile. (4) There are cases in which a cholecystitis presents the picture of a biliary colic, in which gall stones are diagnosticated, when in reality there is only a cholecystitis. (5) Such cases of cholecystitis may run their course during an attack of biliary colic. In a few days the pains cease, the swelling of the gall bladder diminishes, icterus and fever, if they existed, disappear. (6) The cholecystitis may occur independently at an earlier or later date. The pains concentrate themselves in the gall bladder, or they assume a secondary importance, while symptoms of infection (fever, general malaise, prostration) become prominent. Such cases may prove fatal on account of metastatic deposits, or they may lead to a chronic cholecystitis, to hydrops or empyema of the gall bladder, or they may finally run a favorable course by expulsion of the stone. (7) Cholecystitis and cholangitis give rise to numerous sequelæ of gall stones, such as abscess of the liver, perforation of the stone toward the exterior or into an internal organ, as well as numerous fistulous tracts. (8) According to Riedel, the colic is caused by the pushing of the stone into the cystic duct, on account of the serous transudation which results from the inflammation of the mucous membrane of the gall bladder. (9) The diffuse cholangitis goes hand-in-hand with the calculous cholecystitis. If the cholecystitis is the cause of the swelling of the gall bladder, then the cholangitis is due to the painful swelling of the liver. A cholangitis which spreads to the finest gall capillaries (cholangitis capillaris) can give rise to jaundice very quickly, by directly influencing the secreting liver cells. (10) The cholecystitis and the cholangitis calculosa are infectious from the outset. Whereas normal bile is sterile, the fresh cases of cholecystitis calculosa always showed the bacterium coli in the gall bladder. In older cases the bile may be found sterile; the bacterium coli seems to die very quickly at times. This cholecystitis and bacterium-coli cholangitis seldom become purulent, except when pyogenic bacteria—staphylococci and streptococci—infect them; they must be distinguished from empyema of the gall bladder and suppurative cholangitis; still they may give rise to severe local and general symptoms without becoming purulent. (11) A cure of the cholecystitis and cholangitis may be expected when the circulation of bile is once more established and the gall stones are dislodged. Even if the stones be not displaced, the case may terminate favorably, according to Riedel. Then it may be that the symptoms are simply on the retrograde, while the cholecystitis still exists, remaining latent only to recur again; or the biliary colic may in reality be cured, for a long time at any rate. (12) Apart from the cholecystitis and cholangitis, the gall stones become a source of danger on account of the chronic obstructive icterus. The latter depends principally upon the closure of the common bile duct with stones. The large stones which are found in the common bile duct have wandered, in most cases, from the gall bladder when quite small, and have grown larger and larger. The cause of chronic jaundice in cholelithiasis is by no means always a stone in the ductus communis choledochus; in many cases the seat of the stone may be the cystic duct, and thus give rise to compression of the common duct. On the other hand, very large stones may exist in the common duct without giving rise to icterus. (13) There is no positive differential point for determining which cases are going to be successful and which will result otherwise; the symptoms are the same and the passage of stones does not decide the question. In those cases in which stones are found in the stools, others may remain behind, and even though we do not find any stones it does not prove that the attack is a favorable one. (14) In more than half of the cases carcinoma is found as the cause of the chronic obstructive icterus. In some cases nodules may be felt in the wall of the gall bladder; in others, metastases in the liver, lymph glands, or upon the peritoneum. One must never fail to examine the pouch of Douglas—that is, to palpate the rectum. In most cases, however, such metastases are not found; then the existing ascites affords corroborative evidence, for

marked ascites with cholelithiasis always points to carcinoma. The significance of cachexia is not to be underestimated; if this occurs rapidly in the course of cholelithiasis, it speaks for carcinoma. In chronic icterus not due to carcinoma, the general strength and nutrition remain good for a considerable period.—*Münchener medicinische Wochenschrift*, October 4th.

Ruptura Vaginæ sub Coitu.—Dr. Finkelkraut reports (*Gazeta Lekarska*, No. 7, 1898) a case of rupture of the vagina sub coitu, and enumerates the following etiological factors: (1) Abnormal erection of the penis during coitus. Normally the penis passes along the posterior wall of the vagina. In retroversion, as well as during coition, the uterus sinks downward and backward; thus the stretched posterior wall is easily ruptured by the abnormally erected penis. (2) Insufficient development of the vagina or the weakness of its walls, as in cases of senile atrophy of the genital apparatus. (3) Too great a disproportion between the male and female genital organs. (4) Extremely impetuous coition with unusual violent erection. In the case reported two of the etiological factors were present—atrophy of the vaginal walls and abnormally violent coition.

Leucocytosis in Whooping-Cough.—Dr. H. Meunier (*Archives de Méd. des Enfants*, April) advises making a blood examination in order to arrive at an early diagnosis of whooping-cough, especially when it is important to exclude the disease from schools and institutions. The writer states that in children suffering from whooping-cough there is a constant and intense leucocytosis of the blood. Sometimes it reaches a very marked degree; at all times it surpasses the leucocytosis accompanying the other febrile affections of the respiratory tract. The leucocytosis is present long before the characteristic whoop appears; it becomes most marked during the whooping stage and disappears with the diminution of the cough. In the catarrhal state there are about 22,700 leucocytes to 1 c.c.; the number increases to 40,000 in the whooping stage. The leucocytosis is most marked in children two or three years of age. The leucocytosis is due especially to the immense increase in the number of the lymphocytes; the normal proportion of the lymphocytes to the polynuclear leucocytes is reversed. It is not simply a lymphocythæmia, however, for all varieties of leucocytes are increased in number. We are still in the dark as to the cause of the leucocytosis, but it is evident that the congestion of the tracheo-bronchial glands has more or less to do with it. The increase in the number of leucocytes would tend to confirm this view. The constancy of the leucocytosis in whooping-cough; its marked intensity as compared with that occurring in all other respiratory affections; and, lastly, its early appearance before the clinical symptoms are marked, make a blood examination imperative whenever it is necessary for prophylactic reasons to establish an early diagnosis.

Natural Labor.—Dr. Robert R. Rentoul, of Liverpool, defines a natural labor as follows: "Labor at the ninth calendar month in a woman free from organic and functional disease of the heart, lungs, kidneys, brain, and other internal organs, and from all fever diseases; when there is no impediment in the maternal passage of either soft or hard nature to the descent of the child; when there is only one child in the womb; when the vertex of the child alone presents in either the first or the second occipito-anterior position; when labor is completed within twelve hours from its commencement; when a living child is born; when neither instrumental nor manual operations have been required; when the afterbirth comes away without the use of manual operation within twenty minutes after the birth of the child; when there is no laceration of any portion of the parturient structures; when the mother does not die within thirty-one days after confinement, and when there is no puerperal fever."

Indications for Irrigation of the Stomach.—Martius states as follows the indications for lavage of the stomach: (1) Acute poisoning; the introduction of the water dilutes the poison and renders it less harmful, and it can be withdrawn with the fluid. (2) Stagnation in the stomach from stenosis of the pylorus, whether due to a benign or malignant growth. (3) All cases of occlusion of the intestines from whatever cause. Irrigation always relieves and may possibly cure without further treatment. Guerin commends it in the current *Archives de Bordeaux* for its action in arresting the painful vomiting of fæcal liquids, while it allows medicines to produce their proper effect. It is also generally indicated in carcinoma ventriculi, acute and chronic catarrh, and all functional diseases of the stomach. Also in tympanites such as occurs in severe abdominal typhus and in nervous dyspepsia and spasm of the œsophagus. Others have found it very beneficial in infantile gastric and bowel troubles, acute and chronic. Some consider it ineffective in neurasthenia gastrica, but it often produces a cure in nervous dyspepsia when the patient can be made to see for herself that her stomach is digesting normally. Minkowki has found it very valuable in arresting hemorrhages. He suggests that the time of using it is very important; if the patient is allowed to eat again soon, the benefits are often lost. He advises it the last thing at night. Quincke also uses the irrigator for removing the liquid.—*Memorabilien.*

Digestive Ferments.—As to ferments, the following general statements may be made: (1) There is no information or reasonable supposition that a ferment of the digestive glands is ever produced in excess. (2) The failure of a ferment occurs only in the most serious organic disturbances—though not necessarily locally organic; thus fever is often attended with failure of ferments. The salivary ferment is particularly resistant to disease, though not of very great importance in health. (3) The administration of ferments should never be resorted to without previous demonstration of their absence. (4) After proving that a ferment really is deficient—something that occurs in scarcely one per cent. of cases—we must ask whether the stomach and intestine are in a condition to digest on the mere supplying of the ferment, or whether predigestion, rectal nutrition, etc., are not indicated. As a rule, the body which lacks ferments lacks the power of using them if artificially supplied.—A. L. Benedict, Buffalo.

Selection of Chloroform as an Anæsthetic.—Dr. Miron I. Marsh is credited with the following statements: Chloroform is generally to be given preference as follows: (1) Organic diseases of the nervous system. (2) Atheroma occurring in those advanced in years. (3) Chronic or acute inflammatory affections of the respiratory tract, as severe bronchitis, asthma, emphysema, or advanced tuberculosis. (4) Protracted operations about the nose, mouth, or pharynx, which necessitate the nose and mouth being uncovered. (5) Night operations with artificial light, unless the light be placed much higher than the ether, its vapor being heavier than air. (6) When the galvanic cautery is to be used in the neighborhood of air passages. (7) When ether has failed or cannot be procured, or when there is a distinct record of deleterious effects during a previous etherization. (8) Renal diseases, both acute and chronic. (9) Chronic alcoholism. (10) Old age, young children. (11) During labor. (12) Puerperal eclampsia when an immediate effect is required.—*Cincinnati Lancet-Clinic*, September 10th.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, November 12, 1898.

FEMALE DISEASES AND INSANITY.

IT is perhaps the inherent vanity in the race that keeps it alive. Were every man to look at himself with the strictly impartial view of his neighbor, his self-appreciation would ooze out, his upwelling ideas would leak away, and his ambitions would sink to the low levels of other men's esteem.

Ah, no! it would not do to stand on the street corners and smite our breasts as miserable sinners. It is far better to congregate in high places, in clubs, in medical societies, and in the editorial corners of our journals, and unite our voices in thanks that we are not as other men are. Then our fellows may see how wise are the tenets of our specialty and how false are other men's.

Who but the greedy, grabbing gynæcologist would insist that it is disease of the ovaries or false position of the uterus that causes the trouble, when it is transparently plain that the nerves are the seat of the disorder? And why should not the triumphant neurologists congregate and rejoice when they see the value of their claims recognized and the fees running in their direction? Witness the recent appreciative abstracts of the Italian observers, Angelucci and Pieraccini, in their international inquiry on the relationships of diseases of woman and nervous disorders.

One of the most pronounced articles illustrating the general point in question, and one which should receive the attention of both neurologists and gynæcologists, has recently appeared in the *American Journal of Insanity*, vol. lv., 1898, No. 1, July, entitled "Surgery among the Insane in Canada," by R. M. Bucke, M.D., president of the Medico-Psychological Association.

He has been led to believe that there is a great deal of pelvic disease in female lunatics, and that such disease has often a causative relation to the mental alienation existing. His investigations in the London (Canada) Asylum, the examinations being made by a competent gynæcologist of that city, show that of 132 patients there was organic disease of the generative organs in 122, only 10 being free. Of the 122 cases of organic disease 109 had been operated upon. In the report of the pathological conditions operated upon, many minor troubles were mentioned. His tables included: menorrhagia, 14; endometritis of various grades, 62; hypertrophied cervices, . rated cervices, 34; cystic cervices, 19; polypi o cervix, 3; fibroids, 7; epithelioma and sarcoma, each 1; retroversions, 33; procidentia, 5; ovarian tumors, 8; perineal injuries, 22; and fistulæ, 2.

The results in the 109 cases were:

(1) As regards bodily condition. Three died from the operations and all of the rest were improved.

(2) With reference to the mental condition. In 39 cases the patients recovered from their insanities, in 32 cases there was marked improvement, and in 35 there were no changes for the better. The author's conclusions, in view of the almost chimerical nature of the results, are worthy of reproduction. "Should it be once conceded by those who have charge of the insane, by those men to whom the general profession looks for guidance in these matters, that utero-ovarian diseases are capable of acting as causes of insanity and that removal of these will in some cases result in the disappearance of the mental disturbance, almost at once it would happen that many insane women instead of being sent to an asylum would be operated upon and relieved at home. More than that, if the connection in question were admitted, these women would not be allowed to remain insane at home for months, and often years, as happens now, but would be examined, operated upon, and relieved within a few weeks of the appearance of the insanity. More even than that, when the eyes of the general profession are fully opened upon this subject, symptoms of subinvolution, endometritis, or laceration of the cervix will be watched for after childbirth, and if present be at once relieved; and the women who might have become insane in consequence of one or other of these lesions will remain sane."

The Italian compilers above mentioned reported, as the result of an international inquiry, hearing from large numbers of both gynæcologists and neurologists, that the relationships in question of pelvic disease and insanity were *nil*. And here we have this roseate picture!

VEGETARIANS IN EVIDENCE.

THOSE who advocate and practise abstinence from animal food are beginning to direct attention to themselves and their theories in several quarters. In Germany the recent bequest, by the will of Professor Baron, of sufficient funds to found and maintain an orphan asylum in which vegetarian principles were to be inculcated and observed, has created considerable discussion in Berlin. It seems that after the professor's bequest had been formally accepted by the mayor of the city, objections were raised by members of the council, which includes such well-known physicians as Virchow, Fürbringer, and Fraenkel. It was contended that the authorities should hesitate before subjecting its orphan wards to what must still be regarded as an experiment in diet.

While it is quite possible that in many countries much more meat is consumed by the individual than the requirements of a healthy system demand, still it

would seem that in some climates the manual laborer actually needs a certain proportion of such food in his daily diet as is furnished by animal muscle and fat. As an indication of what may be accomplished in the way of muscular effort on a purely vegetable diet, the winner of a recent foot race in Berlin, who was a vegetarian, covered the distance of fifteen German miles in fourteen and one-quarter hours without showing any signs of marked fatigue. This was also the case, according to *La Médecine Moderne*, with the five other vegetarians who took part; while of the eleven non-vegetarians in the contest, only one was able to finish, and he came in far behind the others and in bad form.

ACUTE ARTICULAR RHEUMATISM.

That acute articular rheumatism is a disease due to a specific micro-organism has been believed for a number of years, and in recent times several bacteria have been described, but apparently with little or no confirmation. One observer, however, would seem to have fared better, in that recently his claims have been substantiated by other investigators, and it may be hoped that the elusive cause of acute articular rheumatism is finally located.

As early as 1891, P. A. Achalme announced that he had found the bacterium of acute articular rheumatism. For some reason or other he was unable to follow up his discovery with confirmatory proofs, and it was not until late in 1897 that he was enabled again to isolate the organism. He then published, in the *Annales de l'Institut Pasteur*, 11, 1898, p. 845, "Recherches Bacteriologiques sur le Rheumatisme Aigu," a more detailed report concerning the bacterium in question. He describes it as an anaerobic bacillus, which resembles in its general morphology the bacillus of anthrax. It is moderately motile, is colored readily with most of the aniline dyes, showing a capsule. It rarely forms spores, and when formed they are developed on the end. Its maximum growth takes place between 30° and 38° C., and temperatures below 25° or above 40° C. limit or destroy its growth. One interesting fact relative to its biology is that when grown in urine it decomposes this, throwing down extensive deposits of urates. Following Achalme's publication, many bacteriologists claimed that he had isolated only one of the many anaerobic bacteria which were commonly found in dead bodies, and were in reality bacteria of putrefaction. In a more recent communication, "Recherches sur l'Anatomie Pathologique de l'Endocardite Rheumatismal," *Archives de Médecine Experimentelle et d'Anatomie Pathologique*, 10, 1898, p. 370, he reports having found the organism again in two cases, and he controverts the statement that this bacillus is one of the putrefactive post-mortem anaerobes. To verify this he examined thirty post-mortem cases, and in no one was his organism found. Achalme, moreover, states that it was the exception rather than the rule to find the bacillus in the blood of patients suffering with the disease. Finally, in the *Archives Russes de Pathologie, de Médecine Clinique et de Bacteriologie*, 5, 1898, p. 613, Sawthenkow completely confirms the researches of Achalme. He, in addition, shows that the organism elaborates negative chemotaxic substances and also products which produce necrosis in animal tissues. The characteristic endocardium lesions he believes to be due to these latter substances. Experiments made by him would seem to show that the action of sodium salicylate is due to the liberation of free salicylic acid.

THE BERTILLON SYSTEM OF MORTALITY STATISTICS.

A decision, of which the importance can as yet be hardly estimated, was come to at the recent meeting of the American Public Health Association, held at Ottawa, Canada, in September last. The following resolutions, which had been submitted by the committee on vital statistics at Philadelphia in 1897, were favorably reported by the executive committee, and were then unanimously adopted by the association: (1) That the American Public Health Association recommends that the Bertillon classification of causes of death be adopted by all the registrars of vital statistics in the United States, Canada, and Mexico, as soon as the change from the systems now in use can be conveniently made. (2) That the committee on nomenclature of diseases and forms of statistics (now the committee on demography and statistics in their sanitary relations) be authorized to have printed and circulated among the registrars of the three countries a circular containing these resolutions, the report of the committee on which they are based, the three alternative forms of the Bertillon classification, with explanatory notes on inclusion of terms and practical rules for compilation and a list of the registration offices adopting the same. (3) That a proposal be made for an international alliance between the registrars of the three countries included in the association, and the registrars of France and other countries now using, or which shall hereafter adopt, the Bertillon system, and that definite plans for such alliance shall be submitted for action to the next annual meeting of this association. It was also advised that the selection of a plan of international revision should be undertaken at once, in order that the revised classification might be ready for use in 1900, and the statistics of the next century might be begun on a uniform basis.

The need of a uniform system of classification of causes of death has long been felt, and now that the whole continent of North America has taken the initiative in the matter, together with Costa Rica on the Southern continent, the co-operation of the remaining States of South and Central America may be looked for with assurance. But this is not all. France has for a considerable time thoroughly tested and demonstrated the usefulness of the system; some of the smaller European States have followed suit. Does it not therefore seem both desirable and in the interests of the civilized world at large that the other European countries, the British Empire, and Japan, should fall into line and support the plans for an international

alliance of revision? Doubtless there will be many and great difficulties in their way; old countries which have had for years systems in use, and to which they have become by custom welded, may at first feel averse to a change. But none of these difficulties are insuperable, and when the advantages of the proposed revision are weighed in the balance with the drawbacks thereof the most conservative of nations will throw aside all considerations of sentiment or pride and resolve for the good of mankind to adopt a uniform system of statistics.

It is hoped that the first revision may be completed and announced at the International Congress of Hygiene and Demography at the Paris Exposition in 1900. The statement to the following effect is made by Cressy L. Wilbur, M.D., secretary of the United States commission, in the *Michigan Monthly Bulletin of Vital Statistics*, that "a pamphlet containing the official version of the classification, and showing the inclusion of terms, will be ready for distribution about January 1, 1899, and will be sent to all who may signify their desire to aid in the work of revision." When the metric system and the Bertillon system of classification are in universal vogue, matters will be much simplified for sanitarians, medical men, and men of trade.

SCIENCE MADE IN GERMANY.

It was certainly in a facetious spirit that Gruner, advising medical men, wrote in his "Almanach," published in Germany over a hundred years ago: "Go on a trip if possible. Knowledge gathered in Paris or Edinburgh is better than German wisdom." Of course everybody knows that knowledge acquired in Germany was then, as it is to-day, a superior article. Perhaps, in employing the term "everybody," we are making the case too strong, since at least two exceptions can be instanced. In a recent interview with Dr. Heneage Gibbes, who for many years occupied the chair of bacteriology in the University of Michigan, he is reported to have answered a query as to his views on the claims of superiority of German science: "There is no such thing as German science—science is universal. The Mecca of the American physician is Berlin; nothing good can come from any other source than Germany in the science of medicine as taught in American schools. The admiration of German scientists is nothing short of idolatry. In Germany Dr. Koch's theories are generally regarded as theories; in this country they are held to be facts. I taught along the lines of Koch, but presented results only for what they were worth."

The other exception is the editor of the *Medical Brief*, who considers it bad policy to permit an issue of his journal to appear without placing himself on record as opposed to the "greed and narrow-mindedness of Germany" in excluding American products, while sending us useless serums, etc. In speaking of foreign study, he says: "If they must go abroad, far better, it seems to us, would it be for American medical science if students would go to England for their post-graduate courses. See Germany and France, by all means, and pick up all that may be found good; but study in England, where there are conservatism and common sense."

Fortunately the necessities for going abroad for scientific study are becoming year by year so decreased that students will soon not need seriously to consider the matter of where to go. They may finish in the various schools of this city, for example, and then, in pursuance of the "Almanach's" advice, "go on a trip," for the prestige it affords or for the pleasure, but not in the belief that knowledge gathered in foreign parts is always so superior to the domestic article that it must be bought.

A WORD ON THE SPITTING-NUISANCE.

We think that the transportation lines of this city deserve a word of commendation for their efforts to abate the spitting-abomination in the street cars under their control. Most of the cars in the city are now provided with one or two neatly framed signs printed in emphatic type, which state that spitting upon the floor is forbidden by order of the board of health. However, many of the spitters in human form seem unable to see these signs, or else are so unclean and careless as to disregard them, and the employees of the companies do not display any particular enthusiasm in calling attention to the regulation. It seems almost too much to hope that spitting in public places can ever be wholly overcome by anything but the danger of a penalty for the offence, such as a small fine. The authorities of the street railways might, however, insist more strongly that their employees should rigidly enforce the antispitting rule, and, if necessary, eject the offenders. At present the conductors seem willing enough, when requested, to call attention to the rule, but they should take the initiative and not wait for a request. The worst offences are not on the cars of the main lines in the city, but occur on the cross-town and other less prominent lines, in cars which probably get less frequent cleanings than those on more important streets.

To stop spitting upon sidewalks seems too much to expect, unless we can have and enforce a penalty against it. It would probably not take many enforcements for the knowledge to become disseminated that it would cost, say $2, to misuse the sidewalks in this way; and that to this might be added some unpleasant newspaper notoriety, for the spitter is not always one to whom such advertisement would be a matter of indifference. With a little more effort by our car-line officials a very decided abatement of this nuisance in public vehicles can be obtained, and thus indirectly spitting in the street diminished. We ought to be able to depend upon the lay press in this matter, as it is one of common decency and the concern of all.

In Extremis.—Husband: "My darling, when I am gone, how will you ever be able to pay the doctor's bill?" Wife: "Don't worry about that, dear. If the worst comes to the worst, I will marry the doctor."

News of the Week.

Camp Sanitation.—The interest aroused by the alleged unsanitary condition of some of the camps in the recent war has found expression in Buffalo in the desire for a meeting of sanitarians and others—experts in their lines—to present the details of establishing camps of instruction constructed upon strictly hygienic principles—asphalted floors and streets, water system, sewerage. The various phases of the subject will be briefly considered from economic, military, and sanitary aspects, and the consensus of the whole presented with the idea of creating a public demand for such camps. In issuing a circular relating to the proposed meeting, Dr. Ernest Wende, chairman of the topic committee of the Sanitary Club of Buffalo, says that it is not intended that any criticism be introduced in any manner whatever concerning the recent war, but merely to discuss the feasibility of permanent camps of instruction, to be maintained ready for use at any time desired by the general or local government.

Infected by Absorption.—An eye quack, who advertises to cure all diseases of the eyes by the simple process of "absorption," recently admitted to his house a patient with gonorrhœal ophthalmia; and, as it is a poor rule that does not work both ways, and absorption at that time was working freely, many of the other inmates caught the disease. Each sufferer was assured there was nothing the matter, and that it was all in his eye. The true nature of the disease was finally discovered in time to save the sight of the victims, and now the latter are suing the quack in the hope of absorbing some of his dollars as a sort of salve for their sore feelings and sore eyes.

The Gentle Anti.—A dinner was given in honor of Virchow, on the occasion of this grand old medical man's recent visit to London to deliver the Huxley lecture. During the evening, while toasts were being drunk to the health of the guest and complimentary speeches were being exchanged, an unsigned telegram was delivered to Virchow, which read: "Get thee hence, vile vivisector! England spurns thee!"

Standing-in with the Doctors.—An undertaker on the west side of the town has opened an eye to the main chance, and at the same time betrayed his exalted opinion of the physicians in his neighborhood, by addressing to them the following practical suggestion: "Kindly take notice of my new branch office at ——, —— Avenue, for funeral directing and embalming. I am fully prepared to give entire satisfaction and the best of references. Should you have any friends to whom you can refer me, I will allow a liberal commission, say five to fifteen per cent., for such favors shown."

Reciprocity in Registration in Canada.—At the annual meeting of the Canadian Medical Association, held in Quebec in August last, a decided advance was made in the direction of interprovincial medical registration. At present our neighbors suffer, as we do, from the anomaly that a skilful and learned physician who is a legally qualified practitioner in one portion of his country is liable to arrest and punishment as a quack if he attempts to practise his profession in another part, without first submitting to an examination at the hands of a board composed possibly of men in every way his inferiors in medical attainments. It is now proposed to establish a central examining-board for the whole dominion, and those who pass it will thereafter be entitled to practise in any province.

Dr. Sigmund Tynberg has been appointed visiting physician to the Workhouse and Almshouse hospitals.

Orrhotherapy of Hog Cholera.—During the past two years the department of agriculture has conducted a series of experiments in the use of serum as a remedy for hogs affected by cholera or swine plague The experiments were conducted by Dr. D. E. Salmon, chief of the bureau of animal industry, and the results were eminently satisfactory, proving that the disease can be successfully treated easily and inexpensively. Very many remedies have been tried, but nothing even approximating a specific for the disease has ever before been discovered. The experiments thus far made show that 80 per cent. of the affected hogs are now saved, while formerly 80 per cent. were lost. Last year the experiments were conducted in Gage County, Iowa, the results showing a loss of only 20 per cent. of the affected droves. This year the experiments have been much more extensive. The officials of the agricultural bureau treated 922 hogs. Of these 170 died, the number saved being 81 out of every 100. The loss was only 19 per cent. On the other hand, 1,107 hogs in other droves were observed, but not subjected to the serum treatment. Of these 879 died, showing a loss of 79.8 per cent.

A New Degree for Lord Lister.—On October 8th the new Thompson-Yates Laboratories of Physiology and Pathology at Liverpool were opened by Lord Lister, who delivered an address upon the unity of science and practice and the need of raising our practice to accord with the accuracy and certainty of science. Upon the conclusion of his address he was the recipient of the honorary degree of doctor of science of the Royal Victoria University.

Mud Throwing by the Besmirched.—The disgraced Behring, whose desperate efforts to trade in infant lives have been reprobated even by his own countrymen, now seeks to defend his misdeeds by the impudent assertion that earlier medical discoverers and inventors only lacked the opportunity to equal himself in depravity. A writer in the *Berliner Tageblatt*, having asked what would have become of the ophthalmoscope if Helmholtz had made a claim to patent his invention, or what would have become of the methods of immunization devised by Pasteur, or of the antiseptic dressing introduced by Lord Lister, if these gentlemen had acted like Behring, the latter replied that Helmholtz of course could not have attempted to patent the ophthalmoscope as there were no patent laws at that time, and that what Pasteur and Lord Lister would

have done, supposing that it had been possible for them to obtain a patent for their discoveries, he did not know, but he implied that from what he knew of these scientists they would have made money out of their discoveries if they could. This ingenious gentleman forgets to mention, however, that even if the two dead men, whose memory he traduces, and the living one, whom he insults, had stooped ever so low, they could not have fallen to the depths of "lifting" the discoveries of others and attempting to sell them as their own.

Chickamauga Camp comes up once more this week for severe criticism. Since an article in these columns several weeks ago, placing the blame for much of the typhoid and other illness in camp, several surgeons have testified to similar conditions of army and medical mismanagement. Dr. Milo K. Ward, brigade surgeon, has just testified in Chicago, blaming high officials. "The first reason," he said, for the second division hospital of the third army corps having the reputation of being the worst, "is that the hospital had for its corps surgeon a man who never paid any attention to it whatever. His name was Hof. The next reason is that the man in charge of the hospital, the division surgeon, very seldom visited the hospital or paid any attention to it. His name was Jenney. The next reason is that there were not enough doctors to take care of the patients without overworking the doctors and making them too ill to get out of bed. For the first two weeks that I was there there was not a man on duty who was physically fit for duty. The next reason is that the nurses were never competent. They did the best they could. Some of them could not even read. They were forced to do this work under protest. The requisitions made for goods and supplies were approved by the doctors, but they were not brought to the grounds. That was the fault of the doctors in charge of the hospitals."

An Office Thief.—A very shabbily dressed woman, of about forty years of age, with a decidedly "rummy" appearance and odor, is calling at doctors' offices, ostensibly to beg, and improves the opportunity to steal anything upon which she can lay her hands. From one of her victims she stole a pocket case, and after she had gone it was discovered that she had laid some other instruments under a magazine on the floor behind a chair.

Precaution against the Plague.—The Russian government has sent a commission, composed of forty physicians, to Samarkand, to institute measures looking to the protection of Russia from an invasion of the plague.

An Object Lesson for Spanish Sanitarians.—Gen. Leonard Wood, governor of the military department of Santiago, Cuba, authorizes the statement that there has not been a case of yellow fever in the city of Santiago during the last sixty days, and that the ordinary sickness during the same period has been ninety per cent. less than usual. In the mean while, Havana, still under the control of Spanish officials, is reeking with filth and rotten with disease. The Spanish commander is furious against what he calls the "Anglo-Saxon canaille," because the English railway superintendent complained that the Spanish troops used the floor of the station waiting-room as a public urinal. Such squeamishness seems to him to be really too absurd.

A State Laboratory in Vermont.—The legislature of Vermont has just passed an act establishing a State laboratory for the chemical and bacteriological examination of water supplies, milk and all food products, cases and suspected cases of diphtheria, typhoid fever, tuberculosis, malaria, and other infectious and contagious diseases. Five thousand dollars has been appropriated for the establishment of the laboratory, and $8,000 annually for its maintenance.

Small-Pox in Cuba.—Dr. Woodson has reported to Gen. Leonard Wood concerning the epidemic of small-pox now raging in the Holguin district in Cuba. He says that there are more than five thousand cases in the district, and half of the town of Gibara is infected. The epidemic has been in progress for more than three years, and no attempt whatever has been made to check it. The disease is exceedingly virulent. Dr. Woodson established a hospital with one hundred and fifty beds at Gibara, and made arrangements for a large supply of vaccine, by means of which he hopes to arrest the epidemic.

Yellow Fever in Mexico.—Many deaths from yellow fever have occurred at Monterey, where the disease recently broke out. The Mexican government is looking forward hopefully to the time when the disease will be stamped out of all the Gulf towns, for it is believed that when the American government completes the reconstruction of the sewerage system of Havana and cleans out the bay, with moderate care in Mexican Gulf ports yellow fever can be stamped out. The fever has almost disappeared from these ports now, owing to the occurrence of several "northers" recently.

The Plague in Vienna.—According to a dispatch from Vienna on November 1st, there had been a total of nine cases of plague, most of them of the pneumonic form, in that city. Of these nine cases, three terminated fatally. Some nervous people here have suffered from fear that the disease might be brought to this port by Austrian immigrants. Although the danger of such an occurrence is infinitely remote, the health authorities have taken precautions to prevent the chance of importation of the disease. The consuls at the ports of departure will examine each emigrant before he is allowed to go aboard ship, and, if he comes from the infected districts, his baggage will be disinfected and every other precaution taken to prevent the spread of disease. In no case will an emigrant be allowed to proceed if there is any reason to believe that he has been in contact with the infection. As the cases of plague in Vienna have all been among physicians or hospital attendants, and every one exposed even remotely to contagion has been quarantined, the infection of anybody coming from that city is exceedingly improbable.

Society Reports.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, October 12, 1898.

T. Mitchell Prudden, M.D., President.

A Case of Acute Yellow Atrophy of the Liver.—Drs. R. S. Adams and Rowland G. Freeman presented the report of this case, which occurred in the service of Dr. J. J. Reid of the New York Foundling Hospital.

Dr. Adams said that, as only a few over two hundred cases had been reported in medical literature, the following history might prove of interest. The patient was Annie D——, aged twenty-four years, a laundress, from Ireland, who had been one year in the United States, and was nursing her first baby, born about two months previously. She had been confined at another institution—the City Hospital—but there had been nothing noteworthy about the confinement, and she seemed in excellent health for the next two months. Then she suffered for about ten days with symptoms referable to a mild gastro-enteritis; viz., languor, slight nausea, occasional vomiting, anorexia, and gradually increasing jaundice, constipation, clay-colored movements. Then began hallucinations, fear that her baby would be taken away because she, the mother, was sick. The temperature was 99°–100° F.; there was much thirst; and although usually quiet, she occasionally became almost maniacal and told of strange visions. Examination showed jaundice, slight enlargement of the liver, and a normal condition of the heart and lungs. Shortly afterward she became very much excited, and on March 18th she was sent to the hospital ward, the mild symptoms having then continued for about ten days. At this time the temperature was normal; the pulse was full and about 90; the respirations were natural and about 18; the mind wandered a little; there was severe pain in the back; the jaundice deepened. She was very drowsy, and at times quite stupid. She passed plenty of urine, high colored and containing a trace of albumin, bile pigment, and bile acids. There were frequent semisolid movements of a clay color. A diminution in the size of the liver could already be made out, especially in the left lobe. The spleen was slightly enlarged. Owing to the profound changes in the blood, and the good effects of the transfusion of saline solution in uræmia being considered, phlebotomy was performed, about four ounces of blood removed, and in its place eight ounces of decinormal saline solution infused. A considerable but fugacious improvement in the mental condition followed. On the following day, March 20th, her temperature was 97° F., the pulse was about 78, the respirations were deep, and she was quiet and apparently suffering no pain. The liver was smaller. A few spots now appeared on the chest, abdomen, and legs—papules and reddish ecchymoses—but the eruption was painless and did not itch. No hemorrhages elsewhere were observed. In the afternoon another saline infusion was given, in view of the apparent utter hopelessness of any other medication. This was followed by a chill, incoherent and muttering speech, and slight delirium. She was very slow of comprehension and, when aroused, was very irritable. There was marked thirst. On March 21st, she was quiet and apparently very weak. Perspiration very free and of a peculiar odor; temperature, 95° F.; pulse feeble; respirations very deep. Diminution in size of the liver was now extremely marked; she had apparently lost her liver over night, and there was now some incontinence of fæces. The urine was about normal in quantity, of a specific gravity of 1.028, and contained a trace of albumin, bile pigments, leucin, and tyrosin crystals. On March 22d she passed from unconsciousness to coma, with deep noisy breathing; the temperature rose gradually from subnormal to 105° F. before death, the pulse becoming accelerated some time before, and keeping pace with the temperature. She died on March 22d, about two weeks after the commencement of the symptoms, and about four and one-half days after the first severe symptoms, at which time only could the diagnosis be made with certainty.

The autopsy was made sixteen hours after death. The body was well nourished and markedly jaundiced. No œdema was present. The left lung was congested; the right was firmly bound down by adhesions, and was also congested. The heart was negative. The lower border of the liver was at the level of the ensiform cartilage. Its surface was smooth, but it was very soft and friable, and crackled on being pressed, as if it contained air. The gall bladder contained half an ounce of thick yellow fluid. The liver weighed two pounds one ounce. Its cut surface was of a dark red color, and presented irregular areas of bright yellow. The spleen was enlarged, weighing one pound one ounce. It was dark red, friable, and soft. The left kidney was enlarged and soft, the capsules were adherent, and the cortex was quite thin, with rather indistinct marking. The right kidney was similar to the left. The pancreas was markedly enlarged, being nine inches long. It crackled on pressure, as if containing air. In the caput coli was an intersusception, from below up, with marked swelling of the intestine, forming a hard tumor. The uterus was slightly enlarged, its cavity holding one drachm.

The microscopic examination of the tissue showed the liver to have undergone the cell degeneration characteristic of acute yellow atrophy. In addition, there were small empty spaces in the liver, which were surrounded by large, short bacilli. The outline of the cell body was indistinct, and the nuclei failed to stain. The pancreas also showed marked degenerative changes, the nuclei, for the most part, failing to stain with hæmatoxylin, and the outline of the cell body being indistinct. The kidney also showed cell degeneration, the change being more marked in the cells lining the tubules than in those in the glomeruli. Aerobic cultures were made from the organs and showed only the bacillus coli communis, but the bacillus found on microscopic examination surrounding the spaces of the liver differed from the coli communis, and owing to the facts of its morphology, its gas production, and its failure to grow in aerobic plates, the conjecture would seem to be justified that it was the bacillus aerogenes capsulatus. Its identification was, however, incomplete.

Dr. Rowland G. Freeman exhibited under the microscope specimens from this case.

Dr. Harlow Brooks remarked that a number of cases of acute yellow atrophy had been collected, in which the disease had first appeared shortly after labor, and in which there had been reason to believe that there had been some septic infection.

Stenosis of Œsophagus; Carcinoma.—Dr. J. H. Larkin reported a case of this kind occurring in a male, aged forty-five years, who entered the hospital, September 27, 1896, stating that he had always been well up to five weeks previously, when, while at dinner, he had swallowed a fishbone, and it had lodged in his throat. From that time until his admission to the hospital he had been able to take fluid diet only. On admission he was well nourished, and the physical examination of the heart, lungs, liver, and kidneys was negative. There was nothing in the history pointing to the passage of a bougie by the surgeon, and inquiry showed that this could not be done, on account of the

pain. On September 29, 1896, a gastrostomy was done in the left hypochondriac region, and the stomach wall was attached to the abdomen. He remained in the hospital till October 14, 1896, when he was discharged, having learned how to take care of his wound and feed himself properly. He remained perfectly well till April 19, 1898, when he came back, complaining of severe dyspnœa, which had been growing worse for the past three weeks. At this time physical examination gave complete dulness over the right lower lobe of the lung, with absence of breathing and voice. An aspirating needle encountered a firm hard mass, and no fluid was obtained. He continued to grow worse, and died on April 25, 1898. At the autopsy the body was found to be fairly well nourished, and there was a rubber tube in the gastrostomy wound which communicated with the stomach. There was no peritonitis. There were some old adhesions over the left lung posteriorly, and some compensatory emphysema of that lung. The other lung was bound down at its base by firm adhesions. The heart, lungs, œsophagus, and stomach were removed *in toto*, and the following conditions found: The left lung contained a few scattered, hard, white nodules about the size of a pea. The upper and middle lobes of the right lung were emphysematous, while the lower lobe was firm and solid, and presented a grayish-white, glistening appearance. Section of this lobe revealed some of the larger bronchi remaining, but narrowed and compressed. The left bronchus was slit up and found to be patent, a filiform bougie passing out of the cut ends in the lung tissue. The right bronchus was slit up, and the bronchi supplying the upper and middle lobes were found to be patent; but the bronchi going to the lower lobe were stenosed, and a fine filiform bougie could not be passed out into the lung tissue. Both branches of the pulmonary arteries were normal. The right pulmonary vein was stenosed, and its wall was surrounded by a cicatricial mass which had its origin at the root of the lung posteriorly. The vein admitted with difficulty a fine filiform bougie, which passed out of the cut ends in the lung tissue. The œsophagus, from the cardiac end to a distance eight centimetres upward, was stenosed, and its wall thickened and changed into very dense cicatricial tissue. After patient work, a fine filiform bougie was passed from above downward. About the middle of the stricture was a small blackish mass, but this could not be recognized macroscopically as a fishbone, nor under the microscope as bone tissue. The liver contained several very hard and cicatricial metastatic nodules, varying in size from one centimetre to four centimetres in diameter. Some of these nodules were undergoing calcification at the centre. The kidneys were normal except for a few hard metastatic nodules.

Transverse and longitudinal sections of the œsophagus at the site of the stricture were studied microscopically, and found to be composed of very dense cicatricial tissue, in which could be seen small, squeezed, and contorted alveoli, filled with epithelial cells. The latter could be traced from the mucous surface, dipping down and infiltrating the tissues beneath. Sections of the isolated nodules in the lung tissue showed mostly fibrous tissue, with numerous small and contorted alveoli containing closely packed epithelium. The sections of the lower lobe of the right lung showed intra-alveolar and interstitial pneumonia. The outline of the air vesicles was preserved; their walls were thickened, and in the cavity was a dense growth of new fibrous tissue and blood-vessels. Sections of the metastatic nodules in the liver were likewise nearly all fibrous tissue, with the same small alveoli containing epithelial cell nests, with here and there larger and smaller calcareous masses in the centre. The nodules in the kidney were also mainly fibrous tissue, with alveoli containing cells. The sections of the stomach wall proved of interest. On account of the chronic and constant irritation of a rubber tube the glandular coat had disappeared, and its place had been taken by small round cells. The muscular coat was thickened, and the individual muscle fibres were separated by small round-cell infiltration.

To summarize, the most important features of the case were: (1) An almost impassable stricture of the œsophagus, eight centimetres in length, admitting only with difficulty a filiform bougie. (2) Stenosis of the bronchi leading to the lower lobe of the right lung, and stenosis of the right pulmonary vein, both these factors inducing a chronic productive inflammation of the whole lower lobe of the right lung. (3) The peculiar microscopical picture of the metastatic nodules in the lungs, liver, and kidneys, viz., the preponderance of the fibrous-tissue element over the alveoli and epithelial cell nests.

Carcinoma of the Stomach with Perforation.—Dr. Larkin also presented specimens from a case of this kind. The subject was a man, forty years of age, who had been in the hospital for eight months. The diagnosis at the time of his admission was carcinoma. He had complained only of epigastric pain, and had shown no other symptoms worthy of note until a few days before death, when he developed tympanites. The autopsy revealed the presence of a primary carcinoma situated in the wall at the lesser curvature. The anterior wall was normal. The lymphatic nodes in the lesser curvature and those around the tail of the pancreas were involved, but aside from these there were no metastatic deposits. A small perforating ulcer had set up a peritonitis, which had been the immediate cause of death.

Dr. George P. Biggs said that the changes in the lung in Dr. Larkin's first case reminded him very much of two cases in which there had been prolonged pressure on one primary bronchus by an aneurism. In the cases referred to there was no evidence of pressure on the veins, but there was a chronic inflammatory process, with filling up of the alveoli and a decided growth of connective tissue into the alveoli. It was supposed that the interference with the passage of air through the bronchus into the lung and the retention of the secretions had been responsible for the chronic pneumonia.

Dr. Carlin Philips presented a unique specimen of kidney malformation. The specimen was taken from a man, aged thirty-six years, dying from chronic alcoholism. The genito-urinary history was not known. On either side were seen masses of kidney tissue, each having two ureters from separate pelves. These ureters apparently divided dichotomously, as in the normal organ. The upper portion of each kidney mass was hydronephrotic, and the ureters from these portions on either side were markedly dilated, thickened, and tortuous. Below they had no connection with the bladder or urethra and seemed to end blindly in a small pouch beneath the trigonum. Here the pressure of the enclosed fluid had formed for itself a cavity, six centimetres in diameter, projecting up into and carrying with it the mucous membrane of the true bladder in the region of the trigonum. This little sac-like cavity, projecting into the bladder at its base, resembled at first glance an attempt at formation of a second bladder, but in reality was only a secondary phenomenon. The lower portion of each kidney mass was fairly well formed. The portion on the left measured in length seven centimetres, on the right nine centimetres respectively. On either side there was apparently a small band of connective tissue between the cortices of the upper and lower kidney masses, representing a division of kidney parenchyma by distinct

capsule formation. This layer of apparent connective tissue had not yet been demonstrated microscopically. The ureters from the lower portions on either side were normal in every way, and entered the base of the true bladder on either side of the little cystic dilatation. The speaker was of the opinion that the upper portions of the kidney mass on either side were functionally separate organs. He said a French observer, Rayer, had reported a number of cases of supernumerary kidneys which appeared to be similar to the one just reported.

Dr. Mary Putnam Jacobi suggested that the presence of extra ureters was evidence that the kidneys were separate.

Dr. George P. Biggs said that he had several times found single kidneys with two separate pelves, each having a ureter. In some cases the ureters emptied independently into the bladder, while in others they fused before reaching that viscus. The essential difference between such specimens and the one presented, he believed to be the absence in the latter of free outlet for the urine from the superior pelvis, which, therefore, became very much distended, and the resulting difference in appearance of the upper and lower portions would naturally suggest at first glance a double kidney.

Dr. Philips remarked that there was apparently no connection between the ureters from the upper portions of the two kidneys and the true bladder in his case; they terminated blindly in a dilated pouch beneath the trigonum of the bladder.

Dr. Larkin said that if the upper portion of both kidneys had been functionating, the damming back of the urine should have given rise to more hydronephrosis. There must have been some leakage or escape, otherwise there would have been a cystic formation rather than a mere dilatation.

Early Carcinoma of the Cervix.—Dr. Eugene Hodenpyl presented a specimen showing a very early stage of duct carcinoma of the cervix. The patient was sixty years of age, and had first noticed a slight discharge from the vagina, occasionally containing a little blood, about one month previously. Examination by Dr. E. B. Cragin revealed a small ulceration of the cervix, principally about the os, but extending somewhat into the canal. A small bit of the wall of this ulcerated area was examined microscopically by Dr. Matthews, who found in the edge a tiny but unmistakable area of carcinoma. The uterus was promptly removed, together with the tubes and ovaries. The speaker said that his examination of the uterus confirmed the diagnosis of carcinoma and also showed that the lesion was a localized one, it being found only in the immediate neighborhood of the os. It would seem, therefore, that the woman had been spared the fate of a local recurrence. The specimen also emphasized the immense value of microscopic examination in such doubtful cases, for the operation would not have been justified, in his opinion, without the microscopical diagnosis.

A Case of Apparent Absence of the Spleen with General Compensatory Lymphatic Hyperplasia.—Dr. Hodenpyl read a paper with this title (see page 695).

The society then went into executive session.

Dermatitis Maligna.—In beginning Paget's disease of the nipple, partial removal of the breast is not considered safe. When complete operation is refused, I should not hesitate to destroy the area widely and deeply with the Paquelin's cautery. Removal of the entire mamma is, however, probably safer, though cases with good results from the more limited operation are not unknown.—A. Marmaduke Sheild.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNÆCOLOGY.

Stated Meeting, October 27, 1898.

Edwin B. Cragin, M.D., Chairman.

Very Young Fœtus.—Dr. S. Marks presented a fœtus from a very early stage of pregnancy. The woman had skipped three periods, according to the history, and had then aborted. The ovum was only about one centimetre long, and from its general appearance it was impossible that it should have been from a three-months' pregnancy. It was probably about twenty-one days old.

Fatal Hemorrhage from Cervical Laceration.—Dr. Marx then exhibited the uterus removed post mortem from a woman dying on the third day after confinement. She was twenty-five years of age, and this was her third confinement. Her previous labors had been normal, and her general health good. On October 12, 1898, at 5 P.M., labor began, and at one o'clock in the morning the membranes were ruptured artificially and the child was extracted. There was slight but steady hemorrhage, and accordingly the house surgeon packed the uterus with gauze. The gauze was removed on the morning of the third day. This was followed by a sudden and most profuse hemorrhage, and by the time the speaker reached the hospital the patient was dead. The tamponade of the uterus had been renewed, but this had not controlled the bleeding, and the house surgeon had not appreciated the necessity for at once sewing up the laceration of the cervix. Had this been done, it would have saved the woman's life. The post-mortem examination showed a deep laceration on the left side of the cervix, and the uterus filled with clots. The subperitoneal tissue had been dissected up on each side as far as the kidneys, and was infiltrated with blood—in other words, the cause of death was concealed subperitoneal hemorrhage from a cervical laceration.

Treatment of Cervical Lacerations.—Dr. Marx said that in the absence of hemorrhage he never touched a lacerated cervix. Simple traction on the uterus in such a direction as to produce flexion would be found sufficient to check the bleeding in most instances. In the presence of a complication such as this, there was usually some doubt as to the aseptic condition of the parts, and hence he did not favor suturing the cervix. It was not at all uncommon for lacerations of the cervix, which appeared enormous at the time of parturition, to shrink down to an insignificant size afterward, and consequently he did not ordinarily advise immediate suture. He had known a house surgeon to sew up the cervix so tightly as to prevent all escape of lochia. The diagnosis of cervical hemorrhage was not always easy, and in some instances even packing the uterus would not be sufficient. In one such case, when packing alone had failed, he had packed the uterus and sewed up the cervix. In one desperate case he had temporarily checked the hemorrhage, and then, finding the condition of the woman very bad, he had transfused her. As soon as the circulation had been improved in this way the hemorrhage recurred, and she died.

Dr. Francis H. Stuart, of Brooklyn, said that he had had an opportunity once to see a very severe hemorrhage from a lacerated cervix. The cause of the hemorrhage was discovered with the aid of a Sims speculum, and the hemorrhage checked by sewing up the laceration—the only case in which he had practised immediate suture—and the union had been excellent. In his opinion, it was better to examine and locate the source of the hemorrhage than blindly to employ the tamponade. He was not in favor of the

immediate suture of the cervix except when there was free hemorrhage.

Control of Cervical Hemorrhage.—Dr. Philander A. Harris, of Paterson, said that there was an incomplete rupture of the uterus in the specimen presented, in addition to the cervical laceration, making the case a very unusual one. In one such case—seen about four weeks ago—the os and cervix uteri were not included. The hemorrhage dissected up into the broad ligament, producing a large tumor. The patient was on the road to recovery. He had seen only one other case of this kind. Regarding cervical hemorrhage, the speaker said that it could be very quickly controlled in many cases by a plan which he had used for some time—*i.e.*, the application of a long clamp. The clamp was left on for two days. This continued pressure must necessarily cause a little superficial necrosis of the tissues, but it had not seemed to him to be in any sense a harmful expedient. He did not include both sides of the cervix, but simply gripped the tissues on the inside.

Dr. John Polak said he had noticed that if the gauze packing was left in the uterus for three days without removing any portion of it, the uterus was apt to be in a more or less atonic condition when the gauze was withdrawn, and consequently in a condition very favorable to the occurrence of hemorrhage. After seeing a case of fatal hemorrhage occur in this way, he had adopted the plan of removing the tamponade, a portion at a time.

Dr. Marx said that he saw no objection to leaving the gauze packing in as long as three days, provided the uterus and the gauze were known to be aseptic. If he thought its removal at that time would endanger the woman's life, he would be perfectly willing to leave the tamponade in for a week, if need be. A few years ago he had recommended controlling cervical hemorrhage by the application of clamps, but ordinarily it seemed to him better to suture the cervix. This could be done without any special instruments, and with only the help of an assistant to press the uterus within easy reach. If one hot intra-uterine douche did not control the hemorrhage, he was accustomed to resort at once to the uterine tamponade.

Fibroid Uterus.—Dr. H. J. Garrigues presented a fibroid uterus removed from a woman, fifty-eight years of age. She complained of severe hemorrhages and backache, associated with prolapse. The abdominal walls were so fat that it was impossible to feel the body of the uterus. After etherization, he found a large uterus with a tumor on either side. On opening the posterior vault of the vagina, he discovered a number of fibroids. It was necessary to remove nine fibroids before the uterus was small enough to be removed through the vaginal incision. All of the fibromata were held together only by loose connective tissue. The patient did well for some days after the operation, and then developed a pneumonia, from which she died. She had previously been a sufferer from chronic bronchitis, which probably explained the occurrence of the pneumonia. The post-mortem examination showed no evidence of inflammation about the field of operation.

A Blighted Ovum.—Dr. Garrigues also presented the fluid removed from a case in which the diagnosis was not at all clear. A woman came to him recently with the statement that she was pregnant about four or five months, and the size of the uterus indicated that this statement was correct. On making a vaginal examination the vagina was found to be filled with a fluctuating cyst, and inspection showed a very thin-walled tumor filled with fluid. On puncture of the outer wall, some thin fluid escaped, and on puncture of the thick, fibrous inner membrane, a large quantity of thick, brownish fluid was evacuated. The microscopical examination of this fluid showed an entire absence of blood corpuscles and of echinococcus hooklets. There was no fœtus in the uterus. The woman had ordinarily menstruated regularly. The only diagnosis that had suggested itself to him was that of an aborted ovum; still, the condition was very different from anything that he had ever seen before. The cyst itself had not been examined microscopically.

Dr. Marx thought it possible that the case was one of missed abortion with absorption of the fœtus.

Fibro-Cystic Uterus in a Young Girl.—Dr. Brooks H. Wells reported the following case: The patient was an unmarried woman, thirty-two years old, who had always enjoyed good health. Her first menstruation was at the age of thirteen and one-half years, and it had always been regular and normal. She stated that when fifteen years of age her abdomen was large and hard, but was not painful. Last May she struck the right side of the abdomen forcibly against the edge of a piece of furniture, and this was followed by pain, nausea, vomiting, and dizziness. The abdomen steadily grew larger, and she felt quite sick. When seen by him on July 21st, the abdomen measured forty inches in circumference. There was a tense, thin-walled, fluctuating, immovable, rounded tumor, extending to the umbilicus, and somewhat more pronounced on the right side. The tumor was not tender. There were an intact hymen and a very small vagina, and as the patient did not wish to take an anæsthetic the examination was difficult. The diagnosis was made of probable multilocular cyst of the ovary. On September 19th, while stooping over, she was seized with violent pain in the abdomen, accompanied by shock. When seen by him on the 21st, her face was drawn and anxious, and the abdomen tense and tympanitic over the tumor. An immediate operation was advised, but she did not give her consent until five days later. The abdomen was then opened at the Polyclinic Hospital, and found to be filled with viscid fluid from the ruptured cyst. The condition proved to be one of cystic uterus with fibroids. These were removed, and the uterus was extirpated by supravaginal amputation. Immediately after the operation her pulse was 96, and after the eighth day her temperature did not rise above the normal. When fresh and distended, the tumor was about the size of an adult head. The operation revealed a rupture, two and one-half inches long, on the superior surface of the cyst. The contents of the latter were a greenish fluid and masses of coagulated fibrin. The posterior and inferior walls were thickened and nodular, and covered with dilated blood-vessels. The microscope showed the tumor to be a fibroid in an advanced stage of degeneration. This patient gave a history which made it appear probable that she had had this fibroid when only fifteen years old. It was this that made the case a rare one. The accidental blow on the abdomen undoubtedly caused a hemorrhage within the tumor, and this, by increased pressure, resulted in degeneration and final rupture of the cyst. In spite of the fact that the fluid remained in the peritoneal cavity about a week, there was no peritonitis. The speaker said that a review of the literature of these cases showed that the diagnosis before operation in the vast majority had been just what he had made—*i.e.*, multilocular ovarian cyst. The usual point in differential diagnosis between this condition and cystic uterus, as laid down in the books, was that in the former there was usually a deterioration of the general health which was not present in cases of cystic uterus. This certainly did not apply in the present instance. The fundus of the uterus was removed because of the presence there of a small nodule. If it had not been for this, the tumor could have been easily enucleated from the uterus. One ovary was left in, with the idea that the severity of the symptoms of the artificial menopause would be thereby

lessened. Chromicized gut was used in the operation, according to his custom. The speaker had used this in over one hundred and fifty intra-abdominal operations, and without a single case of suppuration. In cases of serious infection he did not use the buried suture; he employed that only in clean cases.

Dr. H. J. Boldt said that in this connection he desired to place on record the report of a case seen at the Post-Graduate School about sixteen years ago. The patient was a woman of eighteen, having a fibromyomatous tumor, extending up to the umbilicus.

Operative Gynæcology, or the Temptation of Skill.—Dr. Eugene C. Savidge read a paper with this title. He said that the theme had been suggested by the remarks of a society woman, of a lawyer, and a gynæcologist. The debt that woman owed to man's surgical audacity was simply enormous. The reparative operations in women should be placed before them in the same light as a gaping wound on any other part of the body. It was by no means settled that lacerations of the cervix required immediate operation. The bad results of the slight lacerations were often entirely ascribable to the woman's own carelessness after parturition. Curettage was really reparative work, and when rightly done was one of the most brilliant life-saving measures. It was surprising what huge perimetric masses might be reduced by curettage and drainage. Regarding retrodeviations, the speaker said that in a recent paper he had had the temerity to predict that operations for these conditions would be almost unknown in the next generation. Touching upon the treatment of appendicitis, he said that it was admitted that seventy-five per cent. of patients recovered under medical treatment, while the surgeons claimed that ninety-eight per cent. should recover by timely operation. But medical men asserted that in one-third of the autopsies on persons dying from other diseases the vermiform appendix showed that an appendicitis had been spontaneously recovered from, just as nature often put a stop to a tuberculous process. It should be remembered that the menopause did not give relief to all persons suffering from fibroids; some of the worst symptoms developed after that time. When there were pus sacs, vaginal incision into them often saved function and at the same time cured. In conclusion, the reader expressed the belief that there could be no doubt of the value of the vast majority of gynæcological operations, and that the list of debatable operations was comparatively small.

Dr. E. W. Peet said that his comments on the paper would be based on an experience with thirteen hundred patients at the out-patient department of the Roosevelt Hospital. He had seen cases of fibroids operated upon and about an equal number treated without operation, and he was compelled to say that, as a class, those not operated upon appeared to to get along better. In two of the operative cases in this series the patients died, while among the non-operative cases only one death occurred.

Vaginal Puncture Not Curative.—It was not common at the present time to see many acute inflammations of pus in the tubes; the majority were chronic. When there was much distention and the abscess invaded the ovary, vaginal puncture would often allay the symptoms, but, according to his experience, these persons were never cured until the diseased tube had been extirpated. The draining of pus tubes, whether through the uterus or through a vaginal incision, had been followed by pregnancy, and the patients had been in much better physical condition than those in whom ablation had been practised. Comparatively few of the unfortunates making up the latter category realized before operation that an artificial menopause would be induced, and when the truth dawned upon them they were of all women the most wretched. They might be improved physically in many instances, but certainly not mentally.

Alexander's Operation Rarely a Complete Success.—In fully one-half of the cases coming under his observation in which Alexander's operation had been done, many of the symptoms still persisted, and to these were added the symptoms of the operation. He had yet to see a case of Alexander's operation which he could honestly call a success.

Lack of Muscular Tone in Women.—Dr. A. E. Gallant said that it seemed to him that the debatable operations were those connected with the tubes and with retrodeviations. His experience with the cases treated by vaginal puncture was that it was apt to be followed by very obstinate sinuses. However, some years ago he had had one case of vaginal puncture in which the sinus had closed without subsequent operation. He thoroughly agreed with the reader of the paper that passive congestions were responsible for a very large proportion of the pelvic pains from which women suffered, and believed that this was largely due to the almost universal lack of muscular tone in women of the present day. It was the exception to find women who were in proper physical condition to bear children. Out of four hundred gynæcological cases coming to him in a dispensary service, he had found that one hundred and eighty were retrodeviations. This seemed to him a very large percentage, and he was sorry to say that he was not at all decided as to what was the best treatment. Most of the cases of Alexander's operation coming to the dispensary were naturally in patients who had not been completely relieved by operation, and therefore desired further treatment. The higher the position of the uterus the better the chance of affording relief.

Incomplete Operations a Prolific Source of Trouble.—Dr. G. W. Jarman said he was sceptical about the decided lacerations of the cervix healing without operation. He took this position because of the action of the circular muscles around the cervix, and of the group of longitudinal muscles coming down from the body of the uterus to the cervix. Many retrodeviations occurred among young women. Here pessary treatment, even if effective, was often undesirable. Moreover, he was not enthusiastic over the results obtained from the use of pessaries under the most favorable circumstances. In a large dispensary experience he could not recall more than three or four cases in which a complete cure had not followed total hysterectomy, with the removal of tubes and ovaries. All the women under twenty-seven years of age in whom the tubes and ovaries had been completely removed had suffered far more than women over thirty years of age who had been subjected to the same operation. He had also noticed that there was more disturbance when a portion of the appendages had been allowed to remain than when total hysterectomy, with complete removal of the appendages, had been done; in short, the subsequent troubles were found almost exclusively in those cases which had been subjected to incomplete operations.

Curettage a Much-Abused Operation.—Dr. Boldt said that he did not know of another single operation that was so much abused as that so-called "simple operation of curettage." The vast majority of cases of pyosalpinx were sacculated pus tubes, and, according to his experience, it was impossible to cure these cases by puncture or by curettage and drainage through the uterus. More than once had he seen pus tubes produced by curettage. The secret of success in operative gynæcology was to be found in the adaptation of the operation selected to the individual case. The great majority of patients with fibro-myomatous tumors who consulted the operative gynæcologist would require operation, unless the future should show that

the administration of thyroid or mammary-gland extract accomplished more than the non-operative methods of the past.

Dr. Savidge, in closing, said that he had seen within the past month two cases in which in spite of the complete removal of the uterus and appendages the symptoms that had existed before operation still persisted. Relief was promptly afforded by measures directed toward relieving the venous congestion. The object of his paper was to show that the value of a very large percentage of gynæcological operations was entirely beyond debate.

The Diagnosis and Treatment of the More Common Bladder Affections in Women by Means of Kelly's Method.—Dr. Hiram N. Vineberg said that with this method extensive dilatation of the urethra was never called for, and anæsthesia almost never. He had not known incontinence to follow the introduction of the No. 12 cystoscope, and he had never had occasion to use a larger instrument of this kind.

"Irritable Bladder."—A very common condition in women was that formerly described as "irritable bladder." Kelly's method had shown that in the great majority of cases the symptoms were dependent upon a local hyperæmia of the bladder, usually of the trigonum. It should be remembered in making a cystoscopic examination that the area of the trigonum was naturally redder than the other parts. This localized hyperæmia was associated with a great variety of pelvic disturbances, and might occur independently of any pelvic affection. By Kelly's method the treatment of what was once the *bête noire* had now been rendered very simple and satisfactory. Half a dozen applications of a five or ten per cent. solution of nitrate of silver to the hyperæmic patches would almost invariably effect a cure. For the first twenty-four hours, however, the symptoms were apt to be aggravated.

Cystitis.—In ordinary catarrhal cystitis the mucous membrane of the bladder was rarely affected uniformly. He had met with two cases of hemorrhagic cystitis, both in pregnant women. The blood rapidly disappeared from the urine after a few applications of nitrate of silver. One of them returned subsequently without hæmaturia, but with irritation of the bladder, and symptoms indicative of tuberculosis of the bladder. In the treatment of tuberculous cystitis he had obtained the best results from local applications of a strong solution of nitrate of silver and of a twenty-five-per-cent. solution of ichthyol in glycerin.

Dr. Boldt said he had had two cases of tuberculous cystitis which had been diagnosticated by the cystoscope. They had proved exceedingly obstinate to treatment.

Suggested Improvement in Kelly's Cystoscope.—Dr. P. A. Harris said that he had met with but one case of tuberculous cystitis. If the cystoscope was removed from the boiling water and the latter carefully expelled from the instrument before re-insertion of the obturator, prior to introduction of the instrument into the bladder, he thought there would be less suction power, and therefore less liability of wounding the wall of the bladder on the removal of the obturator. A slight change in the construction of the instrument would provide for the admission of air to the obturator, and so still further obviate this danger.

Dr. Vineberg, in closing, said that while Kelly had spoken of the liability of injuring the bladder on the withdrawal of the obturator, he had not personally been able to confirm this in his own observations. Possibly this was because he used the instrument with the patient in the knee-chest position.

For Inebriety.—A wineglass of vinegar, it is said, will sober a much-intoxicated person in twenty minutes.

Reviews and Notices.

International Clinics. A Quarterly of Clinical Lectures on Medicine, Neurology, Surgery, Gynæcology, Obstetrics, Ophthalmology, Laryngology, Pharyngology, Rhinology, Otology, and Dermatology, and Specially Prepared Articles on Treatment and Drugs. By Professors and Lecturers in the Leading Medical Colleges of the United States, Germany, Austria, France, Great Britain, and Canada. Edited by Judson Daland, M.D., Philadelphia; J. Mitchell Bruce, M.D., F.R.C.P., London, Eng.; and David W. Finlay, M.D., F.R.C.P., Aberdeen, Scotland. Volume II., Eighth Series. Philadelphia: J. B. Lippincott Company. 1898.

Much of the success of this quarterly depends upon the care on the part of the editors in selecting not only men of known worth and ability, but those who from previous experience have shown themselves to be attractive speakers and writers. It is bad enough to have to sit through a clinical lecture which is dry and lacking in something of the vim and sparkle which can well go with science; to be forced to read such productions is decidedly worse. One advantage of the "Clinics" is that when (and it doesn't often happen) a dull lecture is encountered it can be cut with better grace than if one had to leave the benches in the face of the speaker. The lectures include "The Treatment of Tuberculosis," by Professor Grancher; "The Treatment of Functional and Lateral Curvature by Light Gymnastic Exercise" (excellently illustrated), by James K. Young, M.D.; "Broncho-Pneumonia Following Measles," by John A. Larrabee, M.D.; "On the Relation between Heart Disease, Pregnancy, and Confinement," by A. Pinard, M.D.; "The Etiology and Classification of Cystitis," by N. Senn, M.D., Ph.D., LL.D.; "A Case of Appendicitis, in which the Appendix Became Soldered to the Bladder, Like a Third Ureter, Producing a Urinary Fæcal Fistula," by W. W. Keen, M.D.

Brief Essays on Orthopædic Surgery. Including a Consideration of its Relation to General Surgery, its Future Demands, and its Operative as Well as its Mechanical Aspects, with Remarks on Specialism. By Newton M. Shaffer, M.D., Surgeon-in-Chief to the New York Orthopædic Dispensary and Hospital, etc. New York: D. Appleton & Co. 1898.

This little volume of eighty-one pages contains essays and portions of addresses which have from time to time appeared in current literature, and are collected now in the hope that orthopædic surgery may be benefited by their republication.

The Office Treatment of Hemorrhoids, Fistula, etc., without Operation. Together with Remarks on the Relation of Diseases of the Rectum to Other Diseases in Both Sexes, but Especially in Women, and the Abuse of the Operation of Colostomy. By Charles B. Kelsey, A.M., M.D., late Professor of Surgery at the New York Post-Graduate Medical School and Hospital, etc. New York: E. R. Pelton, No. 19 East Sixteenth Street. 1898.

These sixty-eight pages contain three lectures, the last of which alone has been previously published. The author is well qualified to counteract, as is his present object, the too prevalent idea that operation by a specialist is always necessary in these rectal disorders.

Twentieth Century Practice. An International Encyclopedia of Modern Medical Science. By Leading Authorities of Europe and America. Edited by Thomas L. Stedman, M.D., New York. In Twenty Volumes. Vol. XV., Infectious Diseases. New York: William Wood and Company. 1898.

The table of contents of this, the third volume devoted to infectious diseases, includes the following subjects: Influenza, Typhus Fever, Plague, Glanders, Anthrax, Foot-and-Mouth Disease, Actinomycosis, Rabies, Pyæmia, and Septicæmia. The list of authors, taken in the order of the subject treated by each, includes Ditmar Finkler, University of Bonn; Eduardo Licéaga, president of the superior board of health of Mexico; Kitasato, the discoverer of the plague bacillus, and Nakagawa, of Tokio; Frank S. Billings of Grafton, Mass., who also wrote on Anthrax; Ismar Boas, of Berlin; Emil Ponfick, professor of pathological anatomy, Breslau; N. G. Keirle, chief of Pasteur Laboratory, College of Physicians

and Surgeons, Baltimore; J. McFadden Gaston, professor of surgery, Southern Medical College, Atlanta; and J. McFadden Gaston, Jr. This list brings before the reader a number of rather well-known men from different and at times distant quarters of the globe, whose writings have in several instances been more familiar to general readers from periodical than from book literature. The subjects are all of peculiar interest and have been treated of in the manner which recent additions to our knowledge make necessary, for in almost every one decided advances have been made, either in the discovery of causative factors, in methods of diagnosis, or in plans of treatment. Glanders is perhaps the most unsatisfactory condition of which the volume treats. The question of therapy is dismissed in just six lines. It is considered that the question of a reliable germicide to be gotten from bacteria is one to be solved in the future, and that an antitoxin alone will not do the work in glanders as in tuberculosis. The reaction claimed in actinomycotic patients from the injection of Koch's tuberculin is not confirmed by the experiments of the writer upon this disease. Treatment is briefly considered, but occupies a space proportionate to the whole article. Keirle states that no fully demonstrated case of recovery from rabies in man is on record, and that the death rate among rabic patients who are cauterized is thirty per cent., while in those uncauterized it is eighty. The article takes up seventy pages, and a similar space is given to pyæmia and septicæmia, while Finkler's article on influenza covers two hundred and forty-seven pages, the whole number of pages being six hundeed and fifty-eight. The volume as a whole shows no falling off in the standard of authors contributing or in the character of the articles. The editorial and printers' work is well done and the index is very full.

THE POCKET FORMULARY FOR THE TREATMENT OF DISEASES IN CHILDREN. By LUDWIG FREYBERGER, M.D. Vienna, M.R.C.P. Lond., M.R.C.S. Eng.; Clinical Assistant, Hospital for Sick Children, Great Ormond Street; Curator of the Museum, Pathologist, and Registrar, Great Northern Central Hospital.

THIS neatly arranged compendium of pediatric therapeutics forms a ready and valuable reference manual. Besides giving the dose for children at various ages, the therapeutic action and the incompatibilities of all the important remedies, it devotes a section to the correction of the taste of the bitter and disagreeable drugs.

A TEXT-BOOK UPON THE PATHOGENIC BACTERIA. For Students of Medicine and Physicians. By JOSEPH McFARLAND, M.D., Professor of Pathology in the Medico-Chirurgical College; Pathologist to the Medico-Chirurgical Hospital and to the Rush Hospital for Consumption and Allied Diseases. Second Edition. Philadelphia: W. B. Saunders. 1898.

THIS is a book that has well deserved to reach a second edition, and we doubt not its merits will carry it through several more. It is of moderate size, sufficiently full to answer all the requirements of a work of reference, yet consise enough to serve as a text-book for learners of the science of bacteriology. The illustrations are very good, and are not too numerous. The necessary references are given in footnotes, which are few, and there is no exhaustive bibliographical section either at the beginning or at the end of the book. This is refreshing in these days of pedantic quoting of "authorities," and we hope, in the interests of all but the paper makers, that the author will find many imitators in this respect.

DISEASES OF WOMEN. A Treatise on the Principles and Practice of Gynæcology. For Students and Practitioners. By E. C. DUDLEY, A.M., M.D., Professor of Gynæcology, Northwestern University Medical School; Gynæcologist to St. Luke's Hospital, Chicago, etc. With 422 Illustrations. Philadelphia and New York: Lea Brothers & Co. 1898.

THE aim of each writer of a book should be originality, and if he cannot have an original subject to treat he should at least treat the old subject in an original manner—otherwise he would better hold his peace. The subject of the diseases of women cannot certainly be called original, and so the author has been forced to justify his work by his way of handling it. If not exactly original, this is at least somewhat out of the ordinary. Instead of dividing the genital apparatus into separate organs and discussing the diseases of each individual part from the ovaries downward, Dr. Dudley makes a pathological division, dividing his work into five parts. These are labelled: I. General Principles; II. Inflammations; III. Tumors, Malformations, and Tubal Pregnancy; IV. Traumatisms; and V. Displacements of the Uterus and Other Pelvic Organs, and Massage. There are some disadvantages in this method of classification, but the author justifies it as enabling the reader to grasp more readily the sequence and significance of each pathological process, and giving him a better idea, for example, of metritis by associating it closely with vulvo-vaginitis, salpingitis, oöphoritis, and peritonitis. The work is very profusely illustrated.

PROCEEDINGS OF THE CONNECTICUT MEDICAL SOCIETY. 1898.

A NEATLY bound volume of the transactions of the society, containing a number of interesting papers.

LES ACTUALITÉS MÉDICALES. La Grippe. Par L. GALLIARD, Médecin de l'Hôpital Saint Antoine. Paris: J. B. Baillière et Fils. 1898.

THIS little book is the first of a new series which has for its object the presentation and discussion, in precise and compact form, of the medical topics of the day—diphtheria, neurasthenia, diabetes, exophthalmic goitre, curable albuminuria, tetanus, etc. Beginning with a short history of the disease, the author leads us into the chapters on the microbe, symptoms, clinical types, complications, treatment, and prophylaxis. Pfeiffer is recognized as the discoverer of the specific microbe, and his observations are corroborated by Kitasato, Pfuhl, Klein, Weichselbaum, and others. The various clinical forms are systematically arranged, and the treatment is divided into that of the different stages, forms, and complications. This series is destined to find general favor with those who desire to keep abreast of medical progress. The book is of portable size and neatly bound.

TWENTY-SECOND YEAR BOOK OF THE NEW YORK STATE REFORMATORY, FOR THE FISCAL YEAR ENDING SEPTEMBER 30, 1897.

A REPORT of the work done in this institution during the past year, with special reference to the advantages resultant from the introduction of manual training in 1895.

DIE VERDAUUNG UND ASSIMILATION DES GESUNDEN UND KRANKEN SÄUGLING, NEBST EINER RATIONELLEN METHODE ZUR SÄUGLINGSERNÄHRUNG. Von DR. MED. L. DE JAGER.

AN interesting treatise on digestion and assimilation in the infant, with special reference to treatment based on physiological and chemical results.

EAR RECORDS. Arranged by JOHN C. LESTER, M.D., etc., and VINCENT GOMEZ, M.D., etc. New York: J. W. & G. H. Hahn. 1898.

THIS is a well-arranged volume designed for the recording of cases of diseases of the ear, with additional blank pages for general notes, and an index. The compilers have taken as a nucleus an arrangement devised by Dr. Röhrer of Zurich, which they have modified and added to, producing a very complete record book and one which must prove useful in the office of an otologist.

LECTURES ON THE THEORY AND PRACTICE OF VACCINATION. By ROBERT CORY, M.A., M.D. Cantab., F.R.C.P. Lond. One volume, octavo, 132 pages, profusely illustrated by woodcuts and 12 full-page lithographic plates. Price, $3.25 net. New York: William Wood and Company.

THE six chapters of this work represent six lectures, to which several papers have been added. Having written before the report of the royal commission was published, the author is not indebted to this source, as some readers might suppose, for his information on many of the questions touched upon. First are considered the medical man's duties toward the vaccination laws; secondly, the histology of vaccine and variola vesicles; then the difference between a primary and a secondary vaccination, the eruptions that occasionally follow vaccination, the practical details of vaccination, and, finally, the relation of cow-pox, horse-pox, and camel-pox to small-pox. The whole makes most interesting reading, coming as it does from one of no small experience.

Essentials of Homœopathic Therapeutics. Being a Quiz Compend of the Application of Homœopathic Remedies to Diseased States. A companion to the "Essentials of Homœpathic Materia Medica." By W. A. Dewey, M.D., Professor of Materia Medica in the University of Michigan, Homœopathic Medical College; former Professor in Hahnemann Hospital, College of San Francisco, Cal., etc. Second Edition. Revised and Enlarged. Philadelphia: Boericke & Tafel. 1898.

This is a work especially arranged for the use of students of medicine. It is a relief to find an occasional work not arranged so as to appeal to the practitioner as well as to the student. It is practically a materia medica and intended as a companion to the "Essentials of Homœopathic Materia Medica," and is calculated to prevent the student from "falling into the practice of the ancient school of associating remedies with disease, or diagnosis with treatment." This edition has been carefully revised and the numerous errors of the first corrected. The size of the volume has been extended by the addition of many characteristic indications.

The questions and their answers of which the book is made up cover two hundred and eighty-five pages. The present popularity of the author's name should help sell the work.

Handbook of Materia Medica for Trained Nurses. By John E. Groff, Ph.G., Apothecary in the Rhode Island Hospital, Providence. 12mo, pp. 235. Philadelphia: P. Blakiston's Son & Co. 1898.

This little work is divided into sections on official drugs and preparations and chemistry, and at the end are a lengthy glossary taking in all official drugs, a chapter on toxicology, and one on therapeutics. Not only are the crude drugs described, but the preparations made from them as well. The Latin and English names are both given. Short chapters treat of fermentation, volatile and fixed oils, glucosides, and alkaloids. It will undoubtedly prove a valuable aid to the nurse in securing a knowledge of drugs and their uses, so far as this is of importance to the nurse.

Ophthalmic Diseases and Therapeutics. By A. B. Norton, M.D., Professor of Ophthalmology in the College of the New York Ophthalmic Hospital; Surgeon to the New York Ophthalmic Hospital; Visiting Oculist to the Laura Franklin Free Hospital for Children; ex-President American Homœopathic Ophthalmological, Otological, and Laryngological Society, etc. Second Edition. Revised and Enlarged. Philadelphia: Boericke & Tafel. 1898.

The present issue has been extended to cover six hundred and forty-seven pages, and there are now ninety illustrations and chromo-lithographic figures in the text. The first edition of this work was made the text-book in twenty-one of the twenty-two homœopathic colleges of this country, thus establishing for it a wide reputation and assuring the present edition. The author's object of presenting a concise practical manual has prevented the record of many personal cases or illustrative instances. Much space is given to a consideration of the systemic treatment. Chapter VI. is devoted to a tabulated statement of diseases with more or less characteristic eye symptoms, which will prove useful in the diagnosis of many general diseases. The illustrations showing the proper way to make the various examinations are very good, and the colored plates at the back are worthy of notice. The edition has been decidedly improved and some hundred pages of new matter have been added.

A Clinical Manual of Skin Diseases, with Especial Reference to Diagnosis and Treatment. For the Use of Students and General Practitioners. By W. A. Hardaway, A.M., M.D. Second Edition, Revised and Enlarged, with 42 Engravings and 2 Plates. Pp. 557. Philadelphia and New York: Lea Brothers & Co. 1898.

That a second edition of this little manual should be called for so soon after the appearance of the author's much more pretentious work, written in conjunction with L. Bolton Bangs, of this city, speaks well for the favor in which his writings are held. The arrangement of the subject matter is well adapted to the uses of the student, for whom it seems especially fitted. The illustrations add not a little to the attractiveness of the volume.

Bulletin of the Harvard Medical Alumni Association. No. 12. Paper. Pp. 64. Boston: Published by the Association. 1898.

The "Bulletin" contains a report of the eighth annual meeting, held in Boston, June 28, 1898. There is an address by the president of the association, with other attractive features, and the presswork is of the usual excellence.

An Introduction to Pathology and Morbid Anatomy. By T. Henry Green, M.D., F.R.C.P., Physician and Special Lecturer on Clinical Medicine at Charing Cross Hospital and Physician to the Hospital for Consumption and Diseases of the Chest, Brompton. Revised and enlarged by H. Montague Murray, M.D., F.R.C.P., Physician to Outpatients and Lecturer on Pathology and Morbid Anatomy at Charing Cross Hospital. New (eighth) American Edition. Thoroughly Revised from the Eighth English Edition by Walton Martin, Ph.B., M.D., Assistant Demonstrator of Anatomy, College of Physicians and Surgeons, Columbia University, and Assistant Surgeon, Hospital of St. John's Guild. Illustrated with 216 engravings, of which 6 are in colors, and a colored plate. Philadelphia and New York: Lea Brothers & Co. 1898.

A number of important changes have been made in the sequence of subjects in this well-known treatise and the arrangement of the matter has been adapted to a more logical form and is in better accord with recent advances in our understanding of pathological conditions. Other alterations are the substitution of a chapter on the animal parasites for the sections on scrofulous inflammation, asexual spore formation, conjugation, and fertilization, and in the section on tumors the gliomata have been classed with the benign new growths, the lymphomata grouped under diseases of the lymphatic nodes, and the class of endotheliomata has been introduced. While the size of the book has not been materially increased, much valuable new matter has taken the place of less useful information, with distinctly advantageous results.

A Text-Book of Practical Therapeutics. With Especial Reference to the Application of Remedial Measures to Disease and their Employment upon a Rational Basis. By Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. With Special Chapters by Drs. G. E. de Schweinitz, Edward Martin, and Barton C. Hirst. New (seventh) Edition. In one octavo volume of 770 pages. Illustrated. Philadelphia and New York: Lea Brothers & Co.

Before one has had sufficient time to note the improvements of one edition another appears, with the addition of new drugs of value so far as a year's test of them can be expected to prove their worth. The arrangement is good and practical, and the plan of the index makes reference to any particular subject a matter of ease. The work has proven justly popular.

The Hygiene of the Voice. With 27 Illustrations. By Thomas F. Rumbold, M.D., Member of the St. Louis Medical Society, Permanent Member of the American Medical Association, etc. St. Louis. 1898.

This small brochure springs from the author's experience with singers and other professional people who use the voice a great deal, and is a good, practical, common-sense presentation of the subject. While there is little that cannot be found in good text-books on the nose and throat, the compact grouping permits an easy treatment.

Elements of Histology. By E. Klein, M.D., F.R.S., Lecturer on General Anatomy and Physiology, and J. S. Edkins, M.A., M.B., Joint Lecturer and Demonstrator of Physiology in the Medical School of St. Bartholomew's Hospital, London. With 296 Illustrations. Revised and Enlarged Edition. Philadelphia and New York: Lea Brothers & Co. 1898.

The student of medicine, appalled by the size and thickness of many of the so-called "handbooks," "guides," etc., of late years offered for his perusal in such pleasing variety, has before this turned with a sigh of relief to Lea Brothers' series of "Manuals for Medical Students" and found them refreshingly concise and free from the tautological padding that dis-

tends beyond all endurance the bulk and price of so many of our newer text-books.

The volume under consideration exemplifies all the good points of the others of the series, and in its present revised and enlarged edition succinctly gives the reader a clear insight into the present status of knowledge in the field of human histology. The chapters on the central nervous system have been practically rewritten and considerable additions made to other sections of the work, while many new illustrations and admirable typography will commend it to all interested.

Traité de Médecine et de Thérapeutique. Par P. Brouardel, Doyen de la Faculté de Médecine de Paris, Membre de l'Institut; et A. Gilbert, Professeur agrégé à la Faculté de Médecine de Paris, Médecin de l'Hôpital Broussais. 10 Vol. Illustrés de Figures. Vol. V. Paris: J. B. Baillière et Fils. 1898.

The fifth volume of this valuable treatise on medicine, practically the classic of French practice, maintains the admirable standard set by the preceding volumes. As in these, there is the same careful and elaborate consideration of the pathological features of disease processes which render modern classics so valuable. The chapters on diseases of the liver by Gilbert, Fournier, Garnier, and Sourmont, and those on diseases of the kidneys by Chauffard, are especially complete. The other articles—"Diseases of the Salivary Glands," by Dupré; "Diseases of the Pancreas," by Richardienne and Carnot; "Diseases of the Spleen," by Lannois; "Diseases of the Male Genito-Urinary Organs," by Guinon; and "Diseases of the Female Genito-Urinary Organs," by Siredey—are all monographs by specialists, some of the most competent in France. There is much excellent judgment shown in the editing of this system, as special attention seems to be paid to the general perspective of medicine and therapeutics.

An Abridged Therapy Manual for the Biochemic Treatment of Disease. By Dr. Med. Schüssler, of Oldburg. Twenty-Fifth Edition, in Part Rewritten. Translated by Prof. Louis H. Tafel. Philadelphia: Boericke & Tafel. 1898.

This is a literal translation without addition or change, and differs from the original only in containing an obituary of the author, who died just after the last edition was ready for the press. As a frontispiece is reproduced the letter written by the author giving his consent to translation. In "Some Thoughts on the Allopathic Treatment of Chlorosis," on page 151 it is contended that those allopaths who have recently used lime in chlorosis have unconsciously entered into the paths of biochemistry. The desire for chalk on the subject's part is the cry of the diseased cells for lime, and it is thought that this voice of nature should have been hearkened to before this. Iron and its artificial combinations cannot cure chlorosis, and allopathic doses spoil the stomach. Muriatic acid acts better, but instead we should give natrium muriaticum in minimal dose. Facial diagnosis is advocated, but rules for learning or practising it are not given. In an epilogue complaint is made that previous translators have introduced their own false views to the discredit of the author.

Virchow as Huxley Lecturer.—The *Saturday Review* says: "The selection of Prof. Rudolph Virchow as the second Huxley lecturer was not the most fortunate choice that could have been made. It is, in fact, only explicable as having been made by medical men and not by biologists. In science, philosophy, and politics, Huxley and Virchow were almost as far opposed as men could be. Virchow is the last serious opponent of the evolutionary theory of the origin of mankind, which Huxley did so much to establish. Virchow has always been a reactionary, while Huxley was the foremost champion of the most advanced school of biologists. In politics Virchow is a reckless social democrat, whereas Huxley was an enthusiastic advocate of individualism. Most of the leading English biologists seem to have felt that they honored Huxley's memory most by staying away from Virchow's lecture. We hope that next year a lecturer more in sympathy with Huxley's teaching will be chosen."

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

CLINICAL SOCIETY—MYOSITIS OSSIFICANS—MONGOLIAN IDIOTS—ENEMA RASHES—PIN IN APPENDIX—MEAT AND MILK INSPECTION—COLLEGE OF SURGEONS—SERUM—ROYAL ARMY MEDICAL CORPS—PORT OF LONDON SANITATION—CONSCIENTIOUS OBJECTORS—GUILD OF ST. LUKE—HARVEIAN ORATION.

London, October 21, 1898.

The Clinical Society began its sessions on Friday, when Mr. Langton thanked the fellows for electing him to the presidency for a second term, and congratulated them on the position of the society, which numbers five hundred and eighty-eight. An index to the thirty volumes of the "Transactions" has been edited by Dr. A. E. Garrod.

Dr. Herringham related a case of progressive myositis ossificans in a girl of eight, who was when five years old shown to the society. Then the shoulders were rigid from ossification of the pectorals and the latissimus; the head was fixed from swelling and rigidity of the sterno-mastoids. Microdactyl of the great toes was also observed. Now the back has become so rigid that the spinal column moves like a rod. Bony prominences or nodules are found behind the mastoid process, on the arms (ulnar surface), and one finger; and there are pencils of bone in the abdominal muscles. Skiagrams show the shoulder-joint to be natural, the deposit being in the muscles only. The deformity of the great toe is complex. The lesions of the disease are confined to the somato-pleural layer of the mesoblast, and in this to bone, periosteum, and connective tissue. The disease is congenital, not hereditary, and its pathology uncertain. Injury seems the only proved exciting cause, as there is no satisfactory evidence of any connection with rheumatic affections. Pincus regards it as a form of new growth, and perhaps it may throw some light on the formation of tumors.

Dr. Campbell Williams mentioned a case in which there was a history of rheumatism, and the president asked if rest alone had resulted in improvement.

Mr. Spencer said that in some cases there was ossification of muscles and tendons from injury or rheumatism, but such cases should not be confounded with those which were congenital. In these last, deformity of the toes seemed constant. The skiagrams showed irregularity of the epiphyseal lines. Ossification, he remarked, might spread from periosteum to muscle.

Dr. Herringham, in reply, said that the swelling diminished under rest, and he admitted that rheumatism might be a predisposing factor. The growths did not always spring from bone. Sometimes they occupied muscles and even the areolar tissue between. It was therefore not only bones and muscles that were involved, but the fibrous tissues generally.

The next subject before the meeting was the association of congenital heart disease with the Mongolian type of idiocy. Dr. Garrod mentioned five cases illustrating this, and quoted Dr. John Thompson as to three others. All the subjects were under five years of age. Several had died. It was suggested that the early death common in these cases accounts for the fact that they are not often seen in asylums.

Dr. Gossage mentioned the case of a girl, two and one-half years old, who was a typical Mongolian idiot, and looked to be only about thirteen months.

Dr. Guthrie had secured post-mortem examinations in two cases of the Mongolian type of idiocy, one of which had ultimately become dropsical. In both cases the heart was hypertrophied and its right side

equal in thickness to the left. The septum was defective in both.

In reply to a question, Dr. Garrod said he knew of no mechanical reason in the conformation of the orbits to explain the Mongolian direction of the eyes.

The subject of erythema following an enema in children was brought forward by Dr. Still. Though of little importance *per se*, such rashes may obscure the diagnosis of specific fevers. From a study of twenty-six cases, Dr. Still considers that enema rashes have a characteristic appearance and course. In his cases there was a bright red erythema on the front of the knees, back of the elbows, the buttocks, and the face; in some cases the rash was scarlatiniform, and in others the two forms seemed mixed. It appeared from twelve to twenty-four hours after the enema, lasted from twenty-four to forty-eight hours, and scarcely ever was accompanied by constitutional disturbance. The absence of this and other symptoms differentiate it from scarlet fever, measles, or other exanthemata. It seems not improbable that some cases of "surgical scarlet fever" may have been rashes due to an enema before the operation. The rash must be regarded as the result of vasomotor dilatation, and three possible explanations suggest themselves: (1) absorption of some toxin from the soap or (2) from the fæces; (3) reflex effect on the vasomotor centres.

Mr. Charles Symonds read notes of a case in which the vermiform appendix occupying a hernial sac was found perforated by a pin. He referred to other cases in which true foreign bodies, as distinguished from concretions, had been found, and mentioned two others in which the intruder was a pin.

The president said it was not very infrequent for the appendix to find its way into a hernial sac, and foreign bodies were not uncommon in the appendix. He related two of his own cases. In one a pin, two inches long, was removed; in the other peritonitis occurred a few months after operation, due to the presence of a needle which escaped detection at the operation and brought about eventually a fatal result.

The county council is likely to adopt a resolution of its health committee in favor of superseding all private slaughterhouses by public abattoirs. This would be a first step—and a considerable one—toward establishing an efficient system of meat inspection. Recent events have impressed the public with the necessity for such inspection of meat, milk, and all kinds of food. The council's medical officer, after visiting various cities, has reported strongly in favor of public slaughterhouses as essential to the adequate inspection of meat. This view accords with the recommendations of the royal commission on tuberculosis. That commission also recommended that our health authorities should have the control of the milk supplies, involving *inter alia* power to examine all cows in their districts or all from which milk is obtained and brought into their districts, and to prevent the sale of any milk which might be injurious to health. The county council is ready to undertake the control of both meat and milk, as well as other matters relating to the food supplies, and probably it would be a good thing for the public health that it should do so. We may therefore hope that there will not be delay in conferring on the council the powers necessary for carrying out its purpose.

From the new calendar of the Royal College of Surgeons, just published, it appears that there are now 1,195 fellows, 17,199 members, 1,283 dental licentiates, and 308 diplomates in public health.

Dr. Sims Woodhead's report as director of the research laboratories of the two royal colleges shows that considerable advances have been made. The antidiphtheritic serum prepared is now of three hundred and seventy-five units per cubic centimetre, and special attention is being paid to the standardization of antitoxin. Ehrlich's new method is now employed. There are arrangements for testing any serum sent for examination. No less than two thousand and three doses have been supplied to hospitals and practitioners during the year for use among the poorer classes, in accordance with the conditions of a grant made by the Goldsmiths' Company.

The war minister has invited some of our medical schools to recommend persons for admission to the royal army corps without examination. There is much misgiving as to the propriety of assisting the war office in this way to fill up vacancies which should not exist. There was so much delay in the concessions that the last "competitive" examination did not attract a sufficient number of candidates. It is dangerous to open a door to patronage in this manner, and any man thus selected will probably be looked down upon as inferior. They are frankly informed they will rank after the successful candidates in the last examination until the next, after which their places when they receive their commissions will be determined by the examination in special subjects at Netley next February. It is not a question of the value of the competitive method of appointment, but of the danger of supplementing the deficiencies of that method, instead of removing them.

Dr. Collingridge's half-yearly report shows how important is his work as medical officer for the port of London. In that period the sanitary officers visited 15,531 vessels in the docks and the river. Structural alterations for sanitary defects were consequently carried out on 281 vessels. The medical officers visited 4,876 vessels arriving from abroad, and of them 586 were medically inspected—*i.e.*, passengers to the number of 2,733 and of the crews 6,135 had to be individually examined, and 56 cases of infectious disease were discovered. There were 10 cases of small-pox, 3 of scarlet fever, 30 of typhoid, 3 of diphtheria, and 10 of measles dealt with. One of the cases of diphtheria was landed at the port hospital, and Dr. Hancock, who had examined and removed the patient, caught the disease, but happily had only a mild attack. When there was great negligence, proceedings were instituted against owners, and in some cases convictions obtained.

The conscientious objector to vaccination has developed his conscience to such an extent that he objects to paying the fee of 1*s.* or 1*s.* 6*d.* for his certificate, and there is talk of a lawsuit to ascertain if the fee can be legally enforced. At another town the magistrates were satisfied without oath or even individual declarations, but granted certificates to candidates in batches of ten and twenty at a time who said yes or nodded in reply to the question if they had a "conscientious objection." It is said that in the course of two and one-half hours above six hundred were thus released from their duty to their children. And this in the country of Jenner!

Those doctors who have a *penchant* for masquerading in gorgeous attire had another opportunity provided for them on Wednesday. The guild of St. Luke organized another display at St. Paul's Cathedral. The guild is infected with the ritualistic epidemic, and seeks its solace at the hands of those of the clergy who most delight in "vestments." Graduates were invited to attend the service in their academical dress, and a firm of dealers in clerical attire promised to be present and "robe" the gentlemen who hired from them for the occasion. There was a large attendance, and one of the daily papers said the dome of St. Paul's was brighter than a tulip bed in full bloom. Another reporter says the solemn service began with a procession of robed doctors, choristers, clerical associates of the guild, the clergy of the cathedral, and the bishop, pre-

ceded by the episcopal staff. Some non-graduates seem to have been out of such displays for want of an academical robe. So they have persuaded the College of Surgeons council to approve of a brand-new design. How far such authority may be accepted remains to be seen. We may yet have all our corporations vying with each other as to which will produce the most popular dress, but there is hope that the vestment epidemic may soon die out.

A departmental commission, on which there are two doctors, has been appointed to advise the home secretary as to regulations to be adopted under the recent legislation as to inebriate retreats.

Tuesday, the 18th, was St. Luke's day, when, according to custom, the Harveian oration was delivered at the Royal College of Physicians. This year Sir D. Duckworth was the orator.

OUR BERLIN LETTER.

(From our Special Correspondent.)

THE PATENTING OF REMEDIES—THE CONVENTION OF NATURAL SCIENTISTS AT DÜSSELDORF.

BERLIN, October 15, 1898.

MUCH talk has been occasioned in medical circles here, because Professor Behring after repeated previous attempts has finally obtained a United States patent upon the manufacture of diphtheria serum. This patenting of a scientific discovery by a physician is so contrary to medical custom and usage that it may readily be understood that Professor Behring has been violently attacked by both physician and layman here. The daily journals have taken up the matter, and the *Berliner Tageblatt* says: "Professor Behring places himself on the same standpoint as any commercial man who seeks to protect his discovery through law. Of course he has an entire right to do so. The public, though, looks upon the physician as something else than a business man, one who deals in medicines and remedies. This is the first case of this kind in the entire history of medicine. The discoverers of antipyrin, etc., were not physicians." And in thus expressing itself the *Berliner Tageblatt* but re-echoes the general sentiment of the laity here. Naturally the American and English medical journals criticise Behring's proceedings even more severely, but with less right perhaps; for in our country it is not permitted to patent any medical remedy, while such a prohibition does not obtain in America—at least only morally and not legally. Behring thus defends his actions: he has spent his entire fortune to discover a specific remedy for diphtheria, and, as he has long since given up the practice of medicine to gain his livelihood, he is necessarily thrown upon other resources for his living and for the further pursuit of his investigations. Behring puts the case so that one is led to conclude that dire necessity compelled him to take the course he did; when we, however, remember that he receives yearly 60,000 marks from the "Höch'ste Serum-Fabrik," and has besides an extra income as professor of hygiene at the University of Marburg, we must fail to appreciate the justice of his arguments and excuses. America will now have to pay more for its serum, but there is a possibility of its being soon dispensed with. Here, at all events, the list of those who deprecate its working is steadily increasing.

A striking contrast to the unpleasant impression which such business-like methods on the part of a physician make upon the public is shown by the great appreciation which the purely scientific proceedings of the Düsseldorf convention have awakened. This assemblage, which was held during the latter part of September, was participated in by about twenty-five thousand persons—physicians, scientists, and their ladies.

Professor Tillmann's address upon the progress of military surgery deserves a mention. He called attention to the great decrease in dangers of infection, such as were common, for example, during the Franco-Prussian war. The danger of infection from the clothing of the wounded has been exaggerated; very often there are no pathogenic germs present. In the treatment of gunshot wounds, Tillmann would recommend therefore an expectant treatment, especially in view of the fact that the number of physicians is very small in proportion to that of the patients. In this respect, however, the German war department has made wise preparations; outside of the military surgeons it controls forty-five thousand trained nurses and orderlies. The speaker condemned the Dum-Dum missiles as inhuman. He closed his address with some remarks to the adversaries of vivisection, in which he declared that animal experiments are unavoidable for the progress of our diagnostic and therapeutic knowledge.

In the pædiatric section much attention was allotted to the important subject of the nourishment of infants with sterilized cow's milk, with special ventilation of the food-quantity question for normal bottle-fed babies. Carstens is of the opinion that in this regard clinical attempts have been too much neglected, and that chemical experiments have guided us almost solely. As children who are nourished solely with sterilized milk present in consequence many symptoms of ill health, Carstens is in favor of a mixed diet. The simple boiling of the milk at home is preferable to factory sterilization.

During the main medical session Prof. M. v. Frey (Zürich) read a paper on the action of the heart and certain physiological experiments and deductions therefrom. He had endeavored to keep up the action of the isolated heart of warm-blooded animals by means of suitable nutritive solutions, in the hopes of solving with such a heart a number of important physiological questions. He finally succeeded very recently in continuing the action for an entire day by means of a minute quantity of blood, or of serum even, in the coronary system. It is not necessary here to explain what a grand progress has thus been made for the solution of many questions in the physiology of the heart.

The "Combating of Tuberculosis in Germany" formed the great topic of discussion of the section for hygiene and bacteriology. Minister Count Posadowsky stated that the board of directors of the central committee for hygiene would call a congress to convene in Berlin next spring, with a view to consulting upon all questions pertaining to the establishment and government of healing stations. It was repeatedly pointed out what a great benefit would follow if the Naturalist Assembly should occupy itself with this question, for this body is composed of members of various departments of science united here for a common object. As a final result a permanent committee was organized for the devising of ways and means to combat tuberculosis.

After a long list of papers and addresses, of which one by Martins, on the "Causes of Disease and the Forces which Oppose these Causes," excited especial interest, the assemblage, over which Professor Waldeyer had presided, closed its session, all the participants being well pleased with the work accomplished.

Night Sweats of Phthisis.—Atropine sulphate, gr. $\frac{1}{50}$ hypodermically at bedtime. Also, picrotoxin, gr. $\frac{1}{60}$ hypodermically at bedtime.—WILLIAM MURRELL.

THE CRITICISM OF STATE HOSPITALS.

To the Editor of the Medical Record.

Sir: The report of Hon. S. F. Nixon to the State comptroller, criticising the cost of maintenance and treatment in our insane hospitals under the State-care system, is noticed in a late number of the Medical Record. This cost under the old plan of local management was indeed enormous, being nearly one hundred per cent. greater than in the asylums of New England, Pennsylvania, and other States. One consideration is sufficient to explain this fact. It is that in both the construction and maintenance of our asylums the main object of their managers has been to expend the largest possible sums from State and county treasuries for the benefit of local interests. Needless to say that asylums erected and maintained upon such a plan have not been easily brought under a system of honest and economical management. Their cost of maintenance has, however, been reduced twenty-five or thirty per cent. under the State-care law, while other reforms still more important than economy have also been accomplished.

Most important of all in the administration of an asylum, as every one knows, are the selection and training of attendants. While these were mainly taken from an idle and worthless class who had failed in other vocations, the insane suffered that deplorable neglect and abuse which their helpless condition made easy to commit and difficult to prove. Under the State-care and civil-service laws the hideous evil has been almost entirely abolished. Is it possible to suppose that public opinion will permit a return to the old system of local management and its inevitable consequences?

And yet it is to be feared that this is the underlying motive of the criticism of asylum expenditures which has lately been made. The politicians have seen a million dollars yearly, for the last five years, expended for the building and maintenance of hospital asylums in this State, and which was not shared with them. Let us hope that they may not prevail with the legislature, and that all who are interested in the medical and humane treatment of the insane will see to it that lunacy reform shall not be permitted to fail in the Empire State.

Utica, N. Y., October 26, 1898.

TUBERCULOSIS.

To the Editor of the Medical Record.

Sir: I beg the privilege of correcting the report of my remarks at the meeting of the New York State Medical Association, which appeared in your esteemed paper of October 22d. A few remarks I made were incorrectly reported and I cannot let them go, as they do not represent my views and are contradictions of what I have expressed elsewhere.

(1) I did not say that I was "a convert to the view that the channel of tuberculous infection was the digestive tract." I said that I was willing to admit that formerly I held with many others the view that the dissemination of the germs contained in carelessly deposited sputum of tuberculous patients was the prime and most important factor in propagating the disease, but that recent information which I gained from studying the etiology and history of a large number of cases had converted me to the idea that tuberculous infection by ingestion of tuberculous substances should be considered as frequent as infection by inhalation.

(2) I did not say that in children the place of least resistance to the invasion of the bacilli was the lungs; this is not so. In children it is the delicate intestinal epithelium which offers to the bacilli contained in tuberculous milk the most favorable abiding-place. I said apropos of this mode of infection that the reason we so rarely find primary intestinal tuberculosis in adults, in spite of the frequent ingestion of tuberculous substances, is to be explained by the fact that the epithelial lining of the intestines is stronger and resists the colonization of cultures. If the individual is in poor health and the phagocytic power of the blood enfeebled, the bacilli ingested by a grown person usually find the apices of the lungs to be the *locus minoris resistentiæ*, which they reach through the medium of the circulation of the blood.

If you can insert these corrections in your next number I shall feel greatly indebted.

INSTRUCTION IN INSURANCE EXAMINATION.

To the Editor of the Medical Record.

Sir: I want to enlist the aid of your valued paper in behalf of a department of medical skill which is almost totally neglected in the curriculum of our medical schools. I refer to the examination of candidates for life insurance. Practically no provision is made for instruction in this branch in any medical school, and only a most incidental course is given in some post-graduate institutions. The life-insurance companies of the United States had on their lists about two hundred thousand examiners in 1897. As one examiner frequently held appointments from several companies, the number of physicians actually employed was considerably less. They are selected with great care, and the position is considered one of honor and to be sought for. So they can be regarded as well-picked men, and the companies recognized their claim to the extent of $2,500,000, which was the approximate amount paid out for medical fees in 1897 by the regular companies, not counting the assessment and fraternal associations. This contribution to the income of the profession entitles the companies to more consideration at the hands of the teaching bodies.

Nor can it be said in reply that the ordinary course of instruction covers all that is needed for life-insurance examinations. Something more is wanted than the mere technical skill of a training in physical diagnosis. How can a physician intuit the difference between a private patient seeking advice and an applicant desiring insurance? The most conscientious man regards the examination as a contest, and will not volunteer any information about himself, even though he may answer fully every question that is asked. Of course an examiner learns this fact in time, but while learning it he may pass for a company thousands of dollars of insurance on lives that are below the standard. Likewise the tact that handles smoothly both applicant and agent is acquired after a while, but often with the loss of much good business. The need for thoroughness and the ability to differentiate between essential and petty facts can be taught by precept as well as by the pain and mortification of experience.

For similar reasons instruction should be given in regard to making examination of applicants for positions in the civil service. This line of work is steadily growing, and promises to become of considerable importance. On the other hand, the office of examiner of applicants for pensions is a haven for political physicians, and the selection of the cases is determined usually by the political affiliations of the applicant, rather than by the merits of his disabilities or his deserts. However, there are many excellent considerations which, if fearlessly applied, would materially re-

duce the pension list, and these might be taught in preparation for that happy day when the yawp of the pension agent will no longer be heard in the newspapers.

Some recognition of these allied branches ought to be given by the medical schools. A short course of instruction could easily be fitted into the work of the last year. It could be made compact and concise, and yet furnish all the needed information. I bespeak your co-operation in obtaining this boon.

BRANDRETH SYMONDS, M.D.

October 29, 1898.

BOTTINI'S OPERATION FOR ENLARGED PROSTATE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I noticed in a recent issue of the *Medicinische Monatschrift*, in the report of a discussion on Bottini's cauterizing prostatic operation, that Dr. Freudenberg commended the preliminary filling of the bladder with boric solution, in order to prevent entanglement of any of the mucous-membrane folds with the blade of the incisor—a complication which, he said, had happened in one of his operations. I have tried this, and found it very unsatisfactory. There was considerably more pain than was the case (the same patient, by the way) when the incision was made with the bladder empty.

I found by experimentation that the blade could not be brought to a red glow while under water. Dr. Freudenberg suggested that the close hugging of the prostatic tissue by the instrument would prevent any of the solution from coming in contact with the blade, and the latter would therefore work just as well with the bladder full of fluid as with it empty. Of this I am very much in doubt, and my case mentioned confirms that doubt. I believe the fluid nearest the blade became hot and scalded the adjacent parts, producing the unusually severe pain.

To obviate the defects suggested, and at the same time to accomplish the object of smoothing out the folds of membrane, in my last case I injected air from an eight-ounce bulb syringe directly into the bladder. It was entirely satisfactory. No pain was occasioned thereby, and the air was readily withdrawn by catheter after the operation. BRANSFORD LEWIS, M.D.

ST. LOUIS, MO., October 27, 1898.

"THE MEDICAL ASPECTS OF CAMP MANAGEMENT AT CHICKAMAUGA."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the issue of the MEDICAL RECORD of October 22d, Lieut. H. A. Haubold, assistant surgeon, eighth regiment, New York volunteers, in an article entitled "The Medical Aspects of Camp Management at Chickamauga," goes out of his way to make the following remark: "One writer, a surgeon on a general staff, tells us, in an article in the *Journal of the American Medical Association*, that eighty per cent. of the surgical cases at Chickamauga Park were venereal. When it is remembered that the troops were not under fire, and that the surgical cases were rare, the misleading character of his statement is sufficiently apparent." This sentence is my apology for paying my respects in return, by reviewing his article. In extenuation, however, of its misleading characteristics and various defects, I quote his own apology, namely, that he was on duty in Chickamauga Park from the 24th of May until the 8th day of July—a period of six weeks, which includes the time of his military education. In the third paragraph he says: "It is also a peculiarity on the part of commanding officers to be devoid to a considerable extent of this desire;" namely, "to help and render easier the lot that has befallen the poor devils [sick soldiers] that come under their observation." I suppose he means who come under their observation.

It is a fact beyond controversy, with rare exceptions, that commanding officers, as far as their knowledge of hygiene extends, put forth their best efforts to preserve the health of their men, and it has been my observation that they are almost uniformly solicitous concerning and attentive to sick soldiers.

In paragraph 4 he gives an abstract of the features of Chickamauga Park, which might lead the readers to compare it with the desert of Sahara, provided the latter was covered with "scant woodland." Chickamauga Park is one of the most beautiful parks, beyond the environment of cities, in the world. It is beautifully and healthfully shaded by well-grown timber, free from underbrush and all impediments to easy foot travel. The ground is undulating in all directions. It has a perfect natural drainage, and is traversed by broad, smooth, excellent macadamized boulevards. At various points in the park, which is about seven miles square, there are small farms cleared of timber, and no longer under cultivation. They are now known as "fields" or "battlefields," and mark sites of the conflict in September, 1863. They served the purpose of drill grounds this year. The park is ornamented very profusely with beautiful monuments, erected to the memory of those who took part in or died in that memorable conflict. There are also erected in the park several very high towers; they are built of structural iron. When Chickamauga Park contained forty-five thousand troops, owing to the complete protection of the "scant woodland," an observer in the top of any of these towers was unable to see the tents of soldiers, so completely were they sheltered by the foliage which was "daily kissed by a broiling Georgia sun." This reference to Chickamauga Park is made in order that readers who have not seen it may not be misled as to its character by Lieutenant Haubold.

In paragraph 6 he states that regular troops preceded the volunteers several weeks in their occupation of the park. They arrived there on the 24th of April, one month before, and the regular troops were still there in September. They lived on army rations, food which our author says was "badly selected;" namely, bacon, beef, potatoes, bread, hardtack, tomatoes, onions, beans, and coffee. How the army in 1863 would have cheered this sumptuous fare! During all this period, from April 24th until September 1st, one regular died, and during the same period four hundred and twenty-five volunteers died. Is this diet good for regulars and bad for volunteers?

I indorse all he says in regard to the clay soil and rocky strata of Chickamauga Park, especially what he says in paragraph 8: "The rocky nature of the substrata made absorption or percolation of the contents of the sinks into the earth impossible." But I almost lose my breath when I read in paragraph 9 "that for the first few days my regiment was in camp the water supply did not reach our regimental camp, that water was drawn for drinking-purposes from Chickamauga creek, at points where infection was possible through contamination from drainage from the camp sink holes of other regiments." It was not from overflow of the sinks, for the writer says: "No rain fell for weeks."

As to the water supply, he says, in paragraph 12: "Contrast this warm, nauseous mud soup to clear extract of fæces I have referred to" (see paragraph 8). He further says: "In a short time the water was clarified by sedimentation." Was the influent end of the pipe line at Chickamauga below Crawfish springs in a pool where the law of gravitation was suspended and

where "sedimentation" could not occur, or was there a gang of witches there with sticks constantly stirring up the pool where the pipe line ended and where there "had been no rain for weeks," and were they filling it with "mud soup"?

In regard to proper food for the sick, in paragraph 20 he says: "Water, rice, and milk — these three things were obtainable;" while in paragraph 24 he says: "Grave cases with bloody stools and mucous stools occurred, and were not readily amenable to treatment, due in part to the fact that milk and readily digested food, such as eggs, rice, etc., were not obtainable."

In paragraph 25, Surgeon Haubold, in speaking of venereal diseases, says: "Still it is not true that they were more prevalent than one would have a right to expect." When a soldier enlists in the army he takes an obligation to give his best services to the government for a fixed consideration. When he deliberately disables himself he breaks his contract, perjures himself, lays himself liable to peremptory dismissal from the service. He endangers his messmates, and becomes a dirty, nasty, stinking nuisance to the medical officers; he is simply a male whore, and deserves to be treated as such. How many of these people to a company or regiment would one "have a right to expect"?

In 1863 Rosencrans' army, after a march from Murfreesboro, through incessant rains and deep mud, and with scanty food, almost shoeless and in tattered clothing, and tentless, reached the battlefield of Chickamauga and fought the memorable conflict of the 20th and 21st of September. These troops left killed and wounded on that battlefield forty per cent. of their number; the remainder retreated to Chattanooga, to live out of doors, dig trenches, and to live on one-third rations, while General Wheeler with a large cavalry force swept across the State of Tennessee from east to west, and *en route* destroyed the wagon trains carrying provisions to that famishing army. Did they whimper and whine about their water? Did they cry out to the whole country that they could not get enough ice (to put in a hole in the ground), and that army rations were not well-selected food? Or did they, on the other hand, put their patriotism in evidence and prove to the world that they were the sons of their fathers? I maintain that the army at Chickamauga was very seriously damaged for effective service by venereal disease, and that, notwithstanding surgical accidents were frequent, including also an occasional gunshot wound, by far the most frequent operation was the enucleation of inguinal glands. As a military surgeon, I have never had any other feeling than that of disgust and contempt for those color-blind sidereal knights, who were constantly making observations of Venus, experimenting with Mercury, and giving daily exhibitions of Uranus.

The army at Chickamauga contained representatives of the best blood of the land, and they were good soldiers. But it also contained a large number of worthless milksops and hoodlums. The former should have been accompanied by wetnurses and kept on ice, while the latter in hundreds of instances should have been sent to military prisons, and decent messmates would have been relieved of the hardest lot that can befall a soldier, viz., living, eating with, and sleeping beside a dirty scoundrel with gonorrhœa or syphilis, or both. Have decent volunteers a right to expect this? The Chickamauga army was followed by an army of prostitutes, capable in time of ruining it, and the amount of venereal disease existing in the army was very great. The food was good. The water from the springs was delicious; that from the pipe line pure and wholesome, but warm. I had an abundance of ice, which I did not keep in a trench; a gum sheet and a stretcher made a tub, and baths were given right along. For a few days I was short of lumber and cots, but this deficiency did not last and the brave boys did not complain, nothwithstanding that a dozen hoodlums with gonorrhœa and syphilis were at that moment occupying cots on a board floor. R. S. SUTTON, M.D.,
Major and Chief Surgeon, Commanding Second Division Hospital, First Army Corps, Chickamauga.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 5, 1898:

	Cases.	Deaths.
Tuberculosis	178	152
Typhoid fever	56	14
Scarlet fever	92	5
Measles	104	3
Diphtheria	133	14
Laryngeal diphtheria (croup)	6	3
Cerebro-spinal meningitis	0	8
Yellow fever	0	1
Chicken-pox	19	0

Bismarck's Brain. — The *Medicinisch-Chirugisches Centralblatt* says that an anthropologist named Ammon states that Bismarck's brain was probably the heaviest on record. He judges from measurements of Schäfer's bust of the great chancellor that his brain must have weighed 1,867 gm. (over 58 ounces); Cuvier's brain weighed 1,830 gm.; Byron's, 1,807; Kant's, 1,650; Schiller's, 1,630; and Dante's, 1,420. The average for a well-built European man is given as 1,380 gm.

Unnatural Death.—Dr. Hill, master of Downing College, Cambridge, read a paper at the recent meeting of the Sanitary Institute of England, with the above title. He told his hearers that about one million babies were born annually in England. Thirty thousand of the million would die violent deaths from accident, 30,000 would die unnecessarily from tuberculosis, and 120,000 more from other absolutely preventable causes, such as small-pox, measles, and scarlet fever. Only 45,000 would be allowed to live out their natural lives, and nearly 1 in 20 would die because the machine was worn out. One-fourth of all the diseases which destroy life are absolutely preventable, and fifteen years would at once be added to its average duration if the practice of hygiene were placed on a level with its theory. Dr. Hill attributed the greater number of the diseases over which the individuals affected by them have personal control to mistakes in eating and drinking.—*London Times.*

Bullet in the Heart.—A French surgeon in 1875 presented to the Paris surgical faculty the heart of a woman who had been shot with a revolver. The bullets measured three lines (one-fourth of an inch) in diameter. One of them had passed through the right lung, had penetrated the heart by the posterior wall of the left ventricle, and was found lodged in the latter. She lived eighteen days, and nothing during life led to the suspicion that such a lesion had taken place. Auscultation revealed nothing and the pulse was regular. The hole made by the ball could hardly be discerned.—*Lancet*, 1876.

Syphilis in the Sixteenth Century.—The father of Catherine de Medici (the wife of Henry II. and queen mother during the reigns of Francis II., Charles

IX., and Henry III.) is stated to have died of syphilis a few days after his daughter's birth. Catherine was an only child and her mother died at her birth. Her portraits, which are numerous, show no evidence of inherited taint. At that time syphilis was a new disease in Europe, and, as it had not been in any way associated with sexual habits, no disgrace was supposed to be attached to it. Historians felt no delicacy in recording the fact that any one of whom they wrote had suffered from it. Many deaths of ecclesiastics as well as of civilians were attributed to it.—ROSCOE, "Life of Lorenzo de Medici," vol. ii.

Strange Foreign Body in Vagina.—Probably the strangest foreign body ever discovered in the vagina was one found by me—a cockchafer lying beside a pomade pot.—TREVES, "Surgery," vol. iii., p. 387.

Want of Tone.—A tendency to perspire on the slightest exertion is not unfrequently coincident with habitual chilliness, and both are indicative of want of tone.

Death of Sterne.—Lawrence Sterne died rather suddenly in lodgings in London, at the age of fifty-five years (1768). He had been suffering from a chest ailment for several years, and had been sent for long periods to the south of France. He was liable to attacks of what he termed "my vile influenza." It was from one of these that he died—no doubt, intercurrent catarrhal pneumonia.—HUTCHINSON, "Archives of Surgery."

A New Idea in Blackmailing.—Seldom has a more infamous system of blackmail been exposed than the diabolical plan for extorting money devised by the man Mitchell. The wonder is that anybody could have been silly enough to fall into his trap, but his victims were entirely women, whose utter ignorance of law and government made them an easy prey. His method was to send a typewritten letter to ladies who had purchased at a certain establishment some quack female pills or other medicine. This document, which was signed "Charles J. Mitchell, public official," contained an intimation that legal proceedings had been commenced against the recipient, who was charged with committing a criminal offence. These proceedings were to be stopped on receipt of £2 2s. (about $10), costs, and a solemn promise in writing that the offence should never be repeated. The police found evidence that more than five hundred persons had been frightened into paying the amount demanded, and the neighborhood of Northumberland Avenue, where Mitchell's office was situated, was besieged by unhappy victims, trying to obtain an interview with the blackmailer. If it had not been for the husband of one of the threatened persons, this new terror might have gone on indefinitely, with the most tragic results. —*Saturday Review.*

Strange Foreign Body in Groin.—A man developed an abscess in the groin. When the abscess was opened, it was found to contain a small spelling-book. It was ascertained that this patient, when a boy, was shot, and it is supposed that the spelling-book was in his trousers pocket, and was shot into the groin.—*Medical Press and Circular*, 1884, vol. ii., p. 419.

Drink Question in Belgium.—For some time past the drink question has been exciting among thoughtful people in Beligum serious reflections, and the figures collected by M. Jules Le Jeune, ex-minister of justice, certainly justify them. The population of Belgium is still less than seven millions, but it can boast of one hundred and ninety-eight thousand wine and beer shops, or one for every thirty-five persons, women and children included. The total drink bill of the country is valued at £20,000,000 ($100,000,000). It is said that seventy-nine per cent. of the paupers living in the State are drunkards, that eighty per cent. of the suicides have a similar origin, and finally that forty-five per cent. of the lunatics were victims to what is called the alcohol habit.—*London Times.*

THE RADICAL TREATMENT OF PROSTATIC HYPERTROPHY.[1]

BY EUGENE FULLER, M.D.,

NEW YORK,

PROFESSOR OF VENEREAL AND GENITO-URINARY SURGERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL, ETC.

THE term prostatic hypertrophy in its proper and generally well-recognized sense should be applied only to the senile hyperplastic changes peculiar to the organ. This hypertrophy is the result of a proliferation of the muscular and of the glandular structures. The changes in these different tissues, however, bear no definite ratio to one another, although as a general rule the great bulk of the increase in size is dependent on the muscular element. Associated with the hypertrophy of the tissues just mentioned there is also a proliferation of the connective tissue of the part. When the connective-tissue proliferation is abundant and dense the diseased organ is never greatly increased in size and is correspondingly hard and sclerous. When the opposite condition prevails, the hypertrophy may attain great size and is usually soft and succulent. Although a hypertrophied prostate as it presents itself to the touch of the finger tip on rectal exploration may, and often does, appear quite uniformly enlarged, there is in my experience practically no uniformity in connection with its enlargement, with reference to the prostatic urethra and bladder. Its encroachments on those cavities are, in the popular professional mind, represented by the growth of a so-called middle prostatic lobe, which is situated with a considerable degree of exactness dependently and just back of the vesico-urethral orifice. This projection is also usually pictured as a rounded knob, varying in size from that of a hazelnut to that of an English walnut. Such a condition may of course occur; still, as a result of much experience wherein I have been able to examine conditions minutely, by the sense of both sight and touch, through the medium of a suprapubic vesical opening, I cannot call to mind any two instances in which the existing lesions have presented perfectly similar evidences. Sometimes hypertrophies have occurred, packed more or less closely about the prostatic urethra, or a mass, in connection with the floor, the roof, or either side of that portion of the canal, has bulged into its cavity as an irregular tumefaction. Intravesical projections caused by the enlargement may jut into the vesical cavity as a collar about the vesico-urethral orifice or as irregular single or multiple tumefactions situated as regards the vesico-urethral orifice below, laterally, or above. Among the especially grotesque intravesical projections which I have encountered, mention may be made of the case of a negro, in which the lesion consisted of a mass about the shape and size of the terminal third of a banana, which from an attachment behind and to the upper left side of the vesico-urethral orifice extended downward and to the right, so as to lie entirely across the vesical outlet. In another case two projections, one from above and one from below the vesical outlet, each about the size and shape of the terminal half of the forefinger, met and projected backward into the bladder. I make mention thus particularly of the forms taken by prostatic hypertrophy, so that a clear idea may be obtained of just what one has to contend with in striving to accomplish a radical cure of the vesical disabilities which may be dependent on this lesion. I should further state that in very extreme conditions the hypertrophied tissue may equal a pound in weight, though half that weight is to be considered unusually large. Very many instances, however, are represented by from three to five ounces.

Although, as I have said, the general pathology of the senile change in the prostate just described is well recognized, still the diagnosis of that condition is not infrequently wrongly applied to other ailments producing symptoms of obstruction to urination, such as may be caused by prostatic hypertrophy. Thus it is common to encounter instances of seminal vesiculitis wherein such an error has been made. Simple and tuberculous inflammations of the prostate, and the condition which I have described as chronic contraction of the prostatic fibres encircling the vesical neck,[1] are among the other diseases which may in like manner be mistaken. Accordingly, when one hears of the occurrence of a cure of urinary disability, the result of prostatic hypertrophy, taking place either spontaneously or as the apparent result of medication, *régime*, or some non-eliminative surgical procedure, he has a perfect right to distrust the diagnosis.

Prostatic hypertrophy, no matter how extensive, causes the individual affected little or no discomfort or inconvenience, provided it so extends itself as not to interfere with the function of micturition or with vesical drainage. Accordingly, it is only the instances in which urinary obstruction results that demand the surgeon's attention.

As a further preliminary to the real object of this paper, and without which the question of radical treatment cannot be appreciated, the effects produced on the bladder itself by prostatic obstruction must be understandingly discussed. If a hypertrophy, which has hitherto caused little or no obstruction, suddenly from some accidental cause or complication becomes completely obstructive and vesical overdistention and overflow follow, then atony of the otherwise normal vesical walls results. In most instances the obstruction offered by the hypertrophy develops gradually, and to make up for this the vesical walls undergo a condition of compensatory muscular hypertrophy. In most such cases, however, the prostatic obstruction tends eventually, if nature be left unaided, to overbalance the vesical muscular hypertrophy, so that finally the bladder is here also left atonied from overdistention. In some cases of the latter class the bladder does not give up without a severe struggle, the result of which may be to inflict grave damage on the organ in the form of deep sacculi, the walls of all of which are thin, while in connection with some of them there is no muscular structure, their walls consisting only of peritoneum and mucous membrane. In this

[1] Read before the New York Academy of Medicine, November 3, 1898.

[1] American Journal of the Medical Sciences, October, 1897.

last and most serious form of sacculus severe and continuous vesical tenesmus has caused a hernial protrusion of the mucous vesical structure to take place through the muscular meshwork. So great importance has been attached to these conditions of vesical atony that Sir Henry Thompson held, when McGill introduced his operation of suprapubic prostatectomy, that it would be unsatisfactory in all cases in which complete vesical atony previously existed, since, the bladder having no contractile force, natural urination would not be restored, even though the obstruction causing it were removed. In other words, complete vesical atony caused by overdistention was supposed to be a permanent disability. Guyon not only agreed with Thompson, but went further and declared that senile prostatic hypertrophy was not in the least degree a local lesion, but a general one, identical with arteriosclerosis, and that the bladder was involved equally with the prostate. Caspar and others, as the result of much post-mortem research, have disproved Guyon's assertions. My experience shows me that these atonic bladders, if properly managed, recover their tone, and in three personal instances bladders, severely sacculated as well as atonied, have been made to resume their function. In one of these, natural repair occurred in connection with a diverticulum formed by a hernial protrusion of the mucous membrane through the muscular wall. Aside from the vesical lesions produced by prostatic obstruction to urinary drainage, severe instances of the disability cause dilatation of the ureters and their orifices, together with a certain degree of hydronephrosis. These lesions of the upper urinary tract eventually resolve themselves, provided all obstruction to urine drainage be removed. Their presence somewhat increases the gravity of operation for the removal of the prostatic obstruction.

In advocating a radical surgical procedure for the relief of elderly men suffering from prostatic hypertrophy, it has been my experience to expect opposition from the family and friends of the afflicted, and not infrequently from the profession, although the sufferers themselves are generally ready to accept any treatment which bids fair to relieve them, provided they have reached the stage of acute discomfort. In arguing against a resort to radical measures, the opposition lays special stress on the Bible precept, that three score years and ten fulfil the allotted time. Consequently the idea is not perhaps so much to prolong life as it is to make the end as comfortable as possible. Unfortunately, however, there is no palliative method of treatment by which the terminal stage of existence can be freed from great agony in all cases in which relief is no longer to be afforded by the catheter. In fact, in such cases the agonies of death are much the same as a woman would suffer should she be left unaided in childbirth when, owing to some malposition, natural delivery were impossible. The woman, however, would have the advantage of being relieved fairly promptly by death.

The question of the surgical tolerance of elderly individuals is generally and rightly brought up in opposition by the profession in this connection. Every one knows the serious effects that shock and confinement to bed often have on old people. In my radical treatmen of prostatic hypertrophy I have given the greatest weight to this consideration. I feel that every extra minute that a patient is under the anæsthetic counts against him. The instant he is anæsthetized I begin to operate. Generally at the end of fifteen minutes after the commencement of operation the anæsthetic is discontinued, the calculation being that the patient will be fairly out of his anæsthesia with the completion of the operation. I feel that any operator who is slow and dilatory will have a correspondingly large fatality in these cases. Everything should be done to avoid immediate and secondary post-operative shock. The patient should be taken directly from the operating-table to a warm bed, and hypodermic medication applied to aid the heart, in case that organ shows signs of fatigue. Secondary shock can be avoided by arranging at the time of operation for the subsequent comfort of the patient. This can be accomplished by providing free urinary drainage, and also by so arranging the wound that no pain may be caused by the subsequent adjustment of the dressings. In some of my early experiences, for instance, I feel that the pain and suffering attending the removal of vesical tamponage, such as was formerly thought necessary after a suprapubic prostatectomy, was sufficient to cause a fatal termination to what might otherwise have been successful issues. In order to guard against the bad effects of confinement in bed, the chief of which are hypostatic pulmonary congestion and œdema, the patient should never be allowed to lie long in one position. He should be carefully turned from side to side, and at intervals his shoulders should be elevated. At the earliest feasible time he should be lifted from his bed for short periods, once or perhaps twice daily, and placed, with no exertion to himself, on a reclining-chair. If all these details be carried out, the rule is that there will be developed a satisfactory degree of surgical tolerance. The coexistence of general diseased conditions would, of course, have the same weight in the argument against radical operation, with reference to prostatic hypertrophy, as in other connections. I always make a very grave prognosis, and avoid operating, if possible, in cases of arteriosclerosis wherein polyuria and cardiac hypertrophy have delevoped, and also in cases in which the larger surface arteries have the pipe-stem feel characteristic of advanced atheroma.

The pioneer operations on the prostate were performed through the aid of a perineal incision into the bladder. These operations consisted of little else than cutting through the prostatic floor and then subjecting the case to perineal vesical drainage. They were generally unsatisfactory. If the prostate was large, perineal drainage could not, as a rule, be maintained. If the bladder was atonied and became full of blood clot, then again there was trouble. Besides all this the prostatic obstruction often remained after recovery from the operation. A good result followed some of these operations when the prostatic lesion was really one more of chronic contraction of the muscular fibres encircling the vesical neck than of hypertrophy. The next step of advancement lay in attempting to tear away as much as possible of the hypertrophy, by seizing the same in the grasp of forceps introduced through the perineo-vesical incision and then by twisting it free of its attachments. Some hypertrophies admit of this being done more or less imperfectly. Many of them, however, do not. There is always considerable danger of injuring the vesical neck, and also of severe hemorrhage after such attempts. The final result also, although in most instances beneficial, is not perfect. McGill was the first, through the aid of a suprapubic vesical opening, to attack the prostate, with the object of removing the apparent obstruction to urinary drainage. What he did in most instances was to cut a V-shaped trough, connecting the post-prostatic vesical cul-de-sac with the urethral outlet. In doing this he removed a considerable section of bladder wall as well as some hypertrophied prostate. Belfield, recognizing that the deep wound, as made by McGill, especially when vesical infection pre-existed, required freer drainage than the suprapubic incision offered, advocated the making also of a perineal incision for counter drainage. Numerous strikingly good results followed these radical methods.

The objections to prostatectomy so performed are that the cutting through of a trough as described may not, and often does not, remove the real obstruction to vesical drainage, which may consist of a lateral or superior vesical projection or of a bulging mass packed about the prostatic urethra. Then, again, the cutting away of the section of the bladder inflicts needless damage on that organ, may cause an obstructing cicatrix to result, and, besides, makes the operation very bloody and consequently more dangerous. In fact, the hemorrhage subsequent to such an operation was generally so severe as to demand immediate vesical tamponage, a procedure the objection to which I have already mentioned. After this operation, also, the suprapubic wound was left open, necessitating a longer confinement in bed and thus increasing the opportunity for septic absorption.

In the operation which I have devised and which I practise, I have striven to avoid the objections to the McGill-Belfield procedure. I have also taken advantage of the fact that in most instances prostatic hypertrophies are capable of removal through enucleation rather than through cutting. I first described the technique of my operation in a paper entitled "Six Successful and Successive Cases of Prostatectomy,"[1] which I read at the May, 1895, meeting of the American Association of Genito-Urinary Surgeons, in the following words:

"The patient is placed flat on his back, neither the Trendelenburg position nor the Petersen bag being commonly found necessary. The bladder is carefully washed out, and then left moderately distended, to the extent of from eight to twelve ounces. The next step is to open the bladder suprapubically. The forefinger of the left hand is then introduced into the bladder, the location and extent of the prostatic obstruction are determined, and the vesical opening of the urethra is located. In the right hand is grasped a pair of rough, serrated-edged scissors with a long handle. These scissors are slipped along the left forefinger to the urethral opening, and are made to cut through the bladder wall in that region. The cut extends from the lower margin of the internal vesical opening of the urethra backward for an inch to an inch and one-half. The blades of the scissors, being rough and serrated, make an incision which bleeds but little. Then one of the forefingers, whichever the operator may find the more convenient, is slipped through the vesical hole made by the serrated scissors, while at the same time the fist of the other hand makes firm counter-pressure against the perineum. By means of this counter-pressure the prostatic growth is brought well into the reach of the forefinger of the other hand, which is employed all this time in enucleating the prostatic obstruction, *en masse* or piece by piece, as the case may be. The enucleation can be easily and speedily accomplished in this manner, and should not be desisted from until all the lateral and median hypertrophies, as well as all hypertrophies along the line of the prostatic urethra, have been removed. The vesical walls at the base, as elsewhere, are very elastic and dilatable, so that it will be found that the little cut made through the bottom of the bladder will be large enough to admit of the passage through it of the enucleated prostate.

"A perineal section is then made, and a large-sized (No. 26 American) soft-rubber tube is passed through the perineal cut, and the cut through which the prostate was enucleated, into the bladder. After this, hot-water irrigation is employed for some minutes, to wash out blood clot and to stop oozing. Then the suprapubic wound is closed by a deep layer of catgut sutures, which include the bladder wall, and by a more superficial layer of silkworm gut (Florentine) sutures. About in the middle of the cut the catgut stitch is omitted and a deep Florentine-gut suture is taken, which includes the vesical wall and the whole extent of the lateral abdominal wall. This suture, however, is not tied at the time of operation, thus allowing a rubber suprapubic drainage tube to remain temporarily in position. At the end of four or five days this suprapubic drain may in most instances be removed; then this last Florentine ligature can be tied, thus entirely closing the suprapubic cut. It is best not to remove these Florentine sutures till after the patient is up and about, as without their firm support there is oftentimes a tendency for the soft scar tissue of the wound to give, thus allowing a considerable spreading of the abdominal structures.

"I can say of my method of enucleation that by it the prostatic hypertrophy can be easily and thoroughly removed, without damage to the structures composing the vesical neck, and that hemorrhage resulting from it has always been of little consequence. Owing to the slight amount of bleeding, I have always found it feasible to sew up, as I have described, the suprapubic cut, and have never experienced trouble from secondary hemorrhage. The after-treatment consists largely in careful and thorough vesical irrigation, in conjunction with the internal administration of a large amount of diuretic water, in order to keep the kidney secretion free and active. By the adoption of this method I feel that the customary causes of death after prostatectomy can be in large measure avoided."

As this description of method was written three and one-half years ago, I naturally, as the result of much subsequent experience, have some observations and alterations to make. In the first place, I wish to state that some hypertrophies will be encountered which do not admit of enucleation by the finger in the manner described, owing to the abundance and denseness of the fibrous tissue helping to constitute them. In such instances I have found it necessary to introduce prostatectomy forceps through the hole made in the vesical floor, and, after seizing a piece of the hypertrophy, to twist it free. If sufficient tissue is not removed by the first twisting, the instrument should be reintroduced, and so on, till all obstruction has been taken away. On one or two occasions I have encountered tissue so dense and so adherent to the vesical wall that the forceps and the twisting process have seemed dangerous, owing to the force they would necessitate. In such unusual cases the tissue should be cut away, and for that purpose I would recommend Jessop's prostate scissors.[1] I also favor two suprapubic drainage tubes instead of one, following the example set by Guyon in the after-treatment of cases in which vesical growths have been removed suprapubically. In order to save time, and also because I find them unnecessary, I have discarded the layer of catgut sutures and now employ simply the one layer of silkworm gut to close the wound. One of these sutures after passing through all the abdominal layers includes also the bladder wall at the upper portion of the vesical incision, while another one in like manner includes it at the lower portion of the incision. In this manner the vesical is kept up in close apposition to the abdominal wall, so that there may be no escape of extravasated fluid into the space of Retzius. In doing this operation I very rarely tie a blood-vessel, thereby saving considerable time. In order to be able to perform prostatectomy of this description with neatness and dispatch, a surgeon should have good control of his forefinger and be possessed of some strength of wrist and forearm. I am fortunately sufficiently ambidextrous to be able to change hands in difficult cases, thus obviating the necessity of waiting to rest the tired member.

[1] Journal of Cutaneous and Genito-Urinary Diseases. June, 1895.

[1] See British Medical Journal, December 9, 1893.

There is employed at the present time a method of prostatic enucleation different from the one I have just detailed, wherein the hypertrophy is removed through a spacious perineal incision. Von Dittel was the first to show that hypertrophied prostatic tissue could be so removed. He made a transverse dissection between the rectum and urethra, avoiding both these structures, and thus exposed the prostate. Von Dittel's method is not, however, very practical, since there is need of counterpressure to bring the prostatic enlargement well into reach through the perineal incision. To meet this objection Alexander, of this city, and Nicoll, of Glasgow, both independently and nearly simultaneously advocated opening the bladder suprapubically, so that the forefinger of the operator's left hand could be introduced in order to push the hypertrophied tissues requiring elimination down into reach, thus facilitating their perineal removal. By the intravesical feel also the operator could determine whether or not all obstruction had been removed. Nicoll's plan is not to open the vesical floor but lightly to pack the perineal wound and to drain the bladder suprapubically. Alexander, however, advocates perforating the vesical floor for dependent urinary drainage. A patient after Alexander's operation is thus left with suprapubic and perineal vesical drainage as after the method I employ.

In the August, October, and December, 1895, numbers of the New York *Journal of Cutaneous and Genito-Urinary Diseases* is published the controversy that Mr. Nicoll and myself indulged in regarding our operative procedures, and any one specially interested in the subject can perhaps with advantage study it. I think that Alexander's procedure is better than that of Nicoll, in that it provides more completely for vesical drainage and rest. I consider my own preferable to either of them, since it is quicker of accomplishment and less bloody. Consequently it should be attended by less mortality. A spacious perineal dissection, such as is required for the extraction of prostatic hypertrophy, consumes considerable time, and calls for the ligation of numerous large arteries in positions where the placing securely of ligatures is a matter of some difficulty; whereas my perineal puncture for drainage takes but a minute or two, and, as I have said, in the performance of my operation it is rarely necessary to delay to tie a blood-vessel.

In my opinion these operations, the purpose of which is the entire removal of obstruction and the establishment of a long-continued vesical rest, so that the vesical lesions caused by the obstruction can be repaired, are the only ones to which the term radical can be rightly applied. The result to be expected is likewise lasting. The patient should be expected to empty his bladder completely after the act of urination, and he should have a full and forcible stream. This is owing to the from three to five weeks of complete rest which the bladder receives. Besides accomplishing vesical repair, free vesical drainage effects another potent purpose. It allows the surgeon to rid the urinary tract of the chronic infection which so often complicates these cases. The urinary tract can be so thoroughly flushed out, by making the patient drink for a considerable interval very large amounts of diuretic fluids, that germ colonizations are swept away and so eliminated. This cannot be done in obstinate cases without free vesical drainage, owing to the complications which may arise, due to the rapid accumulation of fluid in a bladder robbed of its function.

In looking over my notes I find the records of twenty-seven personal cases of prostatectomy, most of which were subjected to my method. These cases I have divided into two classes: (1) Those in which all the larger surface arteries were felt to be markedly atheromatous; and (2) those in which such changes were absent or not prominently evident. Five of my cases come under the first heading and twenty-two under the second. Out of the five patients of the first class three died after operation. One of them, who was apparently progressing favorably, experienced a severe seizure of cerebral apoplexy on the third day. In another, the post-mortem showed extensive post-operative hemorrhage into the space of Retzius and underneath the peritoneum, occasioned by the calcareous condition of the blood-vessels. The other died suddenly on the fifth day, perhaps of thrombosis. Out of the twenty-two cases of the other class two died—one of suppression and shock and the other of peritoneal symptoms, but of just what nature, in the absence of autopsy, I could not determine. Many of these latter cases were very bad apparent risks. Some of them were operated upon in emergency, it being impossible to relieve the bladder except by aspiration. Most of them were suffering also from the effects of vesical infection, and in a good percentage of these cases the infection had ascended to the renal pelvis. One patient, sixty-seven years old, had a temperature from infection of 104° F. at the time of operation. Another infected patient who recovered and has since married, was a gentleman, seventy years of age, from the vesical mouths of whose ureters, both right and left, I also removed large encysted calculi, which had aided the prostatic obstruction in damaging the upper urinary tract. One patient was in such a bad physical condition when brought in for operation as to cause a confrère to ask, "What is the use of operating on a corpse?" This man left the hospital at the end of five weeks, having gained during his stay ten pounds. His bladder, although one that was sacculated, has recovered its tone completely. Two cases, both earlier ones, passed from my view with suprapubic fistulæ. They were careless individuals from the lower social strata. I do not feel that such an after-lesion need be reckoned upon as at all likely or necessary, provided a patient co-operates with the surgeon. A post-operative inconvenience sometimes complained of and which is usually of temporary duration, is the loss of a drachm or so of urine when there is some vesical pressure as a result of bodily activity. In one instance vesical incontinence persisted after operation, due, I am inclined to think, to chronic sclerous perivesical inflammation. As a result of my experience I would avoid operating on individuals of the first class except for the relief of suffering, since the chance is against their recovery. The value of the operation, with reference to the other class, speaks for itself.

Castration and Bottini's operation I will refer to briefly. I do not condemn either of them. Their simplicity brings them within the professional reach of all. I do not feel, however, that the term radical can justly be applied to them. They do not provide the element of vesical rest so necessary for the repair of a badly damaged bladder. Neither are they applicable in cases of emergency, when the catheter is no longer of service and when delay in the establishment of free vesical drainage means death. I should also consider a resort to either of them very injudicious in cases complicated by calculus or by an ascending infection which has involved one or both renal pelves. The death rate following castration in old men is as large as, if not larger than, that after skilfully performed prostatectomy. The result on the prostate itself, leaving the bladder lesions out of account, is many times negative, generally imperfect, and rarely wholly satisfactory—that is, the patient being so left that he can completely empty his bladder. Although the loss to old men of their testicles is naturally held by most persons, aside from the patients themselves, to be of little or no account, still I cannot refrain from pitying within myself the old men; and as I have never yet

brought myself to the point of arguing strongly with them against their natural wishes not to part with their organs, I have consequently had comparatively little personal experience with castration in this connection.

The Bottini operation, after having lapsed into desuetude without attracting general attention, has recently been brought afresh to notice by Freudenberg, who has considerably modified the original procedure. I have had the pleasure of seeing Freudenberg operate on one occasion and have noted the quite decided improvement which shortly followed. Numerous instances of this operation are now coming to hand. Whether the results in such of them as have been immediately favorable are to be lasting it is impossible to state, since sufficient time has not as yet elapsed. The operation, as has been noted, is applicable, in my opinion, only to the less serious instances of prostatic obstruction wherein the bladder has not as yet suffered grave damage and which are also free from complications relating to the catheter or to the upper urinary tract. Very few, indeed, of the results reported from the modified operation have been radical, in that although an improvement in the urinary function has followed, still residual urine to a greater or less degree has persisted. This, to my mind, makes it probable that a goodly percentage of what at the present time seem fairly satisfactory cases may not continue so. The objections, in my opinion, to the operation are that it inflicts more damage on the neck of the bladder than on the prostate. The deep furrows which it burns through the vesical tissues will, of course, leave dense contracting cicatrices, which will, I fear, eventually cause a marked stenosis at the vesical neck —a very disagreeable state of affairs for the patient as well as for the surgeon. A stenosed vesical neck would of course interfere sadly with the vesical function. If Bottini's operation is unsuccessful, or if a relapse follows, a subsequent prostatectomy will, I expect, be a very difficult and grave matter, owing to the dense cicatrices which will bind down the hypertrophy, and which will so amalgamate the prostate to the adjacent walls of the bladder that serious lacerations of the vesical neck would attend the removal of the obstructing prostatic tissue.

Although it is evident that the burning of three deep furrows—one dependent and two lateral—such as Freudenberg practises, will immediately do away with much of the obstruction to urine drainage in many of these cases, still there are numerous grotesque forms of prostatic obstruction which would not be obliterated by such means. In cases also in which the obstruction is of great bulk—when, for instance, had a radical prostatectomy been performed over half a pound in weight of tissue, or thereabouts, would have been removed—this method of operation would naturally fail. Genito-urinary surgeons whose experience extends over the last ten years have on two occasions been treated to grave disappointment, with respect to the curative value of electricity as applied to the treatment of stricture. On both occasions the most extravagant claims were advanced in its behalf, but these claims did not materialize. Electrolysis, as far as it relates to stricture, has at the present time the sanction of little or no authority. I hope the Bottini operation will fare better than have the kindred methods just mentioned.

In conclusion, I would recommend that the radical treatment for prostatic obstruction be not delayed till the patient is forced to it as a last resort. It is a question which can often be well raised when the vesical function begins to falter and when dependence on the catheter is imminent. It is the question which should always be brought prominently forward when the passage of the catheter ceases to be followed by a fair interval of vesical comfort, and when through vesical lavage urinary decomposition cannot be kept in abeyance. It is the only question to be considered in an emergency when the catheter can no longer be employed.

In my experience there is no class of results the contemplation of which gives me greater pleasure than those following prostatectomy.

THE TECHNICS OF THE OPERATIVE TREATMENT OF INTESTINAL OBSTRUCTION.[1]

By FREDERICK HOLME WIGGIN, M.D.,

VISITING GYNÆCOLOGIST TO THE ST. ELIZABETH'S AND NEW YORK CITY HOSPITALS, AND ADJUNCT VISITING SURGEON TO BELLEVUE HOSPITAL, ETC.

The various conditions for which operations are usually undertaken for the relief of intestinal obstruction may be enumerated as follows: (1) Strangulation of the gut by bands, extensive adhesions, or apertures; (2) volvulus; (3) compression by tumors external to the gut; (4) obstruction due to foreign bodies, such as gall stones and enteroliths; and (5) fæcal masses.

When the patient is suffering from the acute form of obstruction, little time should be lost in making preparations for his relief, once the diagnosis has been established and he has consented to operation; for it is a fact that a very large proportion of all who succumb to operations for intestinal obstruction do so because of the delay which has occurred between the onset of the condition and the time of operation. Hospital patients, who are more under the guidance of the physician, are operated upon more promptly than private patients, and consequently have a far better chance for recovery than the latter. As haste is a prime requisite when our patient is suffering from an acute form of intestinal obstruction, little can be done in the way of preparing the room selected for the operation. A room, preferably with a north light, should be selected; and, if time permits, the carpets, furniture, and hangings should be removed, the room thoroughly cleaned, and the woodwork and floor, after being scrubbed, should be well washed over with mercuric chloride solution, 1 to 500. But, as a rule, in the acuter forms of obstruction there is no time for this careful preparation of the room. When this is the case, all that should be done is to remove all the loose pieces of furniture, care being taken to avoid raising any dust; and sheets wet in either carbolic-acid solution, 1 to 20, or mercuric-chloride solution, 1 to 500, should be placed over the carpet. A kitchen table and one or two smaller tables which have been well scrubbed and washed with a carbolic or mercuric chloride solution are placed in the room, together with several basins and pitchers, which have been thoroughly cleaned and sterilized. While this is in doing, a washboiler should be thoroughly cleaned and filled with water, which should then be sterilized by boiling for an hour. Some of this water should be rapidly cooled by placing it in pitchers and surrounding them with ice water. In extremely urgent cases the hot water may be taken from the ordinary faucet, but this should be avoided when possible. If the case is urgent and the patient is suffering much pain, it is well to defer the preparation of the abdomen until the administration of the anæsthetic. If there has been much vomiting or great abdominal distention, it is wise to follow Kussmaul's method by introducing a tube into the patient's stomach and washing it out. This is easily accomplished if the tube is carried along the roof of the mouth, and as it passes down the œsophagus the patient is instructed to swallow. The stomach is washed out with a quantity of saline or boric-acid

[1] Read before the New York State Medical Association, October 19, 1898.

solution by the siphon method. In this way large quantities of gas will be removed, and also considerable irritating matter.

In cases in which the patient has been vomiting persistently, and is feeble in spite of resort to the ordinary cardiac stimulants, it is well to introduce from one to three pints of saline solution into the circulation, through the veins, prior to beginning the abdominal operation.

The instruments should have been already prepared by boiling for ten minutes in a two-per-cent. solution of carbonate of sodium, and should then be placed in trays containing sterilized water. The towels for use in the operation should be sterilized, either by the use of a sterilizer or by boiling. A large quantity of saline solution (one teaspoonful to the quart) should be on hand.

These preparations having been attended to and the patient anæsthetized, the skin is made ready for the incision by being thoroughly scrubbed with tincture of green soap, special attention being paid to the umbilical region. A solution of peroxide of hydrogen is next applied, after which a lather is made and the skin shaved. The soap is next washed off with water, and

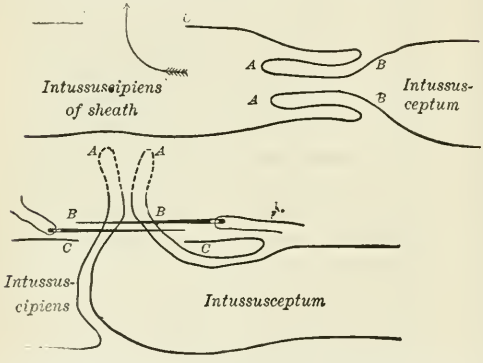

FIG. 1.—Diagram of Longitudinal Section of Intestine, showing an acute irreducible intussusception, and the method of its treatment. *C C*, Longitudinal opening made in the superior border of the intussuscipiens; *A A*, apex of intussusceptum; *B B*, neck of the intussusceptum.

this is followed by an application of equal parts of alcohol and ether to remove the remaining fatty substances. This is, in turn, followed by an alcoholic solution of mercuric chloride, 1 to 500. A final washing is given with sterile water or saline solution. Before the incision is made, the bladder should be emptied by catheter.

When the site of the obstruction cannot be definitely located, the incision should be made a little to the right of the median line, between the umbilicus and pubes, and should be about four inches in length. It should be made through the rectus muscle, because there is less danger of subsequent hernia than when it passes through the linea alba. Such an incision is desirable, as it gives ready access to the cæcum, which should be the first part sought after, and also gives the operator a good command of the small intestine, a large portion of which is usually found in the pelvis. It is also possible through such an incision to make a satisfactory exploration of the colon, and it can be readily extended upward if this should become necessary. It is better to have the incision a little too long than too short, as the longer incision facilitates the manipulations.

When the abdominal cavity has been opened, if greatly distended coils of intestine obstruct the view, the distention should be relieved by aspiration or incision. The incision so made should then be closed by suture, and the spots disinfected by the application of a few drops of hydrogen dioxide. As has been previously stated, the hand should be introduced into the abdominal cavity and an effort made to locate the cæcum. If the latter is found to be much distended, it is good evidence that the obstruction is located in the colon; but if, on the other hand, it is empty or only moderately filled, then it is most probable that the stoppage is in the small gut. If there is reason to believe that the obstruction is in the colon, the hand should be passed over the entire length of this intestine until the obstruction is found. It is presumed that the rectum has been explored prior to operation. When the small bowel is involved, it is well, if possible, to seek the collapsed portion and follow it down to the obstruction. The operator should begin by looking for the non-distended coils in the region of the cæcum or about the brim of the pelvis, as advised by Mr. Hulke. The various hernial orifices should also be examined. Sometimes two forms of obstruction coexist, and it should be borne in mind that one of them is often overlooked.

If the obstruction proves to have been due to bands, the latter should be ligated on both sides near their attachment, which is usually the mesentery, and removed. When the gut is found to be gangrenous, it must be resected in the manner to be hereinafter described. If the obstruction is due to a diverticulum or to an adherent appendix, these portions of the bowel should be removed in the ordinary manner, and the opening in the gut closed with Lembert sutures. While volvulus usually occurs in the sigmoid flexure, it may occur in the small intestine, and in the latter case it is usually necessary to draw the intestine out of the abdominal cavity. It is the writer's experience that, contrary to the usual authorities, this does no harm, provided the exposed bowel is properly protected with gauze or soft towels wrung out of hot saline solution. The following case illustrates well this point:

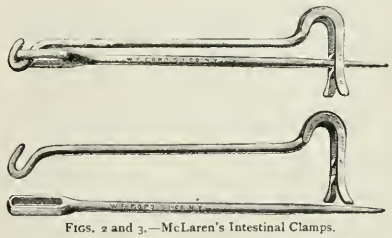
J. K——, forty-five years of age, married, and a native of Ireland, was admitted to Ward 11, Bellevue Hospital, on October 1, 1898. For about a year previously he had suffered more or less from colicky pains in the abdomen, but they had yielded readily to household remedies. Eight days prior to admission, while working in the fields, he was taken suddenly with a chill and a feeling of dizziness. He had been troubled for several days prior to this with obstinate constipation. He went home and summoned a physician, who blistered his abdomen, and tried, but without success, to move the bowels by cathartics and enemata. All this time the man was suffering from nausea and vomiting and complete loss of appetite, and there was pain which he referred to the right side and umbilical region. His physician, being unable to give him relief, advised him to go to the hospital for treatment. On admission, temperature, 99.8° F.; pulse, 108; respirations, 22. Physical examination showed the patient's face to be pale and drawn; the abdomen was considerably distended, and the right rectus muscle seemed rigid. The whole abdomen was tender to the touch, but especially so over the umbilical region. The lower part of the abdomen was blistered and raw. There was no dulness on percussion, and no tumor discoverable on palpation. An enema consisting of two quarts of saline solution was administered, with a fair result. At this time the patient was supposed to be suffering from a catarrhal appendicitis. Temperature, 100° F.; pulse, 60; respirations, 20. On October 3d it was noted that he was suffering from much pain, and an ice bag was applied to the inguinal region. Temperature then, 100.2° F.; pulse, 94; respirations, 20. On October 4th his condition was about the same,

and calomel was administered, without result. It was recorded on October 6th that the patient felt much more comfortable in the morning, but by 6:30 P.M. the colicky pains recurred, and these were followed by an intense, steady pain, referred to a point just above the umbilicus. A saline enema was administered by the house surgeon, with fair result, but it did not relieve the pain; so he then administered morphine hypodermically. Notwithstanding this treatment, the pain continued to increase in severity, and, the general condition of the patient becoming worse, he was stimulated with strychnine and nitroglycerin. About 11 P.M. the patient was seen by the writer and by Dr. Joseph B. Bissell. It was decided that he was suffering from acute intestinal obstruction, and that an operation was immediately demanded. Ether was administered at once, and the field of operation was prepared as already described. An incision was made, about three inches in length, through the right rectus muscle. The cæcum was located, and the appendix was found to be normal. A systematic examination of both large and small intestine was next made, and, as no bands could be felt, the collapsed bowel, which began at the cæcum, was withdrawn. On following it up to the upper portion of the ileum, a point was found where the gut was twisted upon itself and apparently constricted. Above this point the intestine was distended. Several small bands were found passing over the intestine, and these were broken up. During the examination the portion of intestine withdrawn was kept warm and moist by being wrapped up in towels wet with warm sterilized saline solution. Before being returned to the cavity the intestine was washed off with hot sterilized saline solution, and then, the patient having been turned slightly on one side, the bowel was returned to the abdominal cavity, partially by the aid of gravity. The general peritoneal cavity was next irrigated with hot sterilized saline solution, at a temperature of 110° F., and a quantity of it was allowed to remain. The abdominal wound was closed by layers, as the muscular tissue was very deficient. The wound was sealed with ten-per-cent. iodoform collodion and cotton, without drainage. The patient rested well during the night, and exhibited no shock. On the following day it was recorded that, with the exception of slight abdominal pain, he felt well. The bowels moved spontaneously on that day. His further convalescence was uneventful, and the wound healed by primary union.

In those cases in which the obstruction is found at the time of operation to be an intussusception, the best method for reducing the invaginated portion of the bowel seems to be that wherein the tumor is encircled below its apex by the finger and thumb, while the intussuscipiens or sheath is held a few inches lower down, the apex of the tumor being pushed in an upward direction. Traction from above the tumor should not be employed. If, however, the tumor prove to be irreducible, it is the writer's belief that the method described by the late Prof. H. Widenham Maunsell (see Fig. 1) is the best yet devised for treating this most unfortunate complication caused by delay. A slit is made in the intussuscipiens, and gentle traction is exerted on the intussusceptum until its neck appears outside the opening in the intussuscipiens. The base is then transfixed with two straight needles armed with horsehair, and the intussusceptum is amputated one-fourth of an inch above the needles, leaving a fair stump beyond them. The sutures are now passed through the invaginated bowel, caught up in the interior of the bowel, divided, and tied. This having been accomplished, the invagination is reduced and the longitudinal slit is closed.

When the obstruction is due to a neoplasm, the latter should generally be removed. Intestinal surgery has improved so much of late years that these growths can usually be excised, and when this can be done it is better to do so by the method to be described than to perform colotomy. When, however, it is deemed inadvisable to resect the portion of bowel containing the growth, the colon should be opened by the operation described by Nydls. An incision, four inches long, is made over the portion of colon to be opened, and in the direction of the fibres of the external oblique muscle. When the peritoneal cavity is opened, the bowel is drawn upward until its mesenteric attachment is on a level with the external incision. A slit is then made in the mesentery, and a glass rod is passed through and iodoform gauze wound around the ends of the rod. The rod is left in position until adhesions have formed; then the gut is opened. If the fistula is to be a permanent one, the divided edge of the upper portion of intestine is attached to the borders of the skin, and the edges of the lower end are inverted and closed by suture, after which the segment of gut may be returned to the peritoneal cavity. If, on the other hand, the fistula is to be a temporary one, an opening is simply made in the bowel.

When the intestinal obstruction is due to a neoplasm external to the gut, the new growth should be



Figs. 2 and 3.—McLaren's Intestinal Clamps.

removed, if possible; when it is not possible, a fæcal fistula must be established above the point of obstruction. Fortunately, at the present time there are few intra-abdominal neoplasms that cannot be successfully removed, provided the patient is not moribund when the operation is begun.

When the obstruction is due to gall stones or enteroliths, these bodies should be pushed above or below the point where they are found, and then removed through an incision, rather than an opening made at the point where they have been lodged, as at the latter place the gut is likely to be damaged and is not so likely to heal promptly. The opening left in the gut after their removal is to be closed with Lembert sutures. If, however, the foreign body cannot be easily dislodged, the portion of gut containing it should be excised and an end-to-end anastomosis effected in the manner hereinafter to be described.

When the obstruction is dependent upon fæcal masses, these should be removed. This can best be done by the employment of small doses of calomel and soda, accompanied with the use of saline enemas. The enema is best given with the patient lying on the left side, a fountain syringe being used for the purpose, but its reservoir should not be elevated more than three feet above the patient's body. A bulb syringe should not be used for this purpose, for, in the first place, it injects the fluid irregularly and with too much force, and consequently only a small quantity can be employed; and, in the second place, it is apt, with careless use, to admit air to the bowel. The fluid for the enema should have a temperature of 100° F., and should be introduced into the canal slowly, being frequently intermitted as the patient complains of a feeling of distention or of intestinal colic. It should be continued if both of these sensations cease. The patient should be encouraged to retain the fluid as

long as possible, as the object of the enema is to allow the absorption of the water and the softening of the mass, rather than the stimulation of peristalsis. The first effort frequently fails to bring away more than a little fæcal matter, but the latter has commonly a foul odor in cases in which the fæcal accumulation has lasted for some time. After several hours have

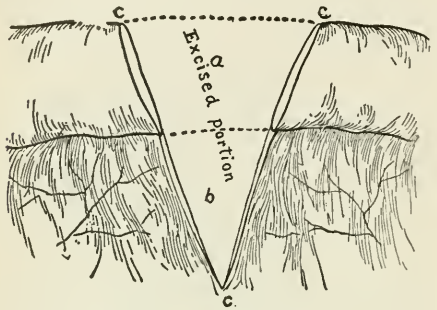


Fig. 4.—*a b*, Portion of intestine and mesentery to be removed; *b b*, mesentery; *c c c*, lines of the incision.

elapsed, it is well to repeat this procedure, as the non-irritating character of the fluid usually causes little discomfort.

In a case in which the writer was called with a view to operating for intestinal obstruction, the statement was made that ordinary cathartics and enemas had failed to produce any result. The patient was vomiting, and had been unable to retain nourishment for some days. On examination of the abdomen, no special point of tenderness could be found, but there was dulness over the entire length of the colon. Permission was given to the writer to supervise the administration of a saline enema. This was given in the manner just described. Two quarts were administered, and were retained for about three-quarters of an hour. When this finally escaped, a few small particles of fæcal matter came away with it, and these had a very foul odor, indicating long retention in the gut. A few hours afterward a similar enema was given, and this was repeated on the following morning, small doses of calomel having been administered meanwhile. The third enema was followed by a copious movement, and the patient then made an uneventful recovery.

When the gut is gangrenous or in a doubtful condition, it is wise, as already stated, to remove it. An end-to-end anastomosis should be effected with the Murphy button, or, preferably, by some form of suture, such as the method suggested by the late Prof. H. Widenham Maunsell, or the writer's modification of it. The original method of Maunsell was fully described by the writer, in a paper entitled "The Technique of Maunsell's Method of Intestinal Anastomosis," which was read before this association on October 17, 1895, and published in the *New York Medical Journal* for December 14, 1895. In the writer's simplification of the operation, which consists in eliminating the invagination and the slit, the steps are as follows: The portion of intestine to be excised having been located, it is brought outside the cavity, accompanied by about six inches of healthy intestine on either side. It is next emptied of its contents above and below the diseased spot, by passing it between the finger and thumb and gently pressing it. The empty gut should be clamped on either side of the diseased portion of bowel at a point six inches distant, to prevent the escape of fæcal matter at the time of excision or during the subsequent manipulation. A useful instrument for this purpose is the McLaren clamp (see Figs. 2 and 3). The general peritoneal cavity should be protected with flat sterilized sponges wrung out of hot saline solution. The portion of intestine to be removed is excised by means of a V-shaped incision, having its apex in the mesentery and its lateral borders on either side of the diseased area (see Fig. 4). The mesenteric vessels are ligated before being cut, by passing a needle armed with catgut around them and tying them. The wound in the mesentery is closed by means of a continuous or an interrupted suture (see Fig. 5). After the divided ends of the intestine have been carefully washed with hot saline solution, followed by a small quantity of a fifteen-volume solution of hydrogen dioxide, the proximal and the distal ends are united by means of two sutures which are passed through all the intestinal coats. The first suture is placed at the inferior or mesenteric border, and is passed in such a manner as to include a portion of mesentery on both sides (as shown in Fig. 6). It is then tied in the bowel and the ends are cut short. The second is placed directly opposite, at the highest point of the superior border, and temporarily secured with a clamp. On either side, and half way between the upper and lower, the third and fourth sutures are passed in a similar way, and clamped. The other sutures are passed in the same way, the needle going from within the gut and piercing all the coats, then back through the peritoneal, muscular, and mucous coats to the interior of the other segment of bowel. The ends are then tied in the bowel. This process is continued with all the sutures, with the exception of the last one or two. Here the Lembert suture is substituted. If the sutures have been properly introduced, about one-fourth of an inch from the edge, and tied sufficiently tight, it will be found that the peritoneum is turned in and the stitches are no longer visible (see Fig. 7). If some of them have been so loosely tied that the sutures are visible in the peritoneal coat, it is best to insert a few Lembert sutures at these points. Before closing the last one or two sutures, it is well to introduce into the gut one or two ounces of a saturated solution of the sulphate of magnesium, to insure the early action of the bowels. The sutured portion of bowel should now be washed with a small quantity of a fifteen-volume solution of hydrogen dioxide, then washed with saline solution, and returned into the abdominal cavity, which should also be washed with saline solution before the abdominal wound is closed.

Usually one row of silkworm-gut sutures is passed through all the coats, from the skin to the peritoneum. These deep sutures should be inserted about one inch apart, and should be loosely tied, to allow for swelling, which ordinarily takes place as soon as the patient rallies from the operation. The edges of the skin are approximated, either by a continuous catgut suture or

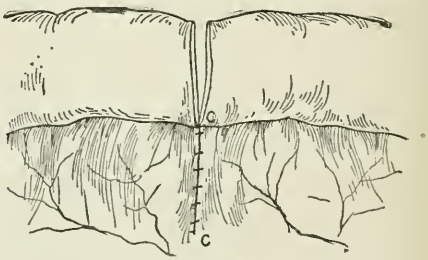

Fig. 5.—*c c*, Incision in mesentery united by continuous suture.

by a subcutaneous suture. After the wound is closed, it is well to use the hydrogen dioxide and follow it with ether or alcohol, for the purpose of drying the skin. The wound is then sealed with a ten-per-cent. solution of iodoform in ether, and a little cotton, after which the usual gauze dressings are applied.

For some time past it has been the writer's opinion

that the chief point of value in the Maunsell method lies in its demonstration of the fact that sutures can be passed through all the coats of the bowel with impunity, and that the invagination and the slit are unnecessary. The following case is illustrative of this point:

L. M——, eighteen years of age, was admitted to Ward 12, Bellevue Hospital, as the writer's private patient, August 2, 1898. She was suffering from bi-

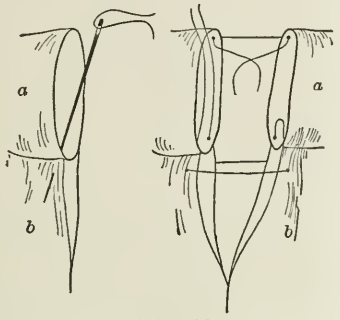

FIG. 6.—*a a*, Segments of bowel; *b-b*, segments of mesentery.

lateral pyosalpinx. On August 4th, after the usual preparations, the abdominal cavity was opened by means of an incision, two and one-half inches long, in the left rectus muscle. The intestine was found to be adherent about the fundus of the uterus and the tubes. These adhesions were separated, and the tubes exposed. As both tubes and ovaries were diseased, the uterus was removed, being amputated just above the internal os. After this had been done, the appendix was examined and found to be inflamed and injured; so it was removed. Further examination of the bowel showed that the peritoneal coat covering a large proportion of the circumference of two and one-half inches of the ileum had been torn in separating the adhesions. An attempt was made to close the peritoneum by means of Lembert sutures, but it was found dangerously to narrow the calibre of the gut. It was therefore thought best to resect the injured portion of bowel. This was done, and the sutures were inserted in the manner already described. Two ounces of a saturated solution of sulphate of magnesium was thrown into the bowel just before final closure. A small rent in the peritoneal coat some distance above the resected portion was closed with a Lembert suture. After the bowel was washed with hydrogen dioxide and saline solution, it was dropped back and the abdominal wound closed as previously described. The operation was a long one, yet only nine ounces of ether was employed. Before the patient regained consciousness, a tube was passed into the stomach and the latter washed out, and one pint of decinormal saline solution left there. She reacted well, and was completely conscious in two hours. On August 5th the patient felt well, and the bowels moved three times. She had not vomited since the operation, and took eight ounces of peptonized milk every four hours. On the morning of August 6th the temperature was 99.8° F., pulse 104; in the evening, temperature 100.8° F., pulse, 104. On the following day the temperature was 98.8° F. and pulse 76 to 96. At this time it was reported that there were no gastric or intestinal symptoms. On August 8th, the fourth day after operation, her temperature and pulse became normal, and her further convalescence was uneventful. The ordinary light solid diet was allowed on the eighth day, and the wound was found to have healed by primary union. The bowels were moving regularly.

The operation having been completed and the dressings applied, the patient should be returned to bed and placed directly within the folds of a blanket and surrounded, if necessary, with hot-water bags or bottles. Care should be taken that they be not overheated, and so blister the still unconscious patient. When a quantity of saline solution has been allowed to remain in the abdominal cavity, the patient generally leaves the operating-table in good condition, and with a warm, moist skin. When the pulse is weak and rapid, it is well to raise the foot of the bed; and when consciousness has been fully regained, to administer one-eighth grain of morphine and one one-hundredth grain of atropine subcutaneously, to quiet the patient. After this one dose, the use of morphine should be discontinued, as it deranges the digestive system and obscures the various symptoms. It is not necessary that the dorsal position should be maintained for several days, as is usually taught, as the nurse can turn him safely from time to time. During the first twelve or eighteen hours following the performance of the operation, nothing should be allowed by the mouth except a little warm water from time to time. If the demand for fluid is urgent, it can be usually successfully combated by two or three large doses of subnitrate of bismuth. During these early hours of convalescence nourishment and stimulants, if needed, should be administered by means of enemas. With the passing of these first twelve or eighteen hours, if there is no nausea or vomiting, and the pulse is about the same as before the operation, a drachm of liquid peptonoids or some other similar preparation may be given, and repeated, if well borne, every twenty minutes until four doses have been taken, when, after an interval of two hours, a small quantity of equal parts of milk and lime water, or of peptonized milk, may be given from time to time until four ounces have been taken. After this there should be an interval of two hours, and then half an ounce of liquid peptonoids may be administered. After another interval of two hours, four ounces of peptonized milk may be given. The quantity of milk should be gradually increased and the interval lengthened until the patient takes eight ounces, or its equivalent in soup, every three hours; but once during the night the interval should be lengthened to six. The general tendency is to give too small quantities of nourishment at too frequent intervals, which fatigues the stomach and is apt to cause irritability of this organ and engender a disgust for food. During the interval, if the patient desires more liquid, egg albumen and water (the whites of

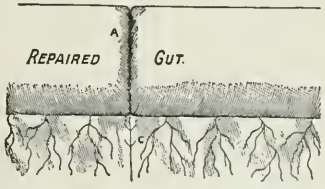

FIG. 7.—This figure shows the intestine after the completion of the anastomosis. *A*, line marking the point of union between the ends of the bowel, showing that the peritoneal coat is well turned in, and that the sutures and knots are all inside the gut.

three eggs to a pint of water, to which a little salt has been added) may be allowed freely.

During the first forty-eight hours after operation, if the patient is disturbed by reason of intestinal gas, great relief is often afforded by the introduction through the sphincter of a short rectal tube. On the third or fourth day, one-tenth grain of calomel and one grain of soda may be given every half hour for five hours, or until the bowels act. If they do not act, however, within three hours after all the calomel has been taken, a Seidlitz powder should be administered, and repeated after another interval of three hours. After the bow-

els have acted, the pulse rate should be normal, in which case the patient may be rapidly allowed to resume ordinary diet.

The dressings should be removed on the fifth day, and if the sutures are beginning to cut the tissues they should be removed and the wound supported with strips of adhesive plaster; otherwise they should be allowed to remain a few days longer. Before the sutures are removed, the wound and its surroundings should be thoroughly cleansed. The suture is then picked up on one side by means of a pair of forceps, and the skin at the angle is depressed by the flat surface of a pair of scissors, the blades of which straddle the strand of gut, which is then cut through. The object of this manœuvre is to cut the portion of suture which has been buried in the tissue, and which is therefore clean, so that in dragging the silkworm gut through the tissues and the peritoneal cavity danger of infection will be reduced to a minimum. The patient should remain in bed about eighteen days, and may then be allowed to sit up, and soon thereafter to walk about and resume his ordinary occupation.

In closing, the writer wishes again to call attention to the fact that the prognosis in operations for the conditions which have been considered in this paper depends more largely upon whether or not the operation is performed early or late in the disease than upon any other factor.

55 West Thirty-Sixth Street.

FIVE WEEKS' EXPERIENCE AT BAD NAUHEIM.[1]

By GEORGE L. PEABODY, M D.,

NEW YORK.

So voluminous has the literature of Nauheim become, especially in England and this country, during the past few years, that I have hesitated to add to it; but it has seemed to me that perhaps a brief account of a personal experience there might be interesting to the society, and I have therefore determined to ask your attention to the subject for a few minutes. I make no pretence of having prepared an exhaustive or elaborate paper; but when I tell you that the most exhaustive and elaborate criticism of Nauheim has been written by men who simply devoted a few hours to the place—stopped over a train, or a night—you will perhaps be surprised that as a result of five weeks' residence there I can do no more. I submit that a time has come in Nauheim's history when it should be taken seriously or not at all.

The place is accessible from all parts of Europe, being less than twenty miles north of Frankfort, on the main line between Frankfort and Hamburg. For Americans who wish to go directly there, the route via Hamburg will probably be more convenient than that via Bremen, for this latter reason.

It has seemed to me that Nauheim has suffered in two ways in its literature: at the hands of its advocates, who claim too much for it, and at the hands of its critics, who often without sufficient investigation indulge in *a-priori* condemnation of it. It was in order to ascertain for myself if possible what its merits really are that I undertook last spring to spend some weeks in its investigation. Accordingly I went there about the middle of May, and remained until after the middle of June.

Professors Heineman and Schott extended to me every facility for my investigations, and were most kind, not only in affording me access to all the many baths and other public places which interested me, but also in placing at my disposal a large clinical material, consisting of their private patients. It was a source of much surprise to me to learn how willingly these ladies and gentlemen lent themselves to my uses when they knew that I was in search of information which they could convey, either by their histories or by allowing physical examination.

The heart cases which seem to be especially benefited by Nauheim are of several kinds. They include those in which with valvular lesion compensation is slow in being established; those in which compensation, having existed, has failed, with the result of the production of all the symptoms of failure of the muscular power of the heart; those in which with or without physical signs angina pectoris has developed as a symptom, and again many forms of cardiac neurosis (other than angina), which may be due to such a great variety of causes.

Much has been said and written about the immediate effect of the Nauheim treatment upon a dilated heart; much acrimonious discussion is possible as to the accuracy of physical examination in determining slight changes in a heart's size and position. All of this appears to me so unnecessary that I was somewhat surprised to see that most of the many doctors who go to Nauheim as I did seem to think it of chief importance to examine a large number of patients before and after the baths and exercises, in order to see for themselves what changes take place in the heart, if any, as the immediate effect of therapeutic procedures. These are points of interest without doubt; but it was to others that I chiefly addressed myself. Before leaving this part of the subject, I may say that I convinced myself that the apex beat does change in position after the baths and exercises, and that the pulse often becomes slower, fuller, softer, and more regular in patients in whom deviation from the normal existed in these respects.

I am permitted by Professor Schott to refer to photographic work of his with the *x*-rays, which he intended to publish this fall as being convincing ocular demonstration of changes in size and shape and position of dilated hearts, as an immediate effect of baths and also of exercises. Professor Heineman, too, has accumulated much material of this kind, which shows the same thing, and he, too, was most helpful to me in assisting me to look up this part of the subject, as he was in regard to every other detail of Nauheim life, therapeutic and otherwise.

This change in size, when it is observable, seems to be chiefly a reduction in size of dilated right-heart chambers. I am not inclined to insist upon this as peculiar to Nauheim methods or as necessarily characteristic of them, or even as of much importance. Careful observations, according to Sansom, have shown that the bulk of the heart may greatly change under varying conditions within very short periods of time. Broadbent admits a diminution of the volume of the heart under the influence of these baths and exercises, but adds that such changes in size of the heart are common under other methods of treatment and from various causes.

As I have said, other matters were to me of greater interest than these: to me it is of small moment what may take place in the dimensions of a heart temporarily as the immediate effect of a therapeutic procedure, if the patient does not improve as a remote consequence of it all. And, conversely, if the patient does get steadily and permanently better under any therapeutic procedure, it matters but very little what the intermediate, transitional steps in the process of improvement may be. They certainly are not worth quarrelling about.

What interested me more at Nauheim, after a careful study of all the methods of treatment in vogue and

[1] Read at a meeting of the Practitioners' Society, October 14, 1898.

a prolonged trial of the effects of these methods upon myself, was to talk with Nauheim patients, chiefly patients from England, and ascertain exactly what their histories had been, how they had suffered and how long, what their ante-Nauheim condition had been, how they had borne the somewhat fatiguing treatment, and what changes in their symptoms had been obvious to them in what I may call their post-Nauheim condition. I was enabled by the kindness of these gentlemen whom I have named to pursue this as well as other branches of the subject to the fullest possible extent, and I came away quite satisfied that it is certainly very common for all the classes of heart invalids which I have named to be materially relieved by the treatment applied. Especially was I impressed with cases of angina, and the great and lasting relief that they derive there. If these cases were few, one would have to think of the possibility of coincidence as explaining them; but they are far too numerous to eliminate the relation of cause and effect. It is not claimed that one single course of treatment, extending over five or six weeks, is sufficient to bring a permanent relief of symptoms—although this occasionally happens; but many of these heart invalids, whose symptoms under usual circumstances are so difficult to cope with, are enabled to lead active lives of usefulness and happiness by an annual resort to Nauheim for four or five weeks. This is much. It is certainly more than our usual therapeutic means can accomplish. There must, of course, be a shadow side to the picture—there must, of course, be failures in these grave cases at Nauheim; and it is only fair to say that such an investigation as mine is not likely to disclose them.

Subacute rheumatism is greatly benefited here, as it is at warm springs in general; and one sees many sufferers from cerebral and spinal paralyses, as to whose improvement there seems to be much less available evidence than there is in the heart cases. Pelvic and abdominal exudations of plastic character, after they are fully organized, seem to yield to the Nauheim methods; but whether there is anything specific in the Nauheim treatment of these maladies, whether they would not be as well influenced by warm baths and massage elsewhere, may perhaps be open to question.

So many descriptions of Nauheim routine have been published that I have concluded not to ask you to listen to my account of it. I shall merely summarize it by saying that treatment is in part dietetic; that the physical part of it consists chiefly of massage, baths in the local water, as well as in this water from which the natural carbonic acid has been allowed to escape, very gentle exercises against resistance which is applied by a trained attendant, together with a period of rest of at least one hour's duration after each bath and each exercise. One is allowed to walk and drive, but not to incur fatigue or excitement, and is urged to live well, but not to eat heartily at any one meal. Coffee is replaced by tea, strong alcoholics are forbidden, and tobacco is kept within narrow limits.

As to exact details of treatment, there seems to be no consensus of opinion among the Nauheim physicians. One will order more frequent baths than another, or baths of longer duration. All agree that one must not bathe every day, but whether the days of rest shall be one, two, or three a week, seems to be a matter of individual preference among the local doctors. Thus the duration of baths varies from four to fifteen minutes, according to different advisers. Much the same discrepancy exists as to duration of exercises.

It would seem to be possible to apply this treatment anywhere to a very satisfactory extent. Heineman, who has tried it, thinks that fully seventy per cent. of the benefit may be thus imparted away from Nauheim by careful attention to details. The salts of the Nauheim waters, obtained by evaporation, can be imported in bulk and dissolved in ordinary water in proper proportion to imitate the natural water; and carbonic acid can be dissolved previously in the water, under pressure, so that the two varieties of baths upon which dependence is chiefly placed can thus be artificially prepared. The exercises can, of course, be equally well done anywhere, with trained attendants.

The best results are seen among the well-to-do, who can afford to give themselves up wholly to the treatment during the few weeks of its application; but they must have sufficient intelligence never to overtax their hearts at any time by overexercise or overindulgence in any way.

That Nauheim methods are not to be carelessly applied, and are potent for evil if too persistently used, admits of no doubt. During the treatment one often feels quite prostrated by it; and the method in general, as well as the duration of the individual baths and exercises, must be carefully adapted to suit the needs and the strength of each patient. Too vigorous a course of treatment, baths too frequently administered or of too long duration, can easily produce quite alarming degrees of prostration; and under circumstances, which occasionally may arise, of weakness induced by other causes—such, for instance, as an attack of diarrhœa or bronchitis—the treatment should be wholly suspended.

Nauheim will not accomplish miracles, but I am convinced that its power in heart cases justifies us in giving it very serious consideration. It is certainly a great deal to be able to relieve distressing and even dangerous symptoms, and to enable people to work who have been led to believe that their days of usefulness were over, as it is also to enable those who are working with undue fatigue and weariness to accomplish their daily tasks with less effort or even with pleasure.

PRIMARY FOCAL HÆMATOMYELIA FROM TRAUMATISM—A FREQUENT BUT OFTEN UNRECOGNIZED FORM OF SPINAL-CORD INJURY.[1]

By PEARCE BAILEY, M.D.,

CONSULTING NEUROLOGIST TO ST. LUKE'S HOSPITAL, NEW YORK CITY.

It is the object of this paper to call attention to a variety of spinal-cord injury which often passes unidentified, although few clinical conditions are more clearly cut than it. It arises from a definite kind of injury; its symptoms differ in association and evolution from those of the commoner traumatisms of the spinal cord. That its prognosis is in general good, is alone sufficient to render it conspicuous among affections of this class. The best designation for the condition seems to me to be primary focal hæmatomyelia from traumatism. The word primary indicates that the bleeding originates from force exerted directly upon the spinal cord, without the intervention of a fracture of the spine. Primary traumatic hæmatomyelia is thus differentiated from the hemorrhages which frequently complicate crushes of the spinal cord and which should be called secondary. In the primary variety demonstrable lesions of the bones to help explain the symptoms are absent, and the hemorrhage accordingly constitutes the chief lesion, being uncomplicated by the general mutilation of the cord, which is unavoidable when pressure is exerted upon it from the outside, as is the case when protecting structures are broken down. The rest of the name proposed for this variety of injury explains itself. Focal, in contradistinction to disseminated, indicates that the hemorrhage is localized; hæmatomyelia, that it is into the substance of the spinal cord; the factor of traumatism is mentioned

[1] Read by invitation before the Johns Hopkins Hospital Medical Society, November 7, 1898.

in order to avoid any possible confusion with idiopathic hæmatomyelia.

Thorburn[1] was the first to call general attention to the frequency and importance of traumatic hæmatomyelia. Valuable as his observations were, and are, they were incomplete. To Minor,[2] of Moscow, is due the credit of having pointed out that the character of the sensory symptoms was the one pathognomonic sign upon which the diagnosis rested. Minor was at first obliged to base his deductions upon clinical observations alone. Within the past two years the correctness of his views has been authenticated by post-mortem testimony, and it has become possible by combining autopsy findings and careful clinical histories to arrive at definite knowledge concerning the causation, pathological anatomy, symptoms, and prognosis of primary traumatic hemorrhage within the spinal cord.

It is incumbent upon any one who proposes an addition to existing terminology or who attempts to reclassify well-recognized conditions to state his reasons for so doing. My apology is this: In Minor's first descriptions, under the title of "Central Hæmatomyelia," of the dissociated anæsthesia observed after certain injuries of the cervical region, and in the subsequent observations by others, it is stated that the ordinary surgical symptoms of fracture or dislocation were absent. Of the various clinical histories accessible to me, I can recall no one in which the pure type of dissociated anæsthesia—*i.e.*, tactile sensibility absolutely normal; sensibility to temperature or pain, or to both, lost—existed together with such surgical symptoms. The presumption from these clinical data that dissociated anæsthesia resulting from traumatisms of the neck does not, as a rule at least, accompany fractures, is borne out by the evidence of operations and autopsies, when the condition of the vertebræ is accurately ascertained. On the other hand, autopsy records are now available which prove that properly exerted force can bring about a central hemorrhage in the cervical region, with a resulting dissociated anæsthesia, without there being any traces of injury to the vertebræ. These facts seem to indicate that traumatic central hæmatomyelia causing anæsthesia of characteristic selective type results most frequently, if not always, from some kind of violence other than the ordinary compression through displacement of some of the component parts of the spine. This does not imply that the same force which acts directly upon the spinal cord may not, at the same time, cause some injury to the column, although experience indicates that such is not often the case; nor is it possible to assert positively that compression from without cannot, under any circumstances, cause the symptoms of a pure central affection, although there is little if any proof that it does so. Even when due allowance is made for these possibilities of confusion, there is abundant evidence that pure central hæmatomyelia from traumatism is most frequently primary, and sufficient reason, as it seems to me, for this class of cases to be considered, for the present, at least, under the proposed designation.

Frequency.—This affection is certainly more frequent than is generally recognized. It receives brief if any mention in text-books on surgery. Yet of twenty-one cases of spinal-cord traumatisms examined by Thorburn, six were interpreted as examples of hæmatomyelia. In none of these were evidences of fracture present during life; in the only fatal case the column was found after death to be intact. Of seven fatal cases examined by Parkin[3] the column was normal in one. Of Stolper's[4] twenty-two autopsies on various spinal-cord injuries, two were examples of primary focal hæmatomyelia.

But the percentage of primary cases, as shown by autopsy, is by no means expressive of their relative frequency, because this is the form of injury to the spinal cord in which recovery occurs most often. Neither are we as yet in a position to determine the frequency from clinical reports, because it is only recently that attention has been directed to the most important diagnostic sign, *i.e.*, dissociated anæsthesia. When search for this symptom becomes part of the routine examination in surgical wards, we may expect to hear more of primary focal hæmatomyelia from traumatism.

Pathological Anatomy.—As implied by the definition, the vertebral column is not injured, or, at least, not in a way to affect the spinal cord. The most prominent feature in the spinal cord is hemorrhage. With it there must be associated a certain amount of primary laceration of the centrally situated nerve fibres. Primary laceration when slight is, however, extremely difficult to identify under the microscope, and we are obliged to rely on the hemorrhage as the index of the violence the cord has undergone. But, reasoning from the clinical side, from the temporary character of many of the symptoms, the inference is unavoidable that laceration, in most cases at least, is not an important element of the lesion.

Knowledge of the disposition of the blood in primary focal hæmatomyelia from traumatism is derived from autopsies on patients who have died of this particular lesion, and, by analogy, from hemorrhagic conditions of different characters in the spinal cord, and by experiment. The hemorrhage is poured out first, and most profusely, in the gray matter. This central limitation of the hemorrhage is often so sharply defined that upon section of the affected segment or segments, when the hemorrhage is profuse, the configuration of the whole gray matter is distinctly marked in red. The total occupation of the gray matter by blood cells, even in severe cases, is usually confined to one or two segments, at the focus of greatest injury. Above and below, the blood decreases in amount, so that parts of the gray matter, especially the gray commissure, are entirely free from it. But if serial transverse sections are made up and down the cord, it can be seen that there have been extensions of the blood in pencils or columns, either upward or downward, or in both directions, from the place of the most extensive hemorrhage. These columnar extensions proceed through two, three, or even four or more segments, in one or both directions. They are not equal in length, one penetrating for a longer distance than the other. In my experience the longest extension is usually the one which goes upward. The seat of the extension is almost always in the gray matter, usually in the anterior or posterior horn, on one side of the cord only; the extension above the seat of the most extensive hemorrhage is usually opposite to the one below. When the original hemorrhage is profuse, it may escape, at the focus of greatest injury, beyond the limits of the gray matter and infiltrate the white columns. This occurs in the form of one large clot, occupying a greater part of the circumference of the cord, or as smaller collections of punctate extravasations. Similarly, though much less frequently with the columnar extensions, they may not be confined to the gray matter, but extend laterally beyond it. When this occurs, it does so most frequently into the white matter just behind the middle commissure. As to the situation in respect from trauma to the long axis of the cord, primary focal hemorrhage has never been demonstrated except in the lower cervical and upper thoracic regions. It is probable, however, that it may occur in the conus medullaris.

The evolution of the lesion is as yet somewhat ob-

scure. The blood degenerates and forms a viscous fluid. If life is prolonged, the natural tendency of this fluid is toward absorption, so that a cavity is left in the parts of the cord which it had occupied. Lax and Müller[1] have recorded a case in which such a cavity was found three years after the accident. In a case to be cited in this paper the cavity had been in large part filled up by new connective tissue. We may therefore deduce that cavity formation is a constant sequel to hæmatomyelia, unless death follows the injury almost immediately, and that the cavity may remain patent or be replaced by new tissue. The extent of damage sustained by the spinal cord is proportionate to the amount of the bleeding. If this latter is excessive, it may burst into the white matter and bring about as disastrous consequences as though the cord had been crushed from the outside, the symptoms then being those of a general lesion. In most cases, however, the hemorrhage remains confined to the gray matter, the symptoms are selective, and the resulting degenerations are not pronounced.

Etiology.—With the exception of pistol-shot wounds primary focal hæmatomyelia results almost exclusively, when the exact cause can be ascertained, from sudden forced flexions or extensions of the neck.[2] As examples may be cited falls on the head, the dropping of heavy weights on the head, or, as occurred in three personally observed cases, by diving into shallow water. Thorburn explained the mechanism of the lesion's production by a momentary dislocation of the cervical vertebræ. In view of the already stated fact, that the symptoms in these cases differ materially from such as are seen when fracture or dislocation can be proved, and that in the autopsies there were absolutely no traces of any change of position in the vertebræ, this theory is hardly satisfactory. I believe that the hemorrhage occurs not from external compression but from a rupture of one or more of the blood-vessels of the central gray matter, brought about by the stretching of the cord during the forced flexion or extension of the neck.

Symptoms.—As neither fracture nor dislocation belongs to primary focal hæmatomyelia, but little need be said as to these conditions. There may be œdema, subcutaneous extravasations, stiffness, pain, etc., in the neck, the results of the sudden and excessive strain to which the cervical vertebræ and superimposed structures have been subjected; but crepitus, false motion, or pathological irregularities in the vertebral spines are conspicuous by their absence. The symptoms directly referable to the spinal cord, as they are the results of an internal and generally circumscribed injury, differ from those of crushes of the cord in which both white and gray matter are commonly implicated. If the hemorrhage is so extensive that it bursts beyond the gray matter and involves the cord, either directly or by pressure in its whole cross-section, the clinical evidences of paralysis, anæsthesia, etc., would be identical with those of a transverse lesion. When, however, as is usually the case, the hemorrhage exceeds the gray confines but little or not at all, the clinical picture has a distinct individuality, of which the most salient features are an initial motor paralysis which soon becomes modified, and anæsthesia for temperature or pain, or both, without impairment of the sense of touch. The motor and sensory symptoms deserve particular mention.

Motor Paralysis.—The paralysis of voluntary motion, with few exceptions, ensues instantly upon receipt of the injury. The muscles involved at the level of the injury (since the hemorrhage is most constant in the lower cervical region) are those of the forearm and hand, and sometimes of the upper arm; those below, of the lower extremities. The paralysis of the upper extremities has a different anatomical basis from that of the lower. The first is due to the blood being poured directly into the spinal nuclei of the brachial nerves, thus constituting a destructive lesion. From such a condition perfect recovery is improbable, and, in fact, most of the patients remain permanently paralyzed, though the paralysis may be very limited, in some of the muscles of the upper extremity. The parlaysis of the legs, on the other hand, is the result of conditions often permitting recovery. The most feasible explanation of this paralysis, from which recovery may be expected, is that the hemorrhage, although occupying the central portions of the cord, exerts sufficient pressure, or is followed by œdema sufficient to compress for a time the pyramidal tracts which lie a little distance from it, and which are carrying the long cerebral fibres destined for the muscle nuclei situated at lower levels. When the hemorrhage ceases, the commotion it has caused in its vicinity subsides and the pyramidal fibres are permitted to resume their wonted function. The distribution of the paralysis varies with the situation and extent of the hemorrhage. If below the first thoracic segment, an unusual situation, the arms escape. If above the second thoracic segment, the paralysis affects the muscles whose nuclei are below the upper limit of the hemorrhage. If the hemorrhage is very small and on one side of the cord only, the paralysis may affect one arm chiefly or only; if larger, but still confined to one side, there is spinal hemiplegia. In the following case the final picture was slight atrophic paralysis of both arms and spastic weakness in one leg:[1]

Case I.—A young man, upon diving into shallow water and striking the bottom with his head, instantly lost power in arms and legs. When examined two years later, much of the paralysis had disappeared, there being left an atrophic weakness of the small muscles of both hands and a spastic paresis of the left leg. There were no signs of fractured vertebræ. The patient could use both hands fairly well and walked easily, though with a limp. The patient stated that he had never lost the sense of touch; it is probable that thermo-anæsthesia existed originally, but there were no traces of it at this late examination. In this case there was undoubtedly a bilateral hemorrhage in the nuclei of the first thoracic segment of the spinal cord, which had also pressed on the left pyramidal tract.

In a large number of cases the hemorrhage is sufficient to cause at first paralysis of both arms and of both legs. When the patient is seen immediately after the accident, the paralysis is flaccid in character. The muscles are soft and yielding, without rigidity, and the paraplegia is complete. The knee jerks are diminished or lost. (This does not indicate a transverse lesion, as is often maintained.) When the lesion is very small, the knee jerks may be hypertypical or exaggerated at once. In the lower extremities the paralysis soon undergoes a change, and from being flaccid, it becomes spastic. The knee jerks, if they were diminished or lost, return and become exaggerated, and ankle clonus is added.

With the establishment of the spasticity strength returns to the legs. Some patients are able to walk a few weeks after being completely paraplegic. The recovery in the legs comes sooner than that in the arms; in the arms it is also less perfect than in the legs, there usually being left a permanent atrophic paralysis in some of the brachial muscles.

[1] Deut. Zeit. für Nerv., 1898, xii., 304.

[2] For a discussion of central hemorrhage caused by pistol-shot wounds, the reader is referred to an excellent paper by Cushing, American Journal of the Medical Sciences, June, 1898. This particular class of injuries will not be considered in the present article.

[1] This case has been fully described by me in "Accident and Injury: Their Relation to Diseases of the Nervous System." New York. D. Appleton & Co., 1898.

Of these muscles the most frequently affected are the small ones of the thumb and the interossei. Thus a patient recovering from this affection may present a picture very similar to that of progressive muscular atrophy (amyotrophic lateral sclerosis), viz., a paralysis of the upper extremities of the peripheral neuron type, with atrophy, fibrillation, and degenerative electrical reactions, and of the lower extremities of central neuron type, with rigidity, increased knee jerks, and ankle clonus.

When distinctive sensory symptoms are added to those of progressive muscular atrophy, the picture changes to that of syringomyelia, and, as has often been emphasized, primary focal hæmatomyelia from trauma has many things in common with syringomyelia. There is little chance, however, of confusing the traumatic affection with either of these chronic and insidious diseases.

Sensory Symptoms.—From the study of syringomyelia, a disease affecting primarily the central gray matter, and having for its most distinctive clinical

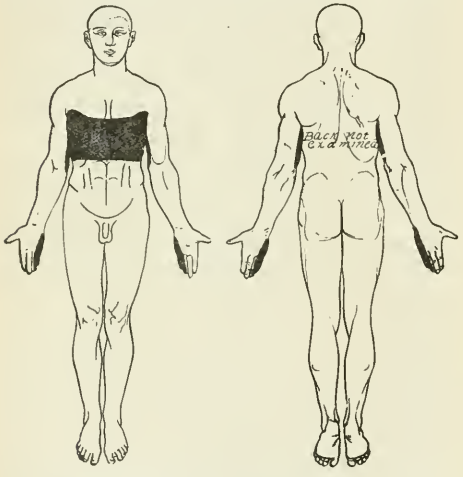

Fig. 1.—Loss of Temperature Sense in a Case of Primary Focal Hæmatomyelia from Traumatism (Case II., verified by autopsy).

manifestation a dissociated anæsthesia, the gray matter of the spinal cord has come to be regarded as intimately connected with the passage brainwards of the sensations of temperature and of pain; and it is further probable that, whatever may be the paths for the sensations of touch, they are not in the gray matter. We expect, therefore, that in all cases, whether chronic or acute, in which the lesion is confined to the structures surrounding the central canal, the ability to recognize thermic and painful stimuli will be impaired or lost, while tactile sensibility remains normal. Such is the condition in primary focal hæmatomyelia, except in the few cases in which the blood clot is so extensive that it causes the total anæsthesia of a transverse lesion. The hemorrhage may be of considerable size without doing so, however, as is illustrated by the following case:

Case II.—A man, twenty-five years of age, dived into shallow water and became immediately paralyzed in both arms and legs. Retention of urine; incontinence of fæces. Two weeks afterward he was brought to St. Luke's Hospital, to the service of Dr. B. Farquhar Curtis, at whose request I saw him. The paralysis in the legs was almost complete. In the upper extremities it involved the interossei especially, although the flexors and extensors of the wrist were very weak. Tactile and pain sensibility was normal everywhere; but thermo-anæsthesia existed below the nipples on the trunk, on the legs, and on the inner sides of the arms. Later the thermo-anæsthesia disappeared from the legs altogether; the distribution, as shown in the cut (Fig. 1), was permanent. The knee jerks were absent for a few weeks and then returned and became exaggerated and associated with foot clonus. The man improved considerably, but was troubled with bedsores and cystitis and died after a few months, with the symptoms of septicæmia. At the autopsy the vertebral column and canal were found intact, but the central portions of the spinal cord were almost totally destroyed in the eighth cervical and first thoracic segments, and partially so in the seventh cervical. The destruction had also encroached considerably on the white matter. Microscopical examination showed that the lesion was hemorrhagic in origin. The holes left by the blood were in large part filled up by new tissue. Thus in this case, although the hemorrhage exceeded the gray confines and was sufficiently extensive to lead to death, tactile sensibility remained perfectly normal.

The clinical characters of the impairment of cutaneous sensibility in primary focal hæmatomyelia vary. The chief characteristic is that while sensibility to touch is not affected, there exists thermo-anæsthesia or analgesia, or both together. The distribution of these disturbances is in general the same as that for the total anæsthesia of transverse lesions. The Brown-Séquard type is often seen, viz., a motor paralysis of one arm and leg, with loss of pain sense and temperature sense in the arm and leg of the opposite side. The degree of thermo-anæsthesia and analgesia is not constant. As a rule, analgesia is the less of the two; in recovery also, it is the first to improve or disappear. From personal experience I can speak only of the loss of temperature sense. That has generally been, for the first few weeks after the accident, complete, so that the patients were not only unable to distinguish between heat and cold, but felt no discomfort from contact with the test tube of boiling water, although other kinds of painful stimuli were appreciated at their true value. When the symptom was incomplete at first, or when time had permitted it to become so, it appeared as delayed perception. The tendency of these affections of the pain and temperature sense is toward improvement and sometimes recovery is perfect.

Of the other symptoms referable to the sphere of sensation, pain is most prominent. Some cases run an entirely painless course; in others, pain, both spontaneous and on motion, is referred to the site of the lesion. The sharp lancinating pains down the arms or legs, the so-called irritative root symptoms, are not prominent in pure central traumatic hæmatomyelia; neither are numbness, tingling, or other forms of paræsthesias frequent. The patient may say that he felt such perverted sensations for a short time after the accident, but that they were temporary; he most frequently states that he "feels everything," being ignorant of the fact that he cannot tell heat from cold, or recognize either one of them. As the hemorrhages are in the vicinity of the centres of the cilio-spinal reflex, pupillary phenomena are constant. If the amount of blood on the two sides is equal, the degree of myosis on both sides is equal. More frequently, however, the myosis, like the paralysis, is more pronounced on one side. Other evidences of lesion of the cilio-spinal centres are less frequently mentioned.

The other symptoms which sometimes occur in primary focal hæmatomyelia may be dismissed with brief mention. Thus retention of urine, incontinence of fæces, bedsores, priapism, œdema, cyanosis of the extremities, distention of the abdomen, chills and fever, all have been observed. These are the general symptoms of any traumatism of the spinal cord, and one or all of them may be present in the special affec-

tion under discussion. In it, however, they are generally characterized by short duration and by one or more of them being absent. Thus, the incontinence of fæces may stop in a day or two; control of the bladder is usually slower in returning, but it generally does return. Bedsores do not occur in mild cases.

Diagnosis.—The nature of the accident, the extent and character of the initial palsy, the sphincter defects, the absence of external signs of bone lesion, may all be the same in other kinds of spinal-cord injuries as in primary focal hæmatomyelia. The chief distinguishing guide, immediately after the accident at least, is to be sought in the sphere of sensation. When the other symptoms are in accord with an acute injury, and when there is anæsthesia for pain or temperature, in characteristic areas, without any impairment of the sense of touch, the diagnosis can be made, I think, without hesitancy. The fact that such a dissociation of sensation occurs in other spinal-cord affections, in certain forms of neuritis, or even in hysteria, can hardly cause confusion to any one who looks at the case from every point of view. The chief difficulties to certainty of diagnosis will be met in cases in which the hemorrhage is very small and in those in which it is very large. In the first category it seems entirely possible that a hemorrhage, if confined to the anterior horns, would cause no sensory symptoms, and few or no symptoms of general commotion, and the diagnosis would therefore have to be made from the paralysis and wasting of one upper extremity. Similarly, if the hemorrhage were in a posterior horn, the resulting sensory defect might easily be overlooked. In an autopsy made on a man who died from rupture of the viscera ten days after a severe general traumatism, I found a small hemorrhage (no vertebral fracture) which occupied about one-fifth of the area of one anterior horn of the first thoracic segment of one side. The man had no symptoms pointing to a destructive lesion in the nervous system, and the fact that his other injuries were complicated by primary hæmatomyelia became apparent only after death. In contrast to these minute lesions are the extensive ones, which lead quickly to death. It is entirely possible for a large central hemorrhage to have the same effect, by pressure or by actual destruction; to cause symptoms, both motor and sensory, identical with those of general crushes. It seems, however, that such cases are unusual; that the fibres for sensibility here as elsewhere are much more resistant to pressure effects than are those of motion. Between these two extremes are the most frequent cases of primary focal hæmatomyelia, which, in addition to the sensory symptom complex, have other characteristics of their own. Among these may be mentioned the strong tendency toward improvement of muscular power, more rapid in the legs than in the arms; frequent unilateral distribution; the comparatively quick return of sphincter control and the general absence of bedsores.

Prognosis.—That this class of cases merits careful observation and record is shown by the favorable course which they so frequently follow. To call good the prognosis of any injury to so vital a structure as the spinal cord, may seem exaggerative. Yet, compared with secondary injuries, the prognosis of primary focal hæmatomyelia is extremely favorable.

That recovery is the rule is shown by the infrequency of autopsy records compared with the large number of clinically reported cases.

To cite instances bearing on prognosis: In Case I., after complete paraplegia, the patient recovered the use of the arms and hands for everything except the finest movements, and could walk easily, though he dragged one leg somewhat. A patient of Thorburn's, paralyzed in legs and arms on December 19th, was discharged on January 16th, "cured, except for some feebleness of the grasp."

Barling[1] reports the case of a man who fell about ten feet, striking on the head and neck. The right upper extremity was almost completely paralyzed and there was general weakness in the right lower extremity. Analgesia in the right leg was the only sensory symptom. There was no evidence of fracture of the spine. In six months the patient resumed his occupation as a fireman on an engine, and "was as well able to do his work as before the accident."

A patient of Minor's, injured on July 6th, walked on the September 5th following, and left the hospital on September 8th. Another patient of the same physician, totally paraplegic at first, could stand alone seven days after the accident. To these citations may be added two personally observed cases.

Case III.—On or about June 20, 1898, a strong man fell thirty feet through a hatchway and was instantly paralyzed in both legs. He was taken to the Hudson Street Hospital, in the service of Dr. P. R. Bolton. Symptoms: Arms unaffected in any way; complete

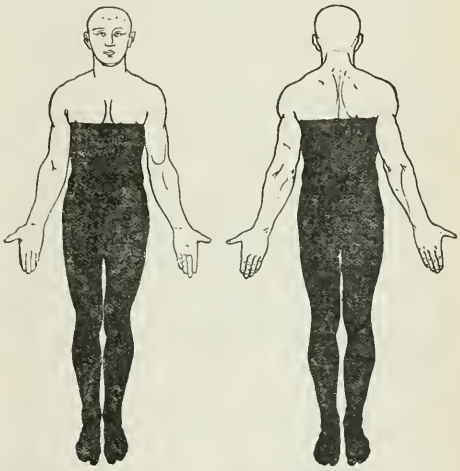

Fig. 2.—Loss of Temperature Sense in a Case of Primary Focal Hæmatomyelia from Traumatism (Case III.).

motor paraplegia of legs, with retention of urine; diminution (almost extinction) of both knee jerks. Sensibility to touch and pain were normal, but a pronounced thermo-anæsthesia was present below the nipples (Fig. 2). No bedsores. Recovery was very rapid. The retention of urine disappeared in ten days and in six weeks the patient could walk unsupported. On August 23, 1898, the patient walked to my office with Dr. A. Michaelis, when the following notes were made: The man now walks easily and without a marked limp, although the right leg is stiff. All movements of the lower extremities are performed quickly and with good force. Both knee jerks have now become exaggerated and there is also double ankle clonus. Thermo-anæsthesia has in large part disappeared, though traces of it are still present in the legs, especially the left. At the first examination the vertebral column appeared normal. At this second examination there was a kyphosis in the upper dorsal region. The patient had secured a place as night watchman, and said he could perform his duties without fatigue. Thus in two months from the receipt of the injury this man had recovered from a complete motor paraplegia with bladder paralysis, and had again become a bread winner.

[1] Birmingham Medical Review, 1893, xxxiv., p. 149.

Case IV.—A healthy man on July 5, 1898, struck his head on the bottom in diving, and became paralyzed in all four extremities. He would have drowned had not his friends pulled him out of the water. At the request of Dr. G. B. Crary I saw him at Roosevelt Hospital on July 18th. His condition had already improved greatly, but for several days after the accident he had been unable to move hand or foot, to pass his water, or to control his bowels.

At the time of my examination sphincter control had already returned, there had been no bedsores, and the patient, though still bedridden, could move both legs and the right arm freely but feebly. In the right upper extremity complete paralysis of the deltoid, of the triceps, and of all the muscles of the forearm remained. The knee jerk was absent on the right side and much diminished on the left. The right pupil was smaller than the left. The only objective anomaly of sensibility was a slight thermo-anæsthesia in the left upper extremity. The spinal column appeared normal. Within four weeks of the receipt of this injury the patient could get around on his legs. Seen again on August 20, 1898, he had regained so much power in the legs that he could walk with ease, without cane or crutches and without noticeable defect, although the legs were somewhat stiff and not so strong as they had been before the accident. He had, however, walked up four flights of stairs, without assistance. Recovery in the left hand had kept pace with that of the lower extremities, but the right hand and arm, though much better, still showed signs of serious involvement. Any movement with them the patient could make, but all the muscles of this member were unmistakably feeble, as shown in the grip, in movements of the fingers, etc. There was a marked atrophy also of the thenar eminence. The patient said that he had, with difficulty, been able to sign his name, but that for practical purposes the right hand was of little service to him. Both knee jerks were now exaggerated and there was a foot clonus on the right side. He complained at this examination, as he had done at the previous one, of pain in the back of the neck. The pain was dull, not particularly increased by movement, and never very severe. These were the only symptoms left in a patient who, forty-six days before, had been unable to move hand or foot, to control his bowels, or to empty his bladder. The disturbances in the perception of thermal sensation had vanished, the restoration of rectal and vesical function was complete, and the man was nearly ready to resume his occupation.

These cases show how complete recovery may be in primary focal hæmatomyelia from trauma, even when the initial symptoms are of alarming character. The prognosis as to life and as to restoration of function is directly proportional to the extent of the hemorrhage. With this latter excessive, tearing and lacerating the cervical cord in nearly total cross-section, the patient usually dies in a few hours or a few days. These are the cases most frequently seen at autopsy. When, on the other hand, the amount of the hemorrhage is small, the degree of possible recovery, as shown in the above-cited cases, is truly astonishing.

Immediately after the accident, it may be extremely difficult to determine the extent of actual injury undergone by the cord. As shown by Case II., the destruction may involve the white matter considerably and the clinical type of central affection still be preserved. But whenever the symptoms remain sufficiently selective to make the diagnosis of primary focal hæmatomyelia possible, the immediate inference is justifiable that the outlook is more favorable than for any other variety of traumatism of like initial severity in the cervical region. More light as to prognosis is shed in the few days following the accident. The early restoration of sphincter control, the quick return of voluntary motor power in some muscles, the absence of the tendency to bedsores, all speak for a favorable termination eventually. It is as yet rather early to speculate as to the ultimate fate of patients who have suffered a primary traumatic hemorrhage in the cervicothoracic cord. Destructive lesions in the brachial nuclei are of course irreparable. Even the legs, in which the recovery is most perfect, are left stiff, and will probably always be weaker than before the accident. It would also be at variance with the general principles of nervous pathology if, after such accidents, the patients themselves were not more irritable and restless, less capable of exertion, less tolerant of fatigue, and less resistant to disease-inducing agents.

Treatment.—After having emphasized the contraindication of all operative interference, there is no occasion to speak of treatment in this paper. It is by no means intended to imply that treatment is unimportant; on the contrary, skilful management of these patients may condition recovery. But the treatment itself is not different in its principles from that of other spinal-cord injuries, and can be found fully described in text-books on surgery.

This paper is a preliminary and consequently much condensed communication from an essay on traumatic hæmatomyelia and other varieties of injury to the spinal cord, in course of preparation by Dr. P. R. Bolton and the writer.

4 West Fiftieth Street.

Progress of Medical Science.

Multiple Abscess of the Liver is another recognized result of dysentery, though I rather think the statement has been exaggerated and more universally accepted than the facts warrant.—John Anderson.

Subjective Dyspnœa a Symptom of Dry Catarrh of the Nasal, Pharyngeal, or Laryngeal Mucous Membrane.—Dr. M. Sänger (*Münch. med. Wochenschrift*, No. 15, 1898) calls attention to a very common yet heretofore overlooked symptom in rhinitis, pharyngitis, and laryngitis sicca—namely, subjective dyspnœa. The patients complain of shortness of breath and of a feeling that they do not receive a sufficient quantity of air during inspiration, with a sense of obstruction in the nose or throat. This subjective dyspnœa is relieved by curing the dryness of the respiratory mucous membrane. The writer attributes this symptom to a diminished sensibility of the terminal filaments of the nerves not permitting a correct conception of the amount of air inspired, and also to the diminished moisture.

Paralysis of the Arm Due to Decayed Teeth.—In the *Münchener medicinische Wochenschrift*, No. 29, 1898, Dr. Mühl Kühner, a surgical dentist of Landen (Pfalz), reports the case of a young woman, twenty-four years old, who for two and one-half years was affected with paralysis of the right arm and right side of the neck. This was supposed to have been the result of a fall, in which her arm was fractured, but appropriate treatment failed to improve the condition. She visited Dr. Mühl Kühner to have her teeth attended to. Several of the teeth were filled, and one, the third upper molar (wisdom tooth) of the right side, was extracted on account of deep-seated caries. The next day the patient returned to inform the doctor that her palsy had disappeared and she was happy in the full and free movement of the previously affected parts. A similar case is reported in the *Correspondenz-Blätter für Zahnärzte* of April, 1898.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, November 19, 1898.

THE QUESTION OF CONSULTATIONS.

IN all walks of life, but particularly in the practice of medicine, consultation with one more versed in his art or supposed to be endowed with a greater practical knowledge of the conditions in question forms a prominent feature of present-day practices. The day has passed in medicine when the patient or his immediate relations and friends feel that the sole care of a severe illness should be left to the discretion and judgment of a single man. If matters are not progressing favorably—even though nothing which would conduce to the best interests and well being of the patient is left undone—they are apt to reason that two heads are better than one, not only because they contain four eyes, but because one may perhaps possess the necessary something which the other lacks. At the present day the tendency is rather to overdo the matter of consultations, and many physicians are forced to submit to them, even perhaps against their will. The slightest unfavorable turn in the course of the disease often seems sufficient ground for the friends to suggest a consultation, all the more so if the attending physician is a young man. It appears almost an impossibility to eradicate from the minds of some people the idea that youth is a crime; the presence of the tinge of gray seems to be requisite for the peace of mind of certain patients and their friends. Yet there are times when even the veteran in practice has to submit to the inevitable, and meet in consultation perhaps a younger confrère at the request of the family. The various reasons for holding consultations are given in Dr. Robert Gersuny's recent book, "Doctor and Patient: Hints to Both": "Various reasons may induce patient or friends to wish for a consultation: (1) A general anxiety to leave nothing undone. (2) An impression that the doctor in attendance shows uncertainty. (3) The protracted length of the illness. (4) The fact that somebody has recommended a certain doctor, and consequently his opinion is desired. (5) The belief that they owe it to their social position and wealth. On the other hand, the attendant doctor demands it because: (1) He will not bear the sole responsibility of a certain case, and wishes to avoid subsequent reproaches. (2) He supposes that his colleague with whom he wishes to consult has a greater special experience than his own. (3) He feels uneasy, and therefore wishes for support from a brother practitioner. (4) He divines the wishes of the patient and his friends, and is glad to meet them half way."

Thus we see that no physician should feel in any wise slighted when a consultation is proposed, provided the consultant named be his professional equal or superior. It is wrong and unjust to one's self, as well as to the patient, to object to a consultation because one "does not believe in it." On the other hand, it is neither wise nor dignified to foster in the minds of patients a constant desire for consultations. Dr. Gersuny states that "in some districts there is a regular mania for consultations. A family doctor is employed by patients only when they are in health; in case of sickness a specialist is at once called in, and sometimes more than one, according to circumstances. The family doctor is reduced to the level of a sort of master of ceremonies, and the patient has the disadvantage of being attended by doctors who see him for the first time."

Moderation in consultations, as in everything else, would seem to be proper, avoiding exaggerated enthusiasm on the one hand and scepticism on the other. It is a safe rule to take the initiative and call for a consultation, when in your judgment an indication for one has arisen, or to acquiesce in such call when those nearest and dearest to the patient deem it desirable to have the opinion of a second man. If it does not prove true in the case in hand that "in multitude of counsel there is wisdom," there will at least be the satisfaction of knowing that an effort was made to give the subject of the conference every chance.

PROFESSOR KOCH'S INVESTIGATIONS IN SOUTH AFRICA.

THE paper read by Dr. Koch, giving the results of his researches in South Africa, would appear on the whole to have occasioned great umbrage to those British medical men who have practised in tropical countries and who have had experience in the treatment of the diseases incidental to the torrid zone. Many of the English journals, both lay and medical, are especially irate at his pronouncement that black-water fever is caused by quinine. This angry feeling is stated not to be caused by professional jealousy, or by any other kind of envy, hatred, or uncharitableness, but simply because the professor has made an assertion calculated, it is claimed, to do infinite harm, without having first sufficiently studied the subject on which he delivers so dogmatic an opinion. The *Indian Medical Gazette*, commenting in a leading article on Professor Koch's statement of views, says: "Had he, distinguished investigator as he is, spent the whole of his life in studying malaria, he would hardly have been entitled to speak with so much authority as he assumes, and certainly only with regard to his experiences in the places he visited." Again, the same journal, referring to black-water fever, says: "Dr. Koch's tendency to jump at conclusions on insufficient evidence as so far published is well shown in his assertion that 'black-water fever' is merely quinine poisoning. Apparently

because he never found the malarial parasite in such cases, therefore they are not malarial." A London lay journal, the well-known *Saturday Review*, harping on the same string, and in its usual scathing and biting language, speaks as follows: "No living doctor has a more world-wide renown than Robert Koch. His early work on the bacillus of tuberculosis secured him a well-deserved reputation in his profession, for that research proved him to be a master of accurate methods of investigation, patient in their employment, and cautious in his deductions. Men predicted that the young Koch was the coming Pasteur—a forecast, alas! that has not been fulfilled. In 1884 cholera broke out in Egypt, and Koch was sent there to study the disease. The telegraph soon spread the news through Europe that Koch had found the cholera bacillus. Bacteriological experts have not accepted this discovery as valid. Klein offered to swallow as much 'cholera bacillus' as Koch chose to prepare. But the expert criticism did not reach the public or lessen Koch's fame. Six years later the world was startled by the pleasing announcement that Koch had discovered a certain cure for consumption. Kaiser Wilhelm and the daily press proclaimed Koch one of the world's greatest benefactors. The subsequent demonstrations that the discovery was a mare's nest, and that the famous tuberculin did more harm than good to the unlucky invalids into whom it was injected, could no more lower Koch's popular prestige than it could deprive him of the high honor and rich rewards which a grateful world had showered upon him. Unwarned by these failures, Koch has not returned to the cautious scientific methods of his early manhood. His reports on his recent researches on various tropical diseases are marred by the careless blunders, reckless haste, and dishonest plagiarism which have previously ruined his scientific reputation. It is not, however, with Koch's reputation that we are here concerned, but with the new danger he has added to life in tropical Africa."

The writer then describes black-water fever, sketches the investigations made and the theories advanced as to its origin by various observers, and remarks that Koch, after studying sixteen cases in the hospital at Dar-es-Salaam, in which he noticed the usual action of quinine in patients suffering from black-water fever, revived the already discredited theory of quinine poisoning and dogmatically asserts it as a now incontrovertible fact. The article ends with this sentence: "The victims of tuberculin may be reckoned by the scores, but Koch's advocacy of the view that black-water fever is quinine poisoning will probably kill its hundreds as well as strike the deathblow to a scientific reputation once of the highest promise."

From the medical men of South Africa has gone forth a unanimous and bitter protest against the acceptance of Koch's deductions, and they predict that the most disastrous results must follow the public expression of his opinions; in fact, it is stated that already in Africa persons suffering from malaria and black-water fever refuse to take quinine, arguing that, if Koch says that it is harmful to do so, they have excellent reasons for their refusal. The quinine-poisoning theory of black-water fever was originally started by Tomaselli, of Catania, who studied the disease in Sicily and Sardinia, and it has been discussed and observed by several others; but it is now almost universally renounced. Dr. W. Sambon, of Naples, certainly one of the greatest authorities on malaria and hæmoglobinuria, and who has spent many years in investigating these diseases, says in reference to the latter that he neither believes that it is an unusually severe paroxysm of the ordinary malaria fever, as held by some, nor does he think that it is a peculiar condition caused by the administration of quinine, the view taken by others; but is of the opinion that it is very closely related to the paroxysmal hæmoglobinuria of temperate regions.

We—while thinking that perhaps Professor Koch would have been better advised had he kept his theory to himself until he had absolutely proved its truth beyond a doubt—still hail the present discussion with a considerable amount of pleasure, for it will act as a spur to those scientific men who are interested in the matter and will undoubtedly tend more quickly to bring about the solution of the origin of one of the most deadly maladies which infest tropical regions, and thus in the end prove a blessing in disguise. Whether Koch, Manson, Ross, or Sambon is the fortunate man is an affair of little moment; they are, after all, but units—the end in view is the benefit of mankind at large.

A WHOLESOME VERDICT.

THE educated and conscientious physician must have read with considerable satisfaction the verdict of the English coroner in the inquest into the death of a well-known writer of fiction, under the ignorant and brutal ministrations of two misguided females calling themselves Christian scientists. The verdict of manslaughter in this case, though perhaps severe on the two women, will undoubtedly have a restraining influence upon other weak-minded specimens who would like to follow in the path of their ridiculous tenets; though we are very likely to hear a wail about "martyrdom" and "persecution" from some unimportant sources. A suitable punishment ought to be inflicted in this case, so that in future those who would like to employ Christian-science methods will be more circumspect in choosing their cases, and will confine their imaginary therapeutics to imaginary diseases. They will be on safer ground. We believe that in this country Christian scientists, "mind-healers," and "faith curers" are about the same in their hypotheses and methods, though we understand that among them there are disputes. However, it is a matter of easy and absolute demonstration that their claims and statements are absurd and dangerous, and it ought to be possible to protect the ignorant and credulous against their own folly. There is never any public objection to quarantining against yellow fever, and it ought to be possible to have a sort of quarantine against "Christian science" and such, for those who are too ignorant to protect themselves. Several attempts have been made in this country to stop this sort of thing, but unfortunately the success has not been very great. A certain por-

tion of the public at least, we fear, really likes to be humbugged, as our late illustrious Barnum often told us. However, we shall continue to have faith in time and education.

News of the Week.

Virchow's Versatility. — The German Anthropological Congress, held in the late summer at Brunswick, was presided over by Professor Virchow. "The Great Problems of the Stone Age" formed the subject of his opening address, in the course of which he pointed to the importance of the latest discoveries in Egypt. Professor Ranke, who gave the yearly scientific report of the society, ended by praising Virchow as the master of research.

A Case of Medical Charity.—An unexpected illustration of dispensary abuse occurred at the City Hospital Dispensary in Baltimore, when a man who had just applied for free treatment, on the plea that he was unable to pay a physician, dropped dead, and in his pocket was found $1,500 in notes.—*Maryland Medical Journal.*

The Meyer Memorial at Copenhagen.—The monument erected by an international subscription in honor of Dr. Hans Wilhelm Meyer, the discoverer of adenoid growths, was unveiled in Copenhagen on October 25th. It is a bronze bust of heroic size, standing upon a granite base, in the Gefion Square in East Copenhagen. It is the work of the Danish artists, Bissen and Runeberg. The memorial was handed over to the authorities of Copenhagen by Sir Felix Semon, who delivered an address in which he pointed out the importance of Meyer's discovery. It had, he said, saved many thousands from deafness and would save many thousands more in the future. He described Meyer as one of the greatest benefactors to mankind that the profession of medicine had ever known.

"Recent Experiences in Military Surgery after the Battle of Santiago."—The *Journal of the American Medical Association* of November 12th publishes an article with the above title, suppressing the name of the author, which article is lifted bodily from the MEDICAL RECORD of July 30, 1898, its aspect, however, being altered by the insertion of illustrations. A clear case of kleptomania.

The Medical and Chirurgical Faculty of Maryland.—The next semiannual meeting of the State Medical Society of Maryland will be held at Frederick, on Wednesday and Thursday, November 16th and 17th.

The Pan-American Medical Congress.—At the request of the Venezuelan government and of the local committee, the next meeting of the Pan-American Medical Congress, which was appointed to be held at Caracas in December, 1899, has been postponed to the same month in 1900. The curious and ludicrous reason alleged for the request is that a revolution and an epidemic of small-pox have agitated unduly the Venezuelan medical profession. The real reason is not allowed to appear.

A Medical College Burned.—The building of the medical department of the University of Tennessee at Nashville was destroyed by fire on November 11th.

Suicide at a Hospital.—A patient in the Post-Graduate Hospital in this city committed suicide one day last week, by jumping from a window on the top floor to the court.

The Killing of Harold Frederic. — The coroner's inquest in the case of Mr. Harold Frederic, the correspondent of the New York *Times*, who died in London in consequence of maltreatment at the hands of a Christian "scientist," was held on November 8th. The jury rendered a verdict of manslaughter against Mrs. Mills, the Christian scientist who attended and treated him, and brought a similar verdict against a young woman, a member of Mr. Frederic's household, who summoned and assisted Mrs. Mills. The verdict of the jury was that death was caused by heart failure, which was accelerated by the absence of medical treatment; that the deceased man was physically incapable and occasionally insane; and that the two women were criminally responsible for his death.

Obituary Notes.—DR. F. O. HART, of West Unity, Ohio, died of apoplexy on October 10th. He was a graduate of the University of Michigan in 1884.—DR. JOHN HELM, of New Brunswick, N. J., died at his home in that city on November 7th, after a long illness. He was a graduate of the medical department of the University of the City of New York in the class of 1860, and served during the civil war as surgeon with the second New Jersey volunteers.

The Tri-State Medical Society of Virginia, North Carolina, and South Carolina.—At a meeting held at Virginia Beach on August 31st, this society was organized by representatives from the three States. A temporary organization was effected by the election of Dr. W. H. H. Cobb, of Goldsboro, N. C., *Chairman;* Dr. H. H. Dodson, of Milton, N. C., *Treasurer;* and Dr. Paulus A. Irving, of Richmond, Va., *Secretary.* The temporary president was authorized to appoint an organization committee from each State, and it was suggested that the first meeting of the society be held before New Year.

Dr. Andrew Von Grimm.—At a stated meeting of the medical board of the St. Mark's Hospital, a resolution was passed to extend the thanks and appreciation of the medical board to Dr. Andrew Von Grimm, one of the attending physicians to the hospital, for his enthusiasm, diligence, and success in securing proper and opportune treatment for the soldiers who were received in the St. Mark's Hospital.

Diploma Cut Rates.—The chancellor of the university, in his report before the council on November 7th, characterized as rate cutting the action of "a sister college," in offering diplomas after three years' study. The report in part said: "Our medical work,

which at the date of the chancellor's report last year was in an unsatisfactory condition, is now very prosperous. The enrolment of students is more than one-half larger than last year. The faculty is most harmonious and efficient. A few unwilling professors have been spared to join an eager sister university. We regret that the eagerness of this out-of-town corporation to collect hastily a medical school has led it to offer to matriculants of one year ago doctor's diplomas after two years' additional study. We could not meet this offer, having announced that the class of 1899 should be our last three years' class. We preferred to lose a score or two of students from our second-year class rather than meet this cut in rates. The present indications are that we shall be the gainers even as regards the number of students by our adherence to our high standard." Co-education in city institutions is looked upon as unsuited for metropolitan conditions. The consolidation with Bellevue is reported as "organic and complete."

University and Bellevue College.—Dr. E. Harrison Griffin has been appointed lecturer on diseases of the nose and throat in the New York University and Bellevue Hospital Medical College.

The Death of Dr. Lindheim.—We of this city should bow our heads in shame over the death in New York, September 16th, of Dr. George W. Lindheim, a Red Cross surgeon. Early in September he passed through Cleveland in charge of a train having on board the sick of the eighth New York volunteers. The superintendent of the Huron Street Hospital and several physicians were at the station, saw the sick on the train, and said it was a crime not to put them in hospitals here. Dr. Lindheim said he had them all well in hand, and as they had come so far and were so near home it would be best to continue. For this, our local papers and some physicians criticised him most bitterly and unjustly. Not a man under his care died, as the sequel shows, but heroic overwork and worry over the unjust attacks upon him emanating from this city so undermined his health that he became infected with typhoid fever, and died raving against his unjust accusers. It is no exaggeration to say that Dr. Lindheim was murdered by the sensational journalism of the day.—*Cleveland Journal of Medicine.*

Boo-hoo Fever.—Dr. Walter F. Robinson describes, in the *Albany Medical Annals*, a peculiar complaint closely resembling epidemic influenza, which attacked nearly all the troops recently sent to Honolulu. There were pains in all the bones, especially in the small of the back; generally severe headache, coated tongue, loss of appetite, and some little fever. The attacks lasted, as a rule, two or three days, and then the patient would feel as well as ever. One symptom, which was almost constant, was mental depression and discouragement. The soldier would lose all his courage and interest in his duties and in the army in general. All his good spirits would desert him, and he would only mope and wish to be sent home. This condition was so peculiar and characteristic that the disease received the name of the "boo-hoo" fever, and as such is known all over the island. Strangers are very apt to be attacked with it, and its cause Dr. Robinson thinks is to be ascribed to the new climatic conditions in which the system of the patient finds itself. On this account the disease is sometimes called climatic fever.

A Memorial to the Late Dr. Greig Smith.—The new operating-theatre for the Bristol Royal Infirmary, erected as a memorial of Dr. Greig Smith, was opened recently at a meeting presided over by Mr. Richardson Cross, ophthalmic surgeon to the infirmary. In opening the proceedings, Mr. Cross said that the infirmary was, with the exception of Addenbrooke's, the oldest provincial hospital in England. Sir William MacCormac delivered an address, in the course of which he compared the appalling mortality from sepsis in the Franco-Prussian and American civil wars with the comparative immunity from such complication in recent times.

Examination of Acting Assistant Surgeons.—At the breaking out of the war the army medical department, not having made provision beforehand, was obliged to employ a large number of contract surgeons on the strength of letters of recommendation, there being no opportunity to prove their fitness by an examination. Now, however, that the press is over, it is intended to convene a medical board to examine all now in the service, as well as any others who may make application for appointment.

The American Medico-Psychological Association.—The next annual meeting of this association will be held in New York, on Tuesday, Wednesday, Thursday, and Friday, May 23 to 26, 1899. The officers of the association are: *President*, Dr. Henry M. Hurd, Baltimore, Md.; *Vice-President*, Dr. H. A. Gilman, Mt. Pleasant, Iowa; *Secretary and Treasurer*, Dr. C. B. Burr, Flint, Mich.

Lost on the "Mohegan."—Among those lost in the wreck of the Atlantic liner *Mohegan* off the Manacles was Mr. John Fallows, a young laryngologist of London, who was acting as medical attendant to a patient coming to this country.

Medical Society of the State of New York.—The business committee of the Medical Society of the State of New York for the coming meeting, which is to be held in Albany, January 24, 25, 26, 1899, consists of Drs. Willis G. Macdonald, Albany, chairman; Edward B. Angle, Rochester; and James M. Winfield, Brooklyn. Members desiring to present papers should notify the chairman of this committee.

The American Academy of Railway Surgeons.—The next session of this society will be held in October, 1899, at Omaha, Neb. The newly elected officers are as follows: *President*, Dr. W. W. Grant, Denver, Col.; *First Vice-President*, Dr. J. F. Pritchard, Manitowoc, Wis.; *Second Vice-President*, Dr. J. P. Lord, Omaha, Neb.; *Secretary*, Dr. T. B. Lacey, Council Bluffs, Iowa; *Treasurer*, Dr. C. B. Kibler, Corry, Pa.; *Editor*, Dr. Fred J. Hodges, Ashland, Wis.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 3, 1898.

EDWARD G. JANEWAY, M.D., PRESIDENT.

THE meeting was in charge of the section on general surgery.

The Radical Treatment of Hypertrophy of the Prostate.—DR. EUGENE FULLER presented a paper on this subject (see page 721).

Personal Experience with Bottini's Operation for the Radical Cure of Hypertrophy of the Prostate.—DR. WILLY MEYER contributed this paper. (To be published in a future issue.)

DR. R. F. WEIR opened the discussion by saying that the reader of each paper had suggested methods which were novel and comparatively untried. The cutting operation of McGill had been modified by the speaker by the addition of persistent siphon drainage, and since this had been done he had not had any mortality and the benefit had been fair. The operations of Fuller and Alexander seemed to him to be founded on good surgical principles, but he could not help looking askance at the Bottini operation. When first proposed, twenty years ago, it had excited a good deal of enthusiasm, but then, as now, it was largely done by one man. Dr. Gouley had strongly advocated it in this country. The reason there was not a more general following seemed to him still to obtain, *i.e.*, the liability to infection from the burn in a part of the body where it was difficult to maintain antisepsis and asepsis. Such a wound was comparable to those made in the mouth, and there was always liability to infection, no matter how carefully the bladder was washed out prior to operation. Although, of course, Dr. Willy Meyer had done the operation only in a small number of cases—twelve—nevertheless the mortality in these twelve was by no means small.

DR. FRANK HARTLEY said that in performing prostatectomy he had never injured the urethra. When the bladder was not atonic and the urethra not injured before operation, he did not establish drainage except through the catheter. His experience with castration and with ligature of the vas deferens had been very poor, as he had seen little or no benefit from these procedures. He relied upon excision of the prostate, either by the Zuckerkandl incision or by the method advocated by Dr. Fuller.

DR. S. ALEXANDER would not say that either prostatectomy or the Bottini operation should be recommended for the relief of prostatic obstruction with the hope of accomplishing a good deal in every instance. Surgeons did not always seem to realize how little was actually known concerning the pathology of the prostate. Dr. Fuller, for example, had stated this evening that the glandular variety was the least common form of enlargement. In an investigation begun by himself some ten years ago, he had collected specimens of one hundred and six prostatic enlargements, together with their clinical histories, and a study of these cases had taught him that the earlier the prostatic enlargement the more likely it was to be glandular, and that the large horny prostates were really due to secondary changes as a result of passive congestion or of secondary inflammatory disturbance in the prostate. This meant that the glandular form was the most common in the earlier stages, and it brought up the important question, "Are we not justified in recommending prostatectomy earlier and more frequently than heretofore?" In reply to this question, he would say that he thought we would ultimately come to regard prostatectomy as the rational and proper surgical procedure to be offered to the patient, just as in the case of a benign tumor elsewhere which was liable to lead to much discomfort or to endanger life. Undoubtedly the earlier the operation was performed the better the result, as to both the vesical function and the mortality.

His Method of Enucleation.—The best method of enucleation of the prostate was at present an open question. So far as his experience went, he had succeeded better with the perineal route than with the suprapubic incision. It had been said that the perineal operation took longer and was attended with greater hemorrhage. Such a statement must be the result of a misconception of the method of performing the operation recommended by him. He made a cross-incision from one tuberosity to the other, dissected down underneath the membranous urethra and prostate, and made his enucleation without opening the urethra. He then drained entirely through the urethra by catheter. The membranous urethra was perforated and cut down to the apex of the prostate. With the finger passed down to the apex of the prostate as a guide, a bistoury was introduced, and made to cut underneath the posterior isthmus; then, the line of cleavage which separated the lower portion of the prostate and the lateral lobes having been found, the enucleation could be easily and rapidly performed. He had operated in fourteen cases in this way, with two deaths and one case of severe hemorrhage. Recently he had tried to operate without the suprapubic incision, selecting for the purpose two lean subjects, in whom suprapubic pressure could be easily made. He had succeeded in both instances, and had checked the hemorrhage by the insertion of a "shirted cannula." Both patients were sitting up on the tenth day, the wounds of both were healed in three weeks, and they were able to empty the bladder completely. Of the two deaths, one was from acute uræmia, and the other from a general septic condition. The other patients recovered within five weeks. One man had incontinence for six weeks, and at times since then after having indulged in alcoholics. The others had continued to empty their bladders satisfactorily, and had good control over the bladder. The method advocated by him seemed important, because it saved the muscular fibres lying over the trigonum. His studies had taught him that the preservation of these fibres had much to do with securing thorough evacuation of the bladder. Regarding the cases of obstruction without an enlargement of the prostate impinging upon the urethra, the speaker said that there would be found accessory prostatic glands in these cases in the region of the trigonum. These interfered with the muscular structures at this point, and so prevented complete emptying of the bladder.

DR. FULLER, in closing, said that he expected the result to be radical after his operation. He agreed with Dr. Alexander regarding the importance of preserving the muscular structures of the bladder. In his opinion, it was a matter of safety to have a suprapubic opening. He had had to make a suprapubic opening after a perineal opening had been established, in one instance, because of very profuse hemorrhage. In a suprapubic operation care should be taken to get the bladder wall up to the abdominal wall, and also not to introduce any instrument into the opening.

DR. WILLY MEYER said that he believed there were in the Bottini operation two dangers to life, viz.: (1) sepsis; and (2) pulmonary embolism. If long incisions were made thrombosis in the veins must be much more rapid and perfect. He could not understand, however, how Bottini, who operated first in the preantiseptic times, had had no death following his operation. It was not uncommon to notice an improvement

in the power to empty the bladder within two or three days after the operation. He thought the advocates of prostatectomy would hesitate very much to subject men of seventy years or over to these cutting-operations, yet even in these old people good results had followed the Bottini operation.

SECTION ON GENITO-URINARY SURGERY.

Stated Meeting, November 8, 1898.

DR. R. H. GREENE, CHAIRMAN.

A Case of Complete Amputation of the Penis for Epithelioma.—DR. S. ALEXANDER presented this case. The patient, A. S——, was forty-five years of age, a Swede, and single. About twenty years ago he contracted gonorrhœa, and about fifteen years ago he suffered from a tumor in the right inguinal region, which was lanced, contents being evacuated; it healed in about two weeks. About two years ago the right testicle became swollen and painful; it gradually increased in size for six months, when it was about double its natural size; then a small pimple appeared on the side of the testicle, which discharged a yellowish fluid. This healed in two weeks, but the testicle did not decrease in size. About four months after another pimple appeared, which discharged for two months. He went into the hospital, where the eruption was entirely healed. In about four months another pimple appeared on the under surface of the penis near the glans, which grew very rapidly, until about a month ago it formed a urethral fistula on the under surface of the penis at the corona. The penis became swollen and a small ulcer appeared on its upper surface; also one on its left side. Examination showed the penis to be swollen, tense, and inflamed. The normal opening of the urethra was closed, the urine passing through a fistula on the under surface near the corona. A large ulcerating surface was present on the left side of the glans, also involving the prepuce. On the under surface of the glans was another ulcer, which communicated with the urethra. The skin covering the whole penis was indurated. On October 4th Dr. Alexander operated. The parts were rendered aseptic. The scrotum was divided between the testicles, the two parts being temporarily united. An incision was then made in the perineum, and the urethra exposed and dissected out. An incision was then made around the penis, one-half an inch from its base. The penis was then dissected away, the crura being removed from the bone with the periosteal elevator. The urethra was divided in the perineum; its remainder with the penis was removed, deep sutures of chromicized catgut being used to unite the deeper structures. The urethra was stitched to the skin with the same material. The bladder was drained with a catheter and washed with saline solution. The skin was united with silkworm-gut sutures, rubber tubing being used to drain the upper portion of the wound. A catheter was fixed in the bladder and aseptic dressings were applied. On October 5th the patient suffered considerable pain. On October 12th there was some sloughing in the perineum and the wound in the scrotum had separated. On October 13th the patient passed water unaided.

DR. ROBERT H. M. DAWBARN thought a prettier result could have been obtained if the operator had adopted the Hilton-Rosa method, which avoided the cutting of the scrotum.

Vesical Calculus with Hairpin Nucleus; Removal with Lithotrite.—DR. S. ALEXANDER presented this specimen.

A Case of Iliac Adenitis.—DR. R. GUITÉRAS presented an Italian, twenty-six years of age, a gardener by occupation. Five years ago the man had had malaria, an acute attack, with enlarged spleen. Since then he had never felt well. Three months ago he noticed a swelling in the right iliac region, and ten days later a swelling in the right groin appeared. He continued his work for a few weeks, when, the swelling becoming painful, he entered the hospital. Examination revealed a swelling below Poupart's ligament, and above this ligament was found a tumor, about two and one-half inches long and one and one-half inches wide; it was exactly under the inguinal canal. He gave no venereal history. The external genitals were normal. There were no lesions in the epididymis, perineum, or anus. The urine was normal. The lymphatic glands in the epitrochlear, groin, and cervical regions were all enlarged. The blood on examination showed anæmia. The question now was: "What is the matter with the man?" In the first place, the question of an incarcerated hernia might have been considered; secondly, a tumor in the inguinal canal; thirdly, an appendicitis. The tumor was a little below the region of the appendix; but sometimes an abscess pointed even below this point. The question of a psoas or iliac abscess might have been brought up. At some time the swelling below Poupart's ligament probably had had some connection with the swelling above. The man was operated upon, an incision being made in the line of the femoral vessels. A mass of enlarged glands was found, two and one-half inches long and one and one-half inches wide. After the groin glands were extirpated an incision was made through the inguinal canal, but no tumor was found there; the cord appeared normal. But just below the transversalis fascia a tumor could be felt, which was thought to be an extension of the inflammation from the lymphatics in the groin; it was about the iliac vessels. The incisions were all sewn up. The tumor afterward gradually diminished in size. When the patient came to the hospital the temperature ranged from 99° to 102° F.; the pulse ran from 76 to 98. As soon as the operation was done the temperature fell to normal. Since then the patient had been on tonic treatment, and had been up and about some time. This was an interesting case, because tumors above Poupart's ligament were rare, few of them occurring in connection with the trouble in the groin. The pathologist's report was that it was a simple adenitis.

DR. HERMANN KLOTZ thought that malaria was a possible cause of this swelling. One occasionally saw suppurative adenitis in the large glands in the muscles of the abdominal wall. This enlargement of the iliac glands is probably seen when there is an extirpation of the superficial glands.

A General Consideration of the Contributing Factors in Hæmaturia.—DR. WILLIAM K. OTIS read a paper with this title. Every hemorrhage of the urinary apparatus resulted from the extravasation of the blood as a whole, or of blood corpuscles, or of the blood pigment alone. The cause lay in increased blood pressure or in changes in the vessels, or in a combination of both. Hemorrhages of the urinary apparatus resulted, therefore, in inflammatory processes, in the exanthemata, in scurvy, and through erosions of vessels in ulcerative processes and neoplasms. Among the more common causes of hæmaturia were stone, including gravel and acid crystals, tumors and tuberculosis and inflammatory conditions, cystitis, nephritis.

Stone in the Bladder.—This caused hemorrhage, either by directly injuring the mucous membrane by its movements induced by more or less violent efforts on the part of the patient; or, as Dr. Guyon had proven, by the presence of the stone alone, which caused a chronic congestion of the mucous membrane. It might also cause hemorrhage, either by its passage through the ureter or by its retention in the pelvis of the kidney. The scratching of the mucous membrane

of the ureter caused bleeding, which was the first symptom of an attack, and patients who had had previous attacks of hæmaturia knew that this bleeding prognosticated an attack of kidney colic. As a rule, however, bleeding did not occur until the gravel had passed into the bladder, and then the hæmaturia was usually of short duration. When the stone was too large to pass and remained in the pelvis of the kidney, hæmaturia was caused in the same way as when it was in the bladder; *i.e.*, by movements of the patient and by the ensuing congestion of the mucous membrane. The hæmaturia in these cases was notably increased by exercise and ceased on repose; but such was not always the case, some patients bleeding profusely even when at rest, probably because the stone was engaged in the pelvis and calyces, which prevented laceration of the mucous membrane. These latter hemorrhages usually were not very profuse or of long duration.

Tumors of the Bladder. — Benign tumors might cause hemorrhage, simply through the presence of a foreign body. Malignant tumors caused hemorrhage by ulceration of the blood-vessels. Renal hemorrhage, as a rule, began spontaneously, was unaccompanied by pain, and uninfluenced by either movement or rest. It was apt to be more abundant than when caused by stone. The duration and intervals between the hemorrhages were very irregular.

Tuberculosis.—When the hemorrhage was due to tuberculous ulceration it could be differentiated from that caused by other neoplasms only by bacterial examination of the urine for bacilli, by the discovery of tuberculous foci in other parts of the body, or by the injection of Koch tuberculin, which gave rise to the characteristic reaction.

Cystitis and Nephritis.—Hemorrhages might occur in either acute or chronic cystitis or nephritis, and were rarely of much severity; the clinical features of either of these diseases would readily determine the cause of the bleeding. The speaker believed that there must be some contributing factor in most hæmaturias, in addition to the lesion by which they were actually produced, to account for the curious intervals which are often noted between the hemorrhages, and also to account for hemorrhages occurring irrespective of motion or rest on the part of the patient and other conditions referred to. He thought this factor to be undoubtedly congestion. Congestion alone, without other lesions, was capable of producing hæmaturias, as seen occasionally in pregnancy, or in obstructive valvular disease of the heart, or in cases of retention of urine, especially in the first retention of prostatics.

Dr. Hermann G. Klotz reported the case of a man, seventy years of age, who had severe hemorrhage in the bladder; when the bladder was opened, nothing was found but a bleeding vein.

Dr. Charles W. Allen was glad to hear the remarks made about congestion alone being a possible cause of hæmaturia. It was a fact that one occasionally met with hemorrhages which could not be classified, according to the clinical symptoms or by ordinary means of investigation, as due to any of the well-recognized causes.

Dr. Pedersen referred to a patient who had hæmaturia more after resting than when he was up and moving about. The diagnosis made in this patient was that of recurrent attacks of crystals in the ureter, with a probability of a renal calculus—possibly a large calculus filling the pelvis and calyces so that the moving about of the patient did not have much effect upon the stone in the kidney. The cystoscope showed hemorrhage coming from the right ureter, which corresponded to the side causing the patient the sensations of pain and discomfort whenever he had these attacks of hæmaturia.

The chairman, Dr. Greene, referred to a form of hæmaturia which was extremely rare. A patient applied to him with a history of hæmaturia, which was proven to come from the left kidney. This condition began one year before the man came under his observation, the attacks being about one week apart at first; later it increased in frequency. The patient lost in weight and was compelled to give up his business. A diagnosis of stone in the bladder had been made by one of the most expert diagnosticians in this country. Operation had been performed upon the left kidney, but no stone found. A history of syphilis had been overlooked by his medical adviser. He was placed upon inunctions of mercury, with the result that in two weeks' time the hemorrhages ceased. When the inunctions were stopped the hæmaturia returned, only to disappear when the inunctions were resumed. Diagnosis was made of gumma of the left kidney. Isreal, of Germany, had reported two such cases; he removed the kidneys and found gumma present.

Dr. Charles H. Chetwood, referring to Dr. Pedersen's case of hemorrhage occurring more during rest, said that accumulations of oxalate-of-lime crystals in the pelvis of the kidney not infrequently caused hæmaturia; he had seen many cases of this. In cases of hæmaturia from stone in the kidney, patients were often directed to take horseback rides. In case of hæmaturia from oxalate-of-lime crystals, exercise was a means of getting rid of these crystals; during rest they accumulated in larger quantities.

Dr. William K. Otis said it was not strange that congestion played such an important part in these hemorrhages, when the blood supply was considered. In fact, it was difficult to see how any other factor could produce hemorrhage when the lesions remained the same, hemorrhages occurring at irregular intervals and being produced by exposure to cold and too much dinner. As a matter of fact, it had been proven by cystoscopic examination that during hemorrhage there was more or less congestion of the bladder; also that when there was no bleeding the bladder was pale and not congested.

The Use of Mercury Hypodermatically in Syphilis.—Dr. S. S. Jones read this paper. He desired to make a few practical observations upon this method, based upon personal experience in private practice, and to give the results of his endeavor to rid it of its most objectionable feature; namely, its tendency to occasion generally considerable pain and inconvenience, and, not seldom, great suffering, which had caused so many to abandon the method altogether, or else to reserve it for exceptionally urgent cases. In order to prove that this last statement was true, the speaker quoted literature from many authorities. The article by J. William White in Morrow's "System" he thought to be most valuable, as giving not only the author's carefully formulated opinions, but those of many at home and abroad; they showed an immense preponderance of opinion against the method. White said: "It is painful and in many patients excites apprehension and strong objection. It is occasionally though rarely dangerous, and sometimes rapidly fatal." In summarizing, White further said: "In the light of the evidence presented above, it seems to me safe to assert that the hypodermic treatment of syphilis has not yet shown results which warrant its adoption as a curative method to the exclusion of or in preference to other methods; but, on the contrary, that it has some apparently insuperable advantages and even dangers which render it improbable that it will ever be adopted." Since the first enthusiasm, inseparable from the advocacy of a new remedy or new method, no one, the speaker said, had advocated its routine employment. If the method was as painful and dangerous as many believed, it should never be employed. The bichloride, calomel, the yellow oxide, the salicylate, oleum cinereum,

the bicyanide, the albuminate, were the forms of mercury that had been proposed as best for use according to this method. On account of its solubility and stability most physicians preferred the bichloride. Various methods had been proposed to lessen the pain of injection, such as the combination of cocaine or morphine with the bichloride in solution, or the injection of morphine before injection of the bichloride. The speaker had been led to look with disfavor upon the method from such a consideration of pain and annoyance to the patient, when the necessity for its use in a very critical case of brain syphilis had caused him to seek a method of lessening its disadvantages. In using this method in this particular case, no abscess supervened nor did any serious condition result; but such cases were sometimes attended by severe and prolonged pain and considerable local swelling and soreness. In searching for a solution that would be free from these disadvantages, he had found that a solution of bichloride of mercury and sodium chloride became turbid upon the addition of cocaine, and that the addition of morphine did not relieve the distress; nor was the injection of the turbid solution with cocaine unattended with pain. He had found, however, that if the original solution had a few drops of cocaine solution, representing, say, one-sixteenth of a grain of cocaine, added to it, and the combination was heated to the boiling-point, the mixture became clear; and, if injected while hot and before becoming turbid, occasioned generally no pain at all and seldom any swelling. It had been stated that cocaine was destroyed by boiling, but the fact remained as stated. The speaker showed a tablet he had made, consisting of bichloride of mercury and chloride of sodium, of each one-fourth of a grain, with one-sixteenth of a grain of cocaine, which he had used in a number of cases without the slightest inconvenience to the patients. Speaking briefly, he believed the method superior to all others when danger threatened organs whose functions were vital or important, as in those lesions which attacked the brain, the heart, the eye, or the ear; secondly, in cases of ulcerations which resembled tuberculous or malignant disease, especially of the tongue; thirdly, in all cases in which other methods were not tolerated or when time was valuable. In regard to the technique of the operation, the speaker believed the directions given by Bloxam, as quoted by Hutchinson, all excellent and adequate while not too complicated. "In order to prevent irritation abscess, the injection should be made into muscle and not into cellular tissue. The needle should always be washed after the syringe has been charged, so that none of the fluid may touch the skin during introduction." The speaker believed the most eligible sites for these injections to be in the cellular or muscular tissue between the scapulæ and iliac crests.

Dr. Charles Warrenne Allen said he was glad to hear Dr. Jones' paper, although the suggestion of incorporating cocaine was not entirely new to him, and Dr. Jones had told him some time ago of his success with it. He had not used this method himself, because he had never felt the necessity for its use. The injection of the bichloride of mercury occasionally gave pain, and sometimes gave rise to quite severe pain at the time of injection; and, again, it might give rise to quite alarming symptoms. In one case the speaker referred to, a strong man turned deathly white, with great oppression in the chest, and it was surmised that some of the injection had entered the circulation through the penetration of a vein by the needle. He thought the whole subject of the injection of soluble and insoluble preparations of mercury was interesting from many standpoints. In 1882 he began using the albuminate of mercury. At the City Hospital ten years ago he used the benzoate and the salicylate of mercury, but was not favorably impressed with them. The speaker said he had never believed in calomel, and to-day believed in it less than ever before. The mere fact of a possibility of embolus should put us upon our guard in the use of this method; there were many reports of death from this cause, especially from France, and he thought there were many cases of death from this cause that were not reported. This danger alone he thought sufficient to make us give up the use of calomel. Yet he knew many men in this city and elsewhere who swore by it. In using bichloride of mercury with salt, he had had only three abscesses result; these injections were given in the cellular tissue, whereas they ought to have been placed deeply in the muscles. The third case was in a strong man, who received the injection in his buttocks; a number of injections gave rise to indurations, and one of these had broken down, resulting in a troublesome abscess. In looking over his case book at the dispensary the day before, he had found twenty-nine cases in which the injections had been recorded as being used, since last January; these did not comprise all the cases, because in many the treatment was not put down. He had used this method in private practice, and had the histories of a number of cases in which it was of marked benefit; so that he must put himself on record as being in favor of the intramuscular injection of the bichloride. The speaker said he would like to call attention to such instances as he had had in private practice, in which patients came to his office after having taken the protiodide or other preparation of mercury internally, and who presented a most deplorable condition, with furred tongue, possibly slight salivation, diarrhœa, etc. Stopping all internal treatment at once and placing the patient on one-half-grain doses of bichloride, injected into the buttocks, would within twenty-four hours be followed by relief, and the patient would come back and say that it had done him a wonderful amount of good; and this, too, without his having had anything to stop the diarrhœa or relieve the other disturbances caused by mercury giving by the mouth. Dr. Allen said he had treated a number of brain and spinal-cord syphilitics, and in two cases he had had remarkable success; he could not speak too highly of the treatment by injection, especially when the absorbent organs were not in condition to do their work. In regard to the element of pain, in his dispensary work the patients were not told that they would suffer pain; when asked after injection if they had pain, they answered No. Many on their return, when asked if they had had pain at any time after leaving the dispensary, made the same answer. He would gladly try the cocaine as advocated by Dr. Jones, but it was hard to tell beforehand which injections would prove painful.

Dr. Lapowski said that the injection of the sublimate solution, even in small amount, would produce pain in some patients; he considered this an idiosyncrasy. In his experience in hospital, cocaine, if used in the way mentioned by Dr. Jones — the solution being boiled and injected while warm — and given to a nervous woman, would always cause a certain amount of pain. This was not so in dispensary practice. If the veins were affected and injections were used, we might have an embolus. In hemorrhagic syphilis he never used the hypodermic injection. In old age one of the most important conditions to consider was that of the kidney. In regard to insoluble solutions, the speaker said that if he had to choose between the sublimate and calomel to make a differential diagnosis, he would always choose calomel. If one used the sublimate injection, two hours afterward mercury would be found in the urine, and most of the injection would surely pass through the system in twenty-four to forty-eight hours. In regard to abscess formation, it had been reported recently

that 176,000 injections had been made and only twelve abscesses had resulted. Abscess formation was certainly not so common as some are led to believe. He thought a great disadvantage in giving the insoluble form of mercury hypodermatically was that it was never known just what amount of mercury was in the system.

Dr. Hermann G. Klotz said that he had used injections of bichloride and bicyanide of mercury twenty years ago in private practice and lately in hospital practice, and was satisfied with the results obtained. There was but little danger connected with injections of soluble salts. He related the history of one case in which severe symptoms followed. The patient had an enteritis with hemorrhage which lasted for several days and was difficult to stop. The speaker had never used cocaine. The bichloride injection was painful for two or three hours. To be effective, the injections should be made every day. He thought the bichloride was especially useful in the condylomatous stage. The bicyanide was much more effective in the later stages, especially in the skin and mucous-membrane lesions. In regard to the insoluble injections, he had made a report of two hundred injections in 1889, which had been published in the *Journal of Cutaneous and Genito-Urinary Diseases;* he also had read before the American Association of Dermatologists a report of eleven hundred injections made in one hundred cases in private practice. The reports of the cases he hoped to publish some time in the near future. He said he had watched the effect of insoluble injections on the kidneys, and had also carefully watched the urine. He remembered one case in which albumin was repeatedly found in the urine in a strong patient; the injections were stopped and the albumin disappeared, only to return when the injections were resumed. Later the albumin did not appear again. Salivation was not a rare occurrence after injection of the insoluble salts. If salicylate of mercury was used, he did not think salivation would occur; it was different with calomel. His experience with emboli of the lung was limited to eight cases, all of which ended in recovery without serious consequences. He had never seen abscesses after the injection of a soluble salt, except small circumscribed abscesses of the skin. Abscess of the skin would never occur if it was scrubbed with alcohol and hot water.

Dr. Mason wished to mention one practical point in regard to the pain. It was in reference to the manipulation of the point of the needle after the injection was made. The needle should be so manipulated that the material injected would be diffused, which lessened the pain very much.

Dr. Robert H. M. Dawbarn wished to make one point in regard to boiling the solution. He had seen the assertion made that when the cocaine solution was brought to the boiling-point the cocaine turned to ecgonin, which was not analgesic. He now injected morphine, and, after waiting a few minutes, injected the solution. The discomfort depended largely upon whether the injection had been superficial or deep. He thought that doctors made a mistake in pinching up the skin previous to inserting the needle; the injection should be made directly into the substance of the muscle. He was surprised that no mention had been made of Kaposi's hydrargyrum oxidulatum tannicum, one-half mercury, in powder. In alkaline blood this was slowly decomposed.

Dr. Charles H. Chetwood said that Dr. Keyes believed in the hypodermatic injection of mercury, and used it a great deal. The speaker had given up calomel on account of abscess, which so often formed. The bichloride caused too much pain. For five or seven years he had used a preparation of salicylate of mercury, in combination with benzoinol—three grains to the drachm. He gave it once, twice, or three times each week. There was no preparation the speaker had used that gave less pain. During the past seven years, using this in a great many cases, he had never seen an abscess form. Many women were hypersensitive to pain, which might account for many complaints. He had never known an embolus to occur; neither had Dr. Keyes. He had used this preparation in brain and spinal syphilis with success.

Dr. R. H. Greene was familiar only with the bichloride, and the only objection he had to its use was the pain it gave rise to. He injected it into the gluteal region and as deeply as he could. During the past ten years he had never had an abscess follow. It was more or less of a nuisance for the patient to come to one's office every day for his hypodermic.

Dr. S. S. Jones said the use of the calomel was good, for the drug was gradually absorbed and the danger attending its use was not large.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

One Hundred and Forty-First Regular Meeting, Held on Friday, October 14, 1898.

Dr. W. Gilman Thompson, President, in the Chair.

A Brief Account of Bad Nauheim and its Methods.—Dr. George L. Peabody presented this paper (see page 730).

Dr. C. L. Dana said that during the past two years he had had some experience in the application of the artificial baths here in New York, largely in cases of locomotor ataxia, in which disease the baths at Bad Nauheim had acquired some repute among German neurologists. The speaker said he had not been able to convince himself that the Nauheim baths, as administered here, did any more good in this disease than ordinary lukewarm baths. Some relief of the sensory symptoms was experienced, as after ordinary baths. In two cases of tachycardia, apparently due to defective innervation of the heart muscle, the baths did not produce any improvement. In one or two cases of severe valvular disease complicating some nervous trouble there was also no improvement. The only cases which had been benefited by the baths were of insomnia and neurasthenic symptoms. In this class of cases they seemed to produce a more soothing effect than the ordinary lukewarm baths.

Dr. Peabody, in closing, explained that the baths at Nauheim were always administered in wooden tubs; this was done because the salts contained in the water would act on metal tubs. The attendant who gave the bath carefully followed the instructions of the patient's physician as to the duration and kind. There were chiefly two kinds of baths administered, *i.e.*, the thermal, which contained little free carbonic acid; and the sprudel, which consisted of the natural water of the place with all its free carbonic acid. The patient remained in the bath from four to fifteen minutes, according to the instructions of his physician, the rule being gradually to lengthen its duration. During the bath the patient remained perfectly quiet; he was then dried by the attendant and instructed to go to his room and rest for an hour or two. The temperature of the water of the baths ranged from 85° to 95° F. They gave rise to a feeling of fatigue out of proportion, seemingly, to the heat of the water. They were usually administered in the forenoon. The thermal baths were the ones which were generally taken during the early course of the treatment, and after fifteen or twenty had been taken the sprudel baths were substituted. A bath was taken once daily for two consecutive days,

and then a day's rest was advised. Some hours after taking the bath a skilled attendant called on the patient and administered massage; this was at first very light, consisting of centripetal movements, the idea being to assist the muscles to send the blood to the heart. In addition to this, the patient was instructed to make voluntary movements with the head, body, and extremities in every conceivable direction, which movements were gently opposed by the attendant. For example, the arm was raised to a horizontal position against gentle opposition, etc. If the patient developed intermission of the heart as the result of any special form of muscular movement, then that special movement was omitted. The exercises were continued for from fifteen to thirty minutes, with intervals of rest, and afterward the patient was again instructed to rest for an hour or more. There were few restrictions on the patient's diet. He was supposed to eat well and was permitted to drink a white Mosel wine; red wines, Rhine wine, and the stronger liquors were forbidden. Coffee was also tabooed, as were frequently also sweets; whether a man was allowed to use tobacco or not depended somewhat on his own condition and somewhat on whether his attending physician was a smoker. The course of treatment lasted from five to six weeks. As regarded the altitude, Bad Nauheim was about on a plane with Frankfort, which was at the sea level. The treatment was regarded as particularly efficacious in cases of cardiac dilatation and enfeebled muscular conditions, with or without valvular lesions. In cases of angina pectoris it apparently often proved very effective, affording relief which lasted for long periods of time. There were twenty practising physicians at Bad Nauheim, and as no two of these gave the treatment in exactly the same way, it must be regarded still as somewhat empirical. In those cases in which there was increased arterial tension, the pulse became softer and more compressible. The treatment was not recommended in cases of advanced nephritis or aneurism.

Value of Blood Examinations in Malarial and Typhoid Fevers.—In a general discussion of this topic the president, Dr. W. Gilman Thompson, said that during the past six weeks he had seen about two hundred patients, many of them soldiers, who had been brought to the Presbyterian and Bellevue hospitals with malaria or typhoid, or both. Among the malarial cases, the æstivo-autumnal type was very common, and by the time the patients reached the hospital the fever was more or less continuous and typhoidal in character. In the diagnosis of such doubtful cases, material aid was afforded by blood examinations. Among the two hundred cases, there were seventeen of undoubted mixed infection. In such the typical course of typhoid would occasionally be suddenly interrupted by a chill and sudden rise of temperature, and the malarial plasmodium in some form or other would be found in the blood. An interesting question arose in connection with these cases, namely, to what extent the malarial infection influenced or modified the typhoid condition. The speaker said his own experience had been that in the majority of instances the plasmodium remained quiescent during the course of the typhoid fever or until a few days after convalescence began; the effects of the malarial poison then became manifest. In exceptional instances, however, the malaria manifested itself during the active course of the typhoid fever. In one case, originating in New York, which Dr. Thompson reported before the Association of American Physicians in 1894, the patient, who was suffering from undoubted typhoid, as evidenced by the clinical picture—pyrexia, rose rash, hemorrhage from the bowels, etc.—suddenly developed a violent chill at the end of the second week, followed by a temperature of 107° F. Malarial infection was suspected, and an examination of the blood disclosed the plasmodium. The patient had several subsequent chills, followed by fever, which were controlled by quinine, given hypodermically. The typhoid fever pursued its usual course, defervescence occurring in the fourth week by lysis. Dr. Thompson showed the temperature chart of a case in which the malaria did not develop until the typhoid had run its course; after convalescence was established the patient had a chill, followed by high fever, and on examination pigmented bodies were found in the blood. In another case, which acted in the same way, there were abundant organisms of the tertian type. In a case at Bellevue seen last year, the malarial plasmodium was found in the blood seven days after the onset of typhoid fever; the diagnosis of the latter disease was established beyond a doubt by a hemorrhage from the bowels, rose rash, and so on, and later by the Widal serum reaction. A similar case, that of a soldier from Cuba, was recently seen at the Presbyterian Hospital, in which the patient developed a violent chill during the active course of a typical typhoid fever (with Widal reaction), followed by a temperature of 107° F.; the chill was apparently not the result of cold baths, as the patient had received no such bath for two hours previously. It was regarded as malarial, but as an examination of the blood proved negative no quinine was administered. Subsequent to this the temperature pursued an irregular course, which was partly attributed to a pneumonic process in the lung. During the sixth week, after convalescence was established, the man developed another violent chill, and at this time organisms of the æstivo-autumnal type in various stages of development were found in the blood. The malaria continued for some time, until it was controlled by quinine. Dr. Thompson said he had no doubt that the chill which developed during the active course of the typhoid fever in this case was also malarial. These cases were very satisfactory when one succeeded in finding the plasmodium, as it relieved the mind with reference to the possible presence of a septic process. The speaker said that an important question to decide in connection with the Widal reaction was how much reliance should be placed upon its presence or absence. When it was present and had been obtained by accurate methods, *i.e.*, with the combined time test and 1 to 40 dilution, it might be regarded as absolutely positive proof of typhoid. At the June, 1898, meeting of the American Medical Association, the committee appointed to investigate this subject reported that in over four thousand cases of typhoid fever in which this serum test had been applied it gave a reliable reaction in about ninety-five per cent. In the remaining five per cent. the result was unreliable. The absence of the reaction, however, did not prove conclusively that the disease was not typhoid. In some cases the reaction could not be obtained until the third week, or even until convalescence was established or a relapse had occurred. In three cases tested by the health board in this city, curious results were obtained, the reaction being found in the early stages of the disease, but not in the later. One decided drawback to the serum test was that the reaction might be found so long after an attack of typhoid fever.

Dr. Peabody said that in former years, before much was known about the plasmodium malariæ or anything about the Widal test, he had seen cases of typhoid fever in which late in the course of the disease the patient would develop a sharp chill, followed by high temperature. The large majority of those patients got well without quinine and showed no subsequent symptoms of malaria. In one case the chill was septic in character and eventuated in fatal septicæmia. At the autopsy the kidneys were found studded with abscesses,

the infection having spread there from the intestinal ulcers. Of course, if in a case of this kind the plasmodium was found in the blood, it proved almost beyond a doubt that the chill was malarial in character; but the fact that in former years these patients occasionally recovered without quinine, and that they had no antecedent or subsequent history of malaria, seemed to him to justify the belief that some other cause than malaria must be supposed to exist in some of them.

Dr. John W. Brannan said that his experience in the treatment of the sick soldiers at Bellevue had been similar to that of Dr. Thompson, although less extensive. The majority of the patients had come from Cuba by way of Camp Wikoff, and were suffering from either typhoid or malaria, or a combination of both. In some of the cases the malaria was the primary disease, and during its course typhoidal symptoms developed, the existence of the latter disease being subsequently proven by the Widal test and the usual clinical symptoms of typhoid. After reporting in detail a case of this character, the speaker called attention to the importance of keeping the malarial patients under observation until the plasmodium had disappeared from the blood and the percentage of hæmoglobin and red blood cells approached the normal. In one case which had been under his care, in which the patient was discharged to a convalescent home when the hæmoglobin had reached seventy per cent. and no more plasmodia could be found in the blood, a relapse occurred three days later and the plasmodium was again found. In the cases he had seen, the anæmia was more profound in the malarial than in the typhoidal patients. In a number of instances coming under his observation, the malarial parasite was found in the blood of patients who had been free from fever for ten days or more and were still taking quinine in full doses.

Dr. Robert Abbe said it was interesting to know from a surgical standpoint that a sudden rise in temperature after operation might be due to the fact that dormant plasmodia had become active. Such a case recently came under his observation. The patient was a soldier whom he had operated on for hernia; his temperature remained normal until four weeks after the operation, and then rose to 101° F., and an examination of the blood revealed the malarial parasites. Dr. Abbe said he had been recently called to operate upon a soldier in a case of perforation of the bowel occurring in the fourth week of malarial typhoid fever. Although the case had been regarded as one of malaria, crescents having been found in the blood, the patient had suddenly developed a severe pain in the abdomen, with other symptoms suggestive of perforation. Twelve hours later, operation disclosed a slit-like perforation of the small intestine, fourteen inches from the colon, close to the mesentery, with a small, clotted vessel, suggestive of an infarction, at its edge. The slit was not in the usual situation of typhoidal perforations, and the adjacent mucous membrane was apparently normal, showing no evidences of that disease. The case was possibly one of mixed infection. An autopsy was not permitted.

Dr. Herman M. Biggs said it was not very unusual to meet with cases like the one referred to by Dr. Thompson, in which the Widal reaction had been obtained once and had disappeared a few days later. The speaker said he knew of a number of instances in which the test was present in a comparatively high dilution, and had then disappeared within twenty-four or forty-eight hours, failing to return. As a rule, however, it persisted for weeks and even months. In regard to the Widal test, it was very important to emphasize the fact that it was a quantitative and not a qualitative test; the Widal reaction not infrequently was obtained in cases which were not typhoid at all, but not in the same dilution. The dilution in which the reaction was secured should always be stated. The failure to obtain the reaction did not in any way exclude typhoid fever, for there were many cases of undoubted typhoid fever in which the reaction could not be obtained until late in the course of the disease, or even until a relapse occurred. When the reaction was obtained in a dilution of 1 to 20, it was almost pathognomonic of typhoid fever.

Dr. Thompson said that at the Presbyterian Hospital the Widal tests had been made by the pathologist, Dr. George A. Tuttle, a 1 to 40 dilution having usually been employed, and ranging from that to a dilution of 1 to 10. The reaction was obtained in a number of very mild cases of fever, possibly "walking" typhoid. In corroboration of the remarks made by Dr. Abbe, Dr. Thompson cited the case of a man who had been an inmate of Bellevue Hospital since last February (nine months), confined to bed throughout, under treatment for a Charcot knee. Recently he developed chills and fever, and malarial parasites, of the ordinary tertian variety, were found in the blood in large numbers. These had apparently been dormant for a long time. Dr. Thompson said he agreed with Dr. Brannan that anæmia was a very pronounced symptom of the æstivo-autumnal type of the Cuban malaria, especially when the patients were seen late in the course of the disease. In the soldiers it had been also accentuated by inanition and lack of proper food.

Dr. James Ewing, who had recently spent several weeks at Camp Wikoff, said he would like to call attention to some of the limitations of blood work in cases of undoubted malarial infection. He had commenced his work in the camp hospital, with the idea that in every case of acute malaria in which no quinine had recently been administered the malarial parasite could be found in the blood; after five weeks' work he had been forced to the conclusion that it was possible for a man to die of acute malaria of the æstivo-autumnal type without the plasmodium being in the blood in sufficient numbers to be detected by a careful examination. In one case coming under his observation, a diagnosis of typhoid fever was made after repeated examinations of the blood had failed to reveal any malarial parasites. The patient died, and an autopsy revealed no typhoidal lesions, but a moderate grade of malarial infection; there were no malarial organisms to be found in the blood after death, but smears from the spleen and marrow showed a moderate number. This patient had originally been treated with quinine, but had received none of this drug for several days before death. The absence of the organisms in some cases could be explained by the tendency of the ring-shaped bodies to disappear during the third and fourth days of the paroxysm. This was distinctly shown in many cases, in one of which, after a very violent seizure, an enormous number of the ring-shaped organisms were found in the blood. The patient was given small doses of quinine, three grains t.i.d., and the organisms were entirely missing on the second and third days, after which the young crescents made their appearance in large numbers. The speaker said that in nine cases of dysentery he had found the amœba dysenteriæ in the stools and malarial parasites in the blood. In examining the blood for the malarial organisms, Dr. Ewing said he had often experienced considerable difficulty in discovering the early ring-shaped forms of the æstivo-autumnal type; unless they were stained very sharply, they might easily be overlooked. Much had been said about the extracellular forms of malarial organisms; the speaker expressed the opinion that a diagnosis of malaria could not safely be based by any one on the presence of these large pigmented extracellular bodies, as they were very difficult to distinguish from cystic leucocytes.

Clinical Department.

WOUND OF THE EYELID.

By I. D. STARR, M.D.,

JAMESTOWN, IND.

On August 29th, a girl, aged two years, was kicked by a horse. She suffered a wound of the upper eyelid, one-fourth inch from the margin and extending from the inner canthus to the outer, entirely exposing the lacrymal gland.

The peculiarity lies in the fact that the wound was as clear cut as an incised wound. There was no other wound or contusion, and neither conjunctiva nor eyeball suffered any inconvenience. Four interrupted subdermal stitches assisted the wound to heal by first intention without scar.

REMOVAL OF OVARIES, TUBES, AND UTERUS FOR VICARIOUS MENSTRUATION.

By FRANK V. CANTWELL, M.D.,

SURGEON TO THE ST. FRANCIS HOSPITAL, TRENTON, N. J.

I submit this case because of the good result and because I have not in my reading happened on a report of operation for this condition. So, until enlightened, I shall claim originality.

Mrs. S——, aged thirty-five, married, has one child, aged ten years. First seen while pregnant with this child. She was then suffering from a severe chorea. After consulting all the specialists within reach—she lived near Philadelphia—she was cured by an old woman of the village.

Several years after, while frying some fat, she was burned on the forearm. An unsightly scar still remains. During several years she vainly sought relief from this affliction. I did not see her during this period, but think from her description that she menstruated vicariously through this ulcer, as it refused to heal. Finally, in despair or faith, she had recourse to Father Mollinger, who at that time flourished, and lo! the ulcer healed and gave no more trouble.

I saw her then in 1897; she was pale, weak, and in bed. Her physician (Dr. W——) told me that he had been called frequently; always at her monthly periods he would find her in collapse, vomiting "quarts" of blood, and suffering agonizing pain. These attacks, with convalescence, would last from five to ten days. During the intermission she would feel well, but weak, until another menstrual period, when she would go through the same storm. She would have normal menstrual flow.

For the third time she was going from hospital to doctor, to quack, without any relief, when I suggested oöphorectomy with removal of the uterus. She readily consented to the operation—anything to get relief.

She was sent to the St. Francis Hospital, Trenton, November, 1897, where I removed the ovaries, tubes, and the uterus low down, leaving only the infravaginal portion. The organs were in a perfectly normal condition. Her recovery from operation was uneventful. She remained at the hospital until after the time for her next menstrual period—about three weeks—when she was discharged cured.

It was with great trepidation that I responded to a call from her house some four months after, but, to my delight, it was to see her boy. She had gained twenty pounds, was doing all her own housework, and since her married life commenced had not been so well or so happy.

At this writing, September 30th, she remains well, except for some little backache. Once she had a slight showing of blood from the vagina.

I will not try to explain the above phenomena, but simply will state that this was a clear case of vicarious menstruation—at first from the ulcer caused by a burn, and then from seemingly a normal stomach, as, other than the blood, there were no symptoms of ulceration. This condition not only destroyed her usefulness but threatened her life. It was a case in which desperate measures were justified and in which the operation was clearly indicated.

A word as to neurosis, whatever that is. From the above history any physician would say: "She is a neurotic; that is the reason she was cured by faith or quackery." But this woman has no indication of hysteria in any form; if she has, I failed to discover it during her residence at the hospital. She is now a level-headed housewife.

I hope that any surgeon or gynæcologist who is consulted in a like case will do likewise. I am satisfied with the result.

TWO CASES OF CHOREA DUE TO EYE STRAIN.

By HERBERT L. STEBBINS, M.D.,

SYRACUSE, N. Y.

After reviewing an article written on chorea thirty years ago, and comparing the theories advanced and the line of treatment prescribed with those of the present day, we find that the medical profession has made but little progress toward the satisfactory solution of this perplexing problem. Rheumatism and malaria were then, as now, generally accepted as the principal etiological factors in its causation. The chronic cases, however, furnish more ample opportunity for research and experiment. Those cases which have extended over a period of months or years, and resisted the usual line of treatment with arsenic, quinine, iron, tonics, galvanism, and hygienic measures, demonstrate conclusively that some organ, or organs, in the physical economy are not performing their functions properly. M. Sée, an early investigator, found the relation between rheumatism and chorea so close as to make their connection almost a pathological law.

A recent observer, however, decided after carefully studying two hundred and seventy-nine cases that only thirty-seven could be attributed to rheumatism, in eighty-two a cardiac murmur could be heard, and in the remainder no cause could be determined. The transitory nature of this neurosis, its intrinsic tendency to recovery with or without treatment, the low mortality, and the presence of no pathological changes that could in any manner explain this peculiar nervous manifestation render investigation extremely difficult and the deductions elicited more or less problematical. While the prevailing opinion among neuro-pathologists seems to favor the theory that this choreic state is due to some toxic agent or principle in the blood, the numerous chronic cases which have been relieved by the correction of refractive errors and muscular insufficiency, after a prolonged course of constitutional treatment, certainly warrant a very different conclusion in certain instances.

The following cases were treated during a period of four months with a diversity of drugs reinforced by galvanism, massage, and hygienic and dietetic measures, with no improvement in one and but slight amelioration of symptoms in the other.

Case I.—Huldah W——, aged nine years. She had an aggravated choreic movement of the head, face, and limbs, with marked impairment of speech and difficult deglutition. This case was referred to me

in August, 1897. Family history: Mother neurotic and myopic. Sister suffered from chorea three years ago. After failing to respond to treatment of several months' duration it was discontinued, and measures were taken to ascertain the condition of the eyes. The refractive errors were corrected and the patient made a rapid and complete recovery. History of case: This patient's parents are in good circumstances, and her environments were all that could be desired. For four months the patient had been suffering from chorea and gradually became worse, although she had received liberal doses of arsenic followed by quinine, tonics, galvanism, and massage. She was emaciated and unable to maintain one position long. Prior to this attack she was an active, healthy child, but for a few weeks had complained of pain in her eyes. When I first examined her she could not go out on the street or play in the yard, as was her custom, without exciting the attention of passers by. Being of a sensitive nature she preferred to remain in the house.

Eye Defects.—On the first visit all medications were stopped. I instilled a four-per-cent. solution of homatropine, but little could be accomplished toward estimating with any degree of exactness the refractive condition of the eyes, on account of the violent muscular contraction of the face, neck, and body. Her mother was directed to return again in three days, which she did, and informed me that the child seemed much more quiet while under the influence of the mydriatic. But as its effects began to pass off she seemed more disturbed. Plus 1.00 D. was ordered. Also, sulph. atropinæ, gr. ss.; aq., ʒ i.—one drop to be instilled into each eye three times a day. She returned to the office in one week very much improved. On examination at this time +0.75 D. in the right eye, and + 0.50 D. in the left eye were found uncorrected. The proper glass was prescribed. One month later she could dress and undress and play with other children. She had but few symptoms remaining, one being a slight twitching of the feet. Shortly after this all symptoms passed away, and she had apparently made a complete recovery. September, 1898, the patient came to my office with her mother, who gave the following history: The patient had made a rapid and complete recovery. Four weeks ago the frames of her glasses became so badly bent that it was impossible for her to wear them, and their use was discontinued for three weeks, when she began to have symptoms of her old trouble. Her glasses were readjusted, and after wearing them a few days she was apparently in good health once more.

Case II.—William O——, aged thirteen years; chorea affected principally his arms and legs. The case was referred to me, August, 1897. Family history: His parents are in fine physical health. His mother has been subject to attacks of muscular rheumatism for years. History of case: He had been suffering for four months from chorea, but when referred to me he was somewhat improved. His physician informed me that although he had prescribed a diversity of drugs and electricity and had looked after his diet and hygienic surroundings, he could not make further progress toward bringing about the recovery of his patient. The general health of the patient had always been good, but for some time prior to this attack he had complained of pain in his eyes and head, which his friends attributed to his studious habits. He spent the most of his time out of school reading. Eye defects: At the first visit the patient had $\frac{20}{20}$ vision with a +0.50 D.; esophoria, 4°; adduction, 40°; abduction, 4°. Plus 0.50 D. was prescribed, combined with prisms of 1° base out. All medication was discontinued. He was directed to return to the office in one week, which he did. He was much improved. Examination developed 7° esophoria. A 2° prism was prescribed, combined with a +0.75 D. for the left eye and a +0.50 D. for the right eye. Two weeks later the patient appeared to have nearly recovered. There seemed but slight weakness in the legs, with no twitching or involuntary movements. He had no headache after he began wearing glasses. He is able to attend school and seems quite well.

WAS IT MATERNAL IMPRESSION?

By A. S. DOLLOFF, M.D.,

BEVERLY, MASS.

I would like to relate the following incident through your valuable journal, thinking it may be of interest to some one.

Mrs. ——, aged twenty-six, during her fifth month of pregnancy, called with a friend upon an old lady who had fallen and sustained a fracture of the hip and was consequently confined to her room, and who, unknown to Mrs. ——, was afflicted with athetosis. The constant movement of the hands made a profound impression upon the latter at the time, and as soon as possible she took her leave. No subsequent discomfort was felt, however, either mental or otherwise, except an occasional flashing of the occurrence through the mind.

After the birth of the child, which was at full term, it being perfectly developed, it was noticed that he had well-marked athetoid movements of the hands, and whenever he became excited mentally these were very much increased. The movements gradually subsided, until when the child was about five months old they entirely disappeared, except when he is under strong mental excitement; at such times he still shows the movements in a slight degree. The child is at present nearly two years old and perfectly healthy.

No such affection had ever appeared previously in any member of the family of either father or mother. Was it maternal impression?

REMOVAL OF THE CÆCUM.

By J. H. CARSTENS, M.D.,

DETROIT, MICH.,

CHIEF OF STAFF AND GYNÆCOLOGIST TO HARPER HOSPITAL; PROFESSOR OF OBSTETRICS AND CLINICAL GYNÆCOLOGY IN THE DETROIT COLLEGE OF MEDICINE; EX-PRESIDENT, AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNÆCOLOGISTS, ETC.

Removal of the cæcum is sufficiently rare, so that every case is interesting and should be reported, in order to clear up all moot questions connected with the technique of the operation and the morbid conditions requiring and justifying the operation.

It is not necessary to enter into a recital of a long list of authors and cases. Two years ago a list showed thirty-three cases operated upon, with a mortality of forty-nine per cent.; this included many fæcal fistulas of a tuberculous nature, which required difficult and complicated operation on the intestines. With our increased power of early diagnosticating cases which require an operation, and also with the bolder surgery of performing exploratory cœliotomy for diagnostic purposes only, we to-day will be able to show a better record. My case briefly is as follows:

Mr. A. E. H——, aged fifty-five, a veteran of the war of the late rebellion, was in good health all these years, except for occasional attacks of rheumatism.

In February, this year, he was taken with pain and distress in the abdomen; some days he would have a sharp attack of colic, and the next day be free from it, but there was no regularity in the attack.

Neither exercise nor variety in diet had any effect

on the attack. It would sometimes occur at night, and awake him from sleep. In the course of two months the attacks became very severe; he would vomit and show symptoms of obstruction of the bowels. The latter were moved with great difficulty, and required the use of strong cathartics or enema.

In the beginning of May the attacks would come on suddenly with excruciating pain, so that he would be doubled up and could be relieved only by hypodermic injections of half a grain of morphine; the attacks simulated those produced by gall stones.

His eyeballs were yellow, the skin was tawny, and certainly gall stones could be suspected. The pain was generally around the umbilicus, a little more to the right, about over the region of the gall ducts.

These attacks increased in frequency—sometimes he would have several a day; inability to retain food became more marked, and his bowels were completely obstructed. When I saw him, June 8th, he had not retained any nourishment longer than half an hour at a time for two weeks, nor had his bowels moved during that time.

Examination: He was a tall man, greatly emaciated; general condition good, except the soreness in the abdomen. Percussion and palpation gave no clew, owing, I think, to rigid condition of the rectus muscles; certainly there was no swelling or tumor of any kind.

I did not make a diagnosis; simply noting that there was obstruction of the bowels somewhere, complicated perhaps by gall stones or renal calculi.

I agreed to do an exploratory cœliotomy and whatever I could to relieve the condition, or, if it was beyond help, to close the abdomen.

He was prepared as usual, and on June 9th, 9 A.M., I proceeded to operate, the patient being under the influence of chloroform.

I made an incision at the outer edge of the right rectus and over the usual location of the gall duct. The abdomen open, I introduced my finger, exploring the gall bladder and duct; found everything normal, reached down to the kidney, and found no stones or any abnormal condition there. Explored downward to the region of the cæcum; I found some swelling and an abnormal condition. This evidently was the seat of the trouble, and I increased my abdominal incision downward two and one-half inches, making it altogether three and one-half inches long.

With retractors, the region of the cæcum could now be thoroughly exposed, and the following conditions were found. The small intestine at its junction with the cæcum was of ordinary size, but above it for eight inches was dilated and immensely hypertrophied, and about the size of the transverse colon. I inverted it with my finger and tried to push it through the ileo-cæcal valve, and there I found the obstruction.

The opening had been reduced to the size of a lead pencil; to overcome the obstruction, nature had kindly produced a compensatory hypertrophy, and the terrible pain was caused by the occasional efforts to empty the ileum. The cæcum was adherent but could be easily loosened; the appendix was lying along its side and adherent to it.

The only thing I possibly could do, it seemed to me, was to remove the whole cæcum and hypertrophied ileum. There was not much difficulty in ligating in sections the mesenteric attachments and removing the whole mass; that is, about nine inches of the small intestine, the whole cæcum, and about two inches of the ascending colon—my object being to remove everything that seemed diseased, as the condition might be malignant.

The small intestine was then joined to the ascending colon by the aid of a Murphy button in the usual manner; the toilet of the peritoneum was quickly made, and the abdominal incision closed with silk-worm-gut sutures, placed by the method of Kehrer, the so-called figure-of-eight interrupted ligatures. The whole operation complete took seventy minutes; the patient quickly recovered from the anæsthetic, and was nourished with beef peptonoid per rectum; nothing was allowed by mouth at first, on account of the constant vomiting he had had.

On the third day, however, he was given a little tea, coffee, and broths; but he developed such a voracious appetite that he was allowed the so-called soft diet, and by the tenth day he was allowed solid food—in fact, he seemed to eat all day and was always hungry. The tenth day the ligatures were removed and he was allowed to get up, and in two weeks he went home.

He has continued to improve, although his appetite has lessened, and a few days ago I heard that he was quite well. The Murphy button was never found. I did not expect to see it before he left the hospital, and instructed him carefully to be on the lookout for it, but he claims that he did not find it. This has happened to me on several other occasions.

I am sorry to say the microscopic examination showed the enlargement or growth to be sarcoma, and consequently we may expect its recurrence sooner or later. In the mean time, however, he is made comfortable and his life is prolonged.

A CASE OF PAROXYSMAL SLEEP, SLEEP EPILEPSY, OR NARCOLEPSY.

By HAROLD N. MOYER, M.D.,

PROFESSOR OF NERVOUS AND MENTAL DISEASES, CHICAGO CLINICAL SCHOOL

Comparatively little has been added to our knowledge of morbid drowsiness since the paper of C. L. Dana (*Journal of Nervous and Mental Disease*, vol. ii., p. 153) in 1884. In that article Dana collected forty-nine cases, which he divided into three classes —epileptoid, hysteroid, and "other forms."

In the first class the disorder seems to have some relation to epilepsy, the morbid drowsiness in some cases apparently replacing an epileptic seizure. Of this class Dana gives eleven examples, some of which are strikingly like the case which has come under my observation.

His second class, the hysteroid, include the lethargics, sleeping girls, and individuals subject to short attacks of sleep and persistent drowsiness.

Under the division "other forms" he includes those cases in which the patients seem to be the victims of a special morbid hypnosis, not allied to epilepsy or hysteria.

The predisposing cause in these various forms is a neuropathic constitution, either inherited or acquired. Sex seems to bear some relation to the form of the disorder. Of twelve patients suffering from a special form of hypnosis, nine were males and three females. Of the hysteroid sleeping states, only five were in males and twenty-one in females. Of the epileptoid, seven were in females and four in males.

The case which has come under my observation was that of a young man, twenty-two years of age. The family history is quite free from nervous troubles. Both parents are living; the father is well, the mother has asthma. No intemperance in the family. The patient developed normally, but was a very nervous child. He attended school until fifteen, and made fair progress in his studies. Through early childhood and youth he was very nervous and complained of indigestion. This appears to have been a mild neurasthenia associated with catarrhal gastritis. At puberty these troubles improved. At the age of fifteen he went to work in a large store. From that time he became somewhat intemperate, using liquor at

times immoderately. His sexual appetite developed early and was unusually strong; for several years he indulged excessively in venery. When nineteen years of age, during the summer of 1895, he became very nervous, suffered from bad dreams, and on a number of occasions had hallucinations in his waking hours. Several times he saw strangely formed animals approaching him. He says that he always recognized the appearances as imaginary.

In the autumn of 1895 he first became affected with the tendency to sleep. It began gradually; at first it was an intense drowsiness, which became so insistent that he would finally seek some place where he could lie down. If allowed to remain quiet, he would sleep about one hour and would awaken refreshed. This tendency toward sleep gradually deepened in intensity, and the attacks increased in frequency until the winter of 1896–97, at which time the trouble was most frequent. He cannot say how many times he would sleep during the day, but places the number at from twenty to fifty. The difficulty in keeping awake led to his changing employment frequently. At one time he ran an elevator, and would frequently sleep while the elevator was passing several floors. The bottom of the elevator shaft was well lighted, and as soon as he came to the opening of the last landing he always awoke. At no time is the sleep profound, and he can always be awakened by a touch or if spoken to.

At present the disorder is not so severe as it was a year ago, but he is unable to follow any occupation in consequence of it. He sleeps many times each day, it being impossible for him to sit quietly for more than a few minutes without sleeping. In riding on the street cars he is compelled to stand, that he may not be carried beyond his destination.

He frequently sleeps while standing. At these times his knees suddenly give way, but he always awakens in time to keep himself from falling. He says he always catches himself and never has fallen.

He describes certain attacks, of which he has had from four to six, which differ from ordinary sleep. On one occasion, while at table, he was seized with sudden loss of consciousness, which lasted only a few moments. His description of this attack is strikingly like that of an epileptic seizure, but I have not been able to confirm this from the description of others. For the past three and one-half years, ever since the attacks of drowsiness became pronounced, he has had none of the seizures with loss of consciousness. These attacks seemed to precede the hypnosis and to correspond with the period when he had the hallucinations, which also disappeared when the hypnotic attacks were well developed.

Examination shows a fairly well-nourished young man, without special stigmata of defective development. The heart, lungs, and kidneys are free from disorder. There are no signs of organic nervous trouble. He has never had gonorrhœa or syphilis. The appetite is fair. The knee jerks are increased; there is some tremor of the hands. There are more or less irregular contractions of all the muscles, and an occasional start or jump which closely resembles tic convulsif. Co-ordination is not impaired. Sensation is intact. The eye grounds and pupils are normal.

He has been under my care for some weeks, but nothing that has been given him has modified the chief symptoms. The possible relation of the disorder to epilepsy being recognized, he was given large doses of the bromides, but this only increased the tendency toward sleep. Full doses of ergot have likewise been of no value.

An interesting point in the history is the failure of persistent efforts to hypnotize him. When exhibited before a medical class he would try to go to sleep, but invariably failed to do so. If, however, he was placed in an adjoining room and left alone for a few minutes, he would invariably be found asleep. He does not sleep very well at night. He commonly retires early and sleeps until early morning. From that time on there is a succession of waking and falling asleep, much the same as he has observed during the daylight hours.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent).

VACCINATION CIRCULAR—HOSPITAL RELIEF—ABDOMINAL INJURIES—VENESECTION—ACROMEGALY—BLACK-WATER FEVER—"CHRISTIAN SCIENCE" AGAIN—GLASGOW UNIVERSITY—NEW STUDENTS—TUBERCULOSIS PREVENTION—CONVICTION OF WHITMARSH—SIR J. BANKS, ETC.

London, October 28, 1898.

The local government board has issued a circular to guardians on the new vaccination act. The changes in the law are pointed out. They will take effect on January 1, 1899, and remain in force until January 1, 1904. But the board has considered it desirable to bring to the notice of guardians certain matters as to which arrangements should be made in advance.

One of the most important points is that the board shows, in accordance with the decision of judges and the opinion of the law officers, that if certain notices are not complied with it under the act of 1871 will be the duty of the vaccination officers to take proceedings. At the same time it is to be remembered that two convictions will completely absolve parents from any further liability to prosecution.

The Charity Organization Society has arranged for a short course of lectures on hospital relief. The first lecture was undertaken by the secretary, Mr. C. S. Loch, who again advocated his scheme of a central board, enforcing his argument by calling attention to the acknowledged growth of the out-patient department, which is so injurious and oppressive to the general practitioner.

Sir W. Broadbent occupied the chair and supported the proposal of a central board, but said it must not be an authority imposed on hospitals from outside, but a board composed of representatives of hospitals of every kind. Mr. Loch can take all the change he finds in that reservation for the benefit of the C. O. S., which is itself outside and too anxious for a finger in the pie.

On Monday the subject of injuries to the abdominal viscera was brought before the Medical Society by Mr. Marmaduke Sheild. He related four cases in which there was no external wound, but shock and symptoms of internal injury were noted. He had opened the abdomen in each case, holding that, though the mortality in such cases must be high, the surgeon should not be deterred from operating, as he might thereby save some lives which would inevitably be lost if he did not. One of his cases was that of a boy who had been run over; a large rent in the mesentery was found and sutured. The patient recovered. In the next case, besides a torn mesentery, the jejunum was torn through. The ends were anastomosed, but the patient succumbed. In another case there was a rent in the liver; it was stuffed with gauze, but the patient never rallied. The fourth case was that of a woman who had obscure symptoms of injury to the bladder, but only some ecchymosis of that organ could be found at the operation. She did not rally, and after death a prolonged search ended in the finding of a rent near the cæcum.

Other cases of the kind were mentioned by Mr. Turner and Mr. Battle. The former had among his two of ruptured kidney giving rise to extensive extravasation of blood. Mr. Battle had operated on three cases, and remarked on the great variability of shock, which is sometimes slight in grave injury, but sometimes very severe in less serious cases.

Dr. Lucas Benham read a paper on bleeding in pneumonia, and related nineteen cases in which it had been beneficial. It is in severe cases that the benefit is most conspicuous, and the venesection must be employed in the earliest stage. This subject should have produced a lively discussion, but elicited only the remark that a practice so firmly established and for so long could hardly have been given up without good cause.

Among the exhibits at the meeting of the Pathological Society there was a skull of the acromegalic type. It was from a collection of modern Italian crania bought by the College of Surgeons in 1870. It was massive and rugged. The changes in the bones were associated with enlargement of the pituitary fossa. All distinction between tables and diploe was lost. A very characteristic feature was lengthening of the face from enlargement of the jaw and prominence of the chin. About forty per cent. of giants are said to be acromegalic, and some writers have said that all cases of gigantic stature are associated with or due to pituitary disease arising during growth. But this extreme view cannot be maintained, for there are normal giants as well as pathological, and the same may be said of dwarfs—some of whom are abnormal, *e.g.*, cretins, but others apparently healthy persons of small stature yet proportionate throughout.

Professor Koch's condemnation of quinine in black-water fever is meeting with protests from most of those who have any experience of the disease. Most of them hold that it is not a separate disease, but merely aggravated malarial fever. Consequently they hold by their well-tried sheet anchor. Some four or five years ago I remarked on this disease, in a letter to you, founded on a number of clinical records submitted to me by travellers, and I cannot help thinking the experience of the many doctors who have resided for long terms in malarious countries is to be preferred to Koch's hasty conclusion.

Mr. W. H. Crosse, F.R.G.S., who spent some nine years in Nigeria, spoke very strongly on the subject at the opening of the Physical Society of Guy's Hospital, when Sir Samuel Wilkes occupied the chair, and his remarks have been supported by others who have enforced them at intervals since. Mr. Crosse declared that those who take quinine freely do not get black-water fever, and the attacks he had suffered in his own person—some ten in number—were generally due to neglect of this precaution when harassed by attending to others more ill than himself. The disease is so grave that it would be absurd to expect all cases to be cured by quinine. Enormous quantities of the red corpuscles seem to be disintegrated by the plasmodium, and some of the patients succumb at once, as if from shock. Others die later on with suppression of urine, probably due to blocking of the kidneys. Jaundice, too, is due to the disintegration of the corpuscles. The vomiting of green bile, which is so frequent a symptom, may be more difficult to trace to its immediate cause, but an explanation of an indirect character may be expected.

Mr. Crosse holds not only that quinine does not cause black-water fever, but that it is a preventive and a curative. In his book, "Notes on Malarial Fevers," he mentioned a case of a white woman who had the disease, and in his late address he spoke of several others—quite enough to confute Koch's statement as to the comparative immunity of women, which, I think, depends (if it exists) rather on the lesser degree of exposure; but there are so few white women compared with men in certain parts that the number of cases is of course less.

Before Mr. Crosse's paper was read, Dr. Moffat, principal medical officer of the Uganda protectorate, protested against Koch's theory, and said he should have kept it to himself until he had proved it—adding that for malaria "there is only one treatment—quinine, more quinine, and yet more quinine." These are his words in the *British Medical Journal*, September 24th, since which Dr. Harford-Battersby, principal of Livingstone College, has written to the same effect. So, too, has Dr. A. W. Robson, who has had two years' experience on the west coast of Africa. So has Dr. A. P. Hillier.

The death of Mr. Harold Frederic, author and journalist, while being attended by a Mrs. Mills, "Christian Scientist," is being inquired into by a coroner's jury. Some rather remarkable evidence has been given. Mrs. Mills called once or twice and gave him "absent treatment" for a guinea a week. The doctors who had been in attendance before this woman was sent for were dismissed. They told the jury that with proper attention Mr. Frederic might have recovered. The inquiry is adjourned for the second time. The revelations of apparently educated persons thus dealing in this wretched mixture of quackery and profanity may well lessen our astonishment at the perversity of the "peculiar people," who are mostly ignorant and without education. We have had another instance of their fanaticism before the magistrates this week, in which a stableman undertook the laying on of hands and anointing, without effect.

The successor to Principal Caird, at the University of Glasgow, is the Rev. Dr. Story, professor of ecclesiastical history. He does not seem to have been a favorite while occupying that chair, and at his inaugural address in his new capacity the students interrupted so much that he told them he would not allow the university to be insulted in his presence, and left the room. I am told he holds opinions similar to those of the English high churchmen, but that is not the reason the freshmen gave him so warm a reception.

The entries at the medical schools are giving satisfaction to the teachers. More than five hundred and thirty freshmen have been registered for the London schools, and there is a further contingent from the provinces. With the present overcrowding of the profession, one may well ask: "What is to become of them all?"

Sir W. Broadbent opened a sanatorium for infectious diseases at Huddersfield on Saturday, and afterward gave an address at the Technical College on "The Prevention of Tuberculosis."

The Golder's Hill committee is to be congratulated. On Thursday the last contribution of £500 was voted by the Middlesex council. This completes the £41,000 required for adding the beautiful estate to the "lungs of London."

The British Medical Association has referred to its solicitors a statement that a pamphlet has been circulated, purporting to be a reprint of a paper in the *Journal*, issued without permission, and in which some parts have been excised and other material added in such a way as to appear as if it were a continuation of the paper.

A third interim report of the dangerous trades committee has been issued.

The second trial of Dr. Whitmarsh, on a charge of murder by producing abortion, ended on Wednesday in a verdict of guilty. The jury added a recommendation to mercy. Sentence of death was passed, and the judge said he would see that the jury's recommendation was forwarded to the proper quarters.

A bold blackmailer got hold of a list of women who had written for some "miraculous female pills." He sent them a letter, pretending to be "official," threatening arrest unless they forwarded two guineas for costs already incurred, with "a promise in writing as on oath before God" not to repeat the offence. No less than six hundred women fell into the trap set by this scoundrel, but some were sensible enough to hand his letter to the police, and he is now "wanted." A few papers have protested against such advertisements being allowed to be issued as those of this and other "female medicines," but the game goes on almost as shamelessly as ever. When will the papers be subjected to penalties for thus promoting crime?

The Vienna cases of plague naturally excite interest here on account of our connection with India, and various are the comments on the way in which the infection spread from the Pathological Institute. But you will no doubt have all the facts as early as we do.

Sir John Banks has resigned the regius professorship of medicine in the Dublin University.

Dr. Sidney Coupland is to have the vacant commissionership in lunacy—a good berth for a good man.

Mr. F. Treves has resigned the surgeoncy of the London Hospital.

SCIENCE AND TYPHOID FEVER.

To the Editor of the Medical Record.

Sir: On page 585 of the Medical Record, in an article on "The Medical Aspects of Camp Management at Chickamauga," the following statements are made: "As to treatment, there is little to be said except in a negative way. . . . None of the so-called abortive or curative methods was attempted. . . . The knowledge of the pathological history and morbid anatomy of the disease precludes indulgence in these *wild absurdities*" (italics mine). "No idea was entertained that the typhoid bacteria could be reached in the glandular structures of the submucosa of the gut."

After the word "attempted" in the above extract, the following words should have been added: "Consequently the mortality was maintained up to the old standard."

It may well be asked, How is it that so many reports are made, in a number of journals, of the successful treatment and the great lessening of mortality by indulging in these wild absurdities? It is true that the principal factors in the propagation of typhoid are the bacilli which find a lodgement in Peyer's patches, setting up an inflammation, the products of which are known as ptomains, or, as they are sometimes called in typhoid, typhotoxins. These ptomains are constantly being generated and as constantly being absorbed; to kill these before absorption, to counteract the effect on the blood if absorbed, by a species of catalysis, is the essential feature of the antiseptic treatment. Science says this cannot be done; nevertheless, in many parts of the country the unscientific but intensely practical country practitioner shortens the course of the disease and adds wonderfully to the record of cures. To use the words of one of the most accomplished physicians of California: "These men care nothing about phagocytes—the science of bacteriology gives them no anxiety; but they do understand the importance of restoring restrained secretion, they know well how to open the great floodgates of waste, stimulate the emunctories, get rid of poisonous and cacoplastic material, and so leave disease nothing to fatten on." While all due honor should be given to the painstaking and conscientious men of science for their many discoveries of untold value, the fact must not be lost sight of that occasionally a theory, based solely on research, must give way or be modified when subjected to the test of actual experience. Again, had there been in the army and in the hospitals more of these unscientific but earnest and practical men, and fewer with a "pull," the death record so far as typhoid was concerned would have been lowered by a tremendous percentage.

W. E. Hughes, M.D.

Rockford, Ohio.

New Instruments.

A CONVERTIBLE AND PORTABLE BED BATH.

By CONSTANTINE I. MacGUIRE, M.D., L.R.C.S.I.,
NEW YORK,
VISITING PHYSICIAN, ST. VINCENT'S HOSPITAL; CONSULTING PHYSICIAN TO CITY HOSPITAL.

Since the Brand treatment of typhoid fever was introduced to the profession, it has steadily grown in popularity and the mortality has as steadily decreased. I have for a number of years adopted the treatment in hospital and private practice; and, though the results have been gratifying, many objections presented that at times made recourse to the bath system of treatment difficult, hazardous, or impossible. In the first place, the patient and the patient's friends, on the introduction of the bathtub into the sick-room, are always somewhat alarmed. They only thus realize clearly the treatment about to be adopted, and frequently decline, refusing what they consider heroic and extreme measures. Passing this over, we are confronted with the next and most material difficulty—the lifting of the patient out of bed and placing him in a bathtub and returning him again to bed. This entails a great expenditure of strength of the patient; and we should bear well in mind that we are dealing with a heart worn out by fever and toxæmia. To my mind this has frequently seemed a hazardous proceeding. We constantly impress on our nurses that under no circumstances should the patient be permitted to help himself, to sit up in bed, or discharge any of nature's functions or take nourishment except in the supine position—so great is our dread of inducing heart failure by any avoidable exertion. How much greater the risk of collapse in the administration of the bath!

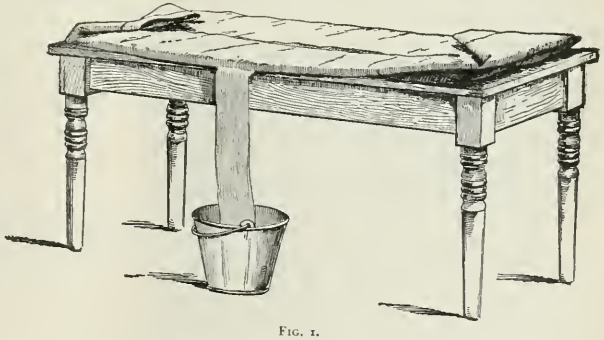

Fig. 1.

The removing of a patient (adult) of average weight from bed to bathtub and back requires the assistance in most cases of three or four people; and to repeat this treatment several times in twenty-four hours entails an expense that can be borne easily in few families, in

some not at all, and even in hospital, when cases of typhoid are numerous, with great difficulty. As a substitute for the bathtub the sponge bath and cold pack in many cases have worked well, but for accuracy of technique do not compare with the tub.

Some two years ago I introduced in St. Vincent's Hospital and have used since what I call a portable collapsible bathtub, which I believe presents all the advantages without the disadvantages of the ordinary tub. When the tub, which is made of a rubber sheet,

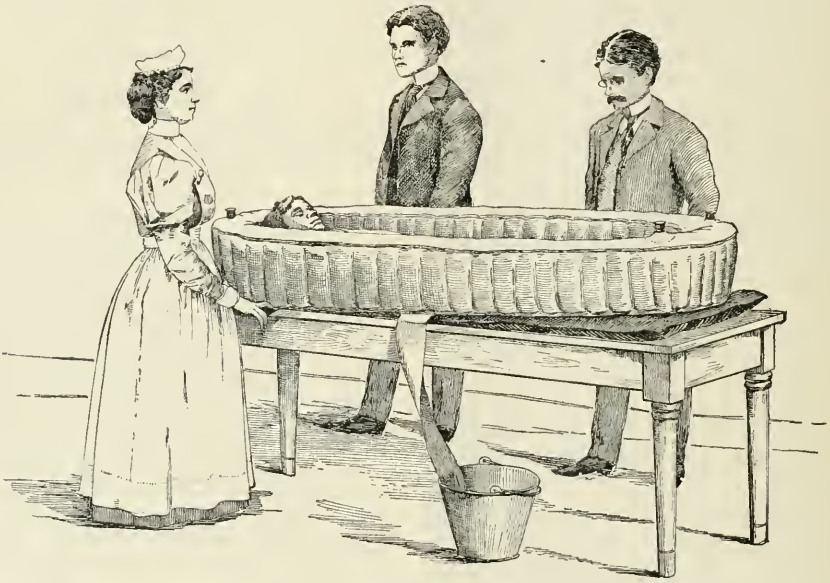

Fig. 2.

is not in use (Fig. 1), its sides may be folded down, the air chamber or chambers being deflated, and in that condition may be placed upon the bed upon which the patient is lying, and the patient placed therein without removing him from the bed or making an appreciable elevation of his person. The air chamber may then be inflated by an ordinary bicycle pump or from a cylinder of condensed air. This inflation can be effected from a cylinder in less than one minute. The effect is to raise the sides of the tub and hold them firmly in the erect position, capable of withstanding any water pressure from the inside of the tub. Fig. 2 shows the tub in action. In the bottom of the tub and about midway of its length, at the point where the greater portion of the weight of the patient will be supported, on either side are openings to which are connected discharge tubes. These discharge tubes are capable of emptying the tub in less than one minute.

The deflation of the tub is effected by four capped valves on the side, which when opened allow the air to escape, and the sides collapse in thirty seconds. At the termination of the bath a dry sheet can be placed over the collapsed tub and the patient made comfortable, or the convertible tub can be removed in the same manner that an exchange of sheets is made by a trained nurse.

It can be readily seen that the substitution of the convertible bed bathtub completely removes the dangers incident to the lifting of the patient in and out of bed, does away with the necessity of more than one nurse, and reduces to a minimum the horror and dread of patient and relatives for the ordinary crude bath-tub.

120 East Sixtieth Street.

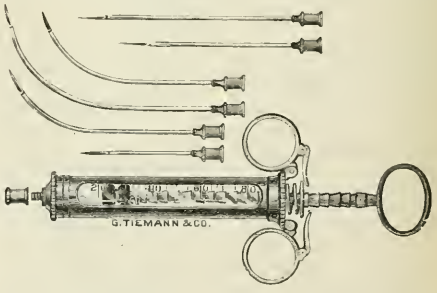
THE RATCHET SYRINGE: AN IMPROVED SYRINGE FOR SCHLEICH'S INFILTRATION ANÆSTHESIA.

By C. G. LEO-WOLF, M.D.,

Niagara Falls, N. Y.

In using Schleich's infiltration anæsthesia in quite a number of cases, I noticed one point which calls for an improvement in the apparatus. When injecting the solution with an ordinary syringe into dense tissues —such as the palma manus, the periosteum, or into the inflamed tissue surrounding a common boil—it requires a considerable force to overcome the resistance offered by these tissues, and the operator risks breaking the needle rather than inject the few drops necessary." With the view of overcoming this difficulty there is one syringe made, which is described by Braun in the *Centralblatt für Chirurgie*, May 1, 1897, page 481; but this necessitates the use of both hands, which I consider a great disadvantage.

My improved syringe is shown in the accompanying illustration, which explains its construction better than



a lengthy description. By pressing the rings down against the syringe, the two levers are freed from the cogs and the piston slides freely up and down, as in any ordinary syringe. If a greater resistance is to be overcome, then by raising the two fingers in the rings the levers are made to depress the cogs on the piston,

and when slightly released will slide over the next ones and have the next grip. This can be done without changing the hold on the instrument, with one hand and without loss of time.

The syringe is fitted with six needles of different length and curvature, and three glasses containing tablets to make, with one hundred cubic centimetres of distilled water each, the three solutions of Schleich.

A NEW CENTRIFUGE TUBE.

By JOSEPH E. FULD, M.D.,
NEW YORK.

The difficulty with the ordinary centrifuge tube, now in use, is that when the fluid has been centrifuged and the sediment obtained, the mere introduction of a pipette usually suffices not only to disturb the sediment but even to annul the work of the centrifuge.

The object of my tube is to provide a simple device whereby the lowest stratum of the sediment can be

removed intact, and in sufficient quantity for microscopical examination. The accompanying illustration represents the instrument. It is a glass tube, narrowed toward one extremity (*A*), and is provided with a snugly fitting rubber stopper. The upper portion (*B*) is wide at its extremity and somewhat constricted, so that the pulp of the finger, fitting over it, will form such an effective stopper that when the cork at (*A*) is withdrawn, the contents of the tube will be held therein by atmospheric pressure. The sediment which has collected upon the cork is utilized by lightly touching a glass slide in two or three places, and covering each drop with a cover glass. The tube can readily be cleansed by allowing water to run through it.

169 East Eighty-Second Street.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 12, 1898:

	Cases.	Deaths.
Tuberculosis	181	154
Typhoid fever	71	21
Scarlet fever	108	5
Measles	98	4
Diphtheria	130	22
Laryngeal diphtheria (croup)	14	10
Cerebro-spinal meningitis	0	6
Chicken-pox	13	0

History of Circumcision.—Fresnel, in an article published in the *Revue des Deux Mondes* in 1838, describes as an invariable wedding-ceremony among the Arabs of Djezan a procedure which, it would seem, would hardly tend to make marriage popular. This operation consists in a most extensive circumcision, which is performed in the presence of the assembled wedding-guests as well as the bride herself. The victim is turned over to the holy operator, who proceeds to remove not only the prepuce but the entire skin of the penis as far back as the scrotum. "Should the happy bridegroom betray any sign of weakness or allow as much as a sign or a groan to escape him, or even allow the muscles of the face to betray the fact that he is not immensely enjoying the occasion, the bride-elect at once leaves him for good, saying that she does not wish a woman for her husband." This operation is naturally frequently fatal, so that the Arabs might be "likened to those spiders which perish during their first and only act of copulation, and are immediately devoured by the female, the difference being that the spider's death is probably a happy one, which can scarcely be said of the Arab's."

The Duke of Argyll on the New Vaccination Bill in England.—The Duke of Argyll, in answer to a correspondent who drew his attention to the statement of an antivaccinationist to the effect that the depopulation of the Highlands to which the duke had referred in a previous communication had been caused, not by small-pox, as he had contended, but by the action in the past of the duke's ancestors, writes as follows: "When Wortley Montagu brought inoculation from Turkey, the Highlanders were sensible enough to adopt it, and from that date the plague was stayed. Vaccination speedily followed, with the result that I have never even heard of small-pox in the population where it used to be so destructive. This is evidence which no quibbling can dispose of. Never mind what you hear of accusations against me. There are a great number of men who can't argue, but are always ready to throw rotten eggs instead, especially against people in my position, when they venture to confront some popular delusion. In Scotland, I am happy to say that our people are more intelligent. I have heard of no difficulty. Perhaps a few outbursts of small-pox, like that of Gloucester a few years ago, will drive it into the heads of even the 'plurality of blockheads' that one of the greatest triumphs of medical science is a providential gift, not to be thrown away. Add to that the principle which has been confirmed by the recent discovery of new immunities to be secured by new kinds of inoculation for other diseases, and vaccination no longer stands alone." From the tenor of this epistle it would seem that the fighting-blood of MacCullum More, the chief of all the Campbells, is thoroughly roused.

Hermaphroditism a Variety of the Female Sex.—Virchow's experience has convinced him that on the whole hermaphrodites belong to the female sex. He has never discovered a testis in any hermaphrodite, although it is a difficult matter to decide exactly the nature of the seminal gland, upon which alone the actual question of the sex depends. There is only one authentic case on record (Obolenski's) in which both testes and ovaries were present.—*Klin.-therap Woch.*

Continence in the Marital Relations.—We, who work in gynæcology, who observe closely, will frequently benefit our patients by sending them from home for a few months, and giving to their husbands a course of lectures before the wife's return. A woman who is doing the work of her family and suckling an infant at the same time needs rest; she needs sleep at nights; she is in no condition to enjoy sexual congress, and it is our duty, as medical men, to tell her so. They look to us for protection in this line—who but we can speak in her behalf? Who but we can point out to her the dangers of making a good woman old before her time? When I go into a house and see a

husband, sleek, fat, jolly, and hearty, and the wife pale, anæmic, and nervous, if she has no definite disease, I can easily guess the cause—incomplete coition. He is killing her. If she has a disease he should let her alone. I do not desire to be understood as advocating continence among married people, but I do say, and from professional observation maintain, that more women are suffering from an overdose of married relation than from almost any other cause. Watch the difference in these patients when they have had rest. Look at the rosy-cheeked young widow, whose step is as elastic as that of a girl in her teens. See the bloom of health upon the cheek of the little wife who has returned from her summer vacation. Note the wives of diabetic husbands who have lost desire. Notice the improved appearance of the deacon's wife while you are treating her liege lord for "gravel," contracted in the camp-meeting lavatory.—Dr. W. B. Pigg, *Tri-State Medical Journal*, September, 1898.

The Sewage of Paris.—The sewage of Paris, says *Revue Pratique des Travaux Publiques*, is conveyed by gravitation to Clichy, where part of it is distributed over a farm of 2,471 acres. An area of some 12,000 acres would be required to deal with the effluent of 17,660,000 cubic feet, which has daily to be pumped and got rid of. Grass is the crop that will stand the greatest quantity of sewage, taking 2,430,000 cubic feet on an acre yearly; lucerne will thrive on 1,790,000 cubic feet. Beet roots, from which sugar is made, will take only 200,000 cubic feet.

This is What it is.—A footnote printed upon the diplomas issued by the school of osteopathy in Missouri defines osteopathy as follows: "Osteopathy is the science of healing without the use of drugs, and is the art of manipulating the various parts of the body on the purely mechanical principle in the reduction of dislocations and fractures and in the removing of obstructions to the current force of fluids of the body, thereby assisting nature to maintain a healthy action of all the functions of the system."

The Danger Signal to Divers.—Dr. James Galbraith Connal, assistant surgeon to the Glasgow Ear Hospital, says: "It is well known that it is essential to the healthy function of the ear that the pressure on both sides of the tympanic membrane should be equal. This is accomplished through the Eustachian tube. The evil influence of sudden and great changes of pressure can be neutralized by the act of swallowing, or by performing Valsalva's experiment. It is interesting to note that divers instinctively adopt the method of swallowing to equalize the pressure of air on both sides of the tympanic membrane. When a diver—in descending the ladder—feels the pressure of the air in the ears, he swallows saliva. If the 'ears crack' he finds he can go down to a considerable depth without discomfort, though the act of swallowing may have to be repeated once or twice before he reaches the bed of the river. If the ears will not 'crack' on swallowing, then he ascends a few steps of the ladder and tries again, but if he fails he must come to the surface. As a rule, divers refuse to go on duty when they have a 'cold,' as they know that there is a great danger of injuring the ears. On this occasion the patient went on duty though he knew the risk he was incurring. The 'cold' and slight sore throat from which he was suffering would probably lead to a swelling of the mucous membrane of the Eustachian tube, and render him, when exposed to sudden and great increase of pressure of air in the external auditory canal, more liable to the rupture of the tympanic membrane."

Stuttering.—Liebmann maintains that stuttering consists in a rushing together of the consonants, and consequently his method of treatment has for its object the teaching of the relative significance of the vowel and consonant sounds. The patient is made to speak sentences with prolonged vowels and short consonants, so that even at the first lesson many sentences are spoken easily and fluently. The psychic effect is soon apparent, the patient regaining confidence in his ability to speak plainly, and the result is excellent in a very short time. This method can also be employed with young children. Stuttering may be caused by the infectious diseases, injury to the head, imitation of other children, or it may be due to heredity. Its more frequent occurrence in males than in females is to be explained by the greater motility of all the voluntary muscles in women than in men, the tongue included.—*Der Kinder-Arzt.*

Difficult Defecation in Infants.—It is generally recognized as a fact that infants and young children strain at stool. The infant and young child strain at stool because of the imperfect development of the anatomic features concerned in the mechanism of defecation. These are: (1) The infant's lower gut is muscularly deficient. (2) Its mobility within the abdomen is obstructive to defecation. (3) The rectal valves are obstructive. (4) The infant's anus, not being sufficiently expansible, is also obstructive to defecation.—*Pediatrics.*

Hæmatemesis and Hæmoptysis: Differential Diagnosis.—

Hæmatemesis.	*Hæmoptysis.*
1. Previous history points to gastric, hepatic, or splenic disease.	1. Cough or signs of some pulmonary or cardiac disease precede, in many cases, the hemorrhage.
2. The blood is brought up by vomiting, prior to which the patient may experience a feeling of giddiness or faintness.	2. The blood is coughed up, and is usually preceded by a sensation of tickling in the throat. If vomiting occurs, it follows the coughing.
3. The blood is usually clotted, mixed with particles of food, and has an acid reaction. It may be dark, grumous, and fluid.	3. The blood is frothy, bright red in color, alkaline in reaction. If clotted, rarely in such large coagula, and mucopus may be mixed with it.
4. Subsequent to the attack the patient passes tarry stools, and signs of disease of the abdominal viscera may be detected.	4. The cough persists, physical signs of local disease in the chest may usually be detected, and the sputa may be blood stained for many days.

—Osler.

Ehrlich's Diazo Reaction in Urine.—Krokiewicz, after an examination of eleven hundred and five different cases, in which he made sixteen thousand one hundred and sixty-seven tests for Ehrlich's diazo reaction, draws the following conclusions: In diseases of the kidneys, not due to tonic medicaments containing coloring matters, it is never found. In carcinoma of the stomach, liver, œsophagus, rectum, pancreas, and uterus the reaction is negative; but in primary carcinoma of the ovaries it is positive. When found in pulmonary tuberculosis the disease runs a short and fatal course. This rule holds good also in the incipient stages. Albuminuria and intestinal ulcers in phthisis have no effect on the reaction. The test is negative in phthisis when complicated with nephritis. In tuberculosis of glands or mucous membranes the reaction is occasionally found. It is constant in miliary tuberculosis. In typhoid it is found in the mildest attacks in the first and second periods of the disease. As long as the diazo reaction is present in urine, typhoid patients cannot be considered convalescent. If in convalescence of typhoid the reaction sets in, it is generally a sure sign of a relapse. The author recommends the test on account of the prognostic value in typhoid and tuberculosis.—*Wiener klinische Wochenschrift.*

MANSLAUGHTER, CHRISTIAN SCIENCE, AND THE LAW.

BY WILLIAM A. PURRINGTON,

COUNSELLOR AT LAW,

NEW YORK.

THE recent death of Mr. Harold Frederic under the treatment of a Christian scientist, and the latter's indictment by an English jury, have renewed the discussion by professional and lay journals of what is and what should be the bearing of the law upon such cases.

The New York *Times*, of which he was correspondent, writes editorially of "Faith-Cure Murders;" *The Sun*, of "Manslaughter by Christian Science." The current law journals comment upon the case. Unfortunately such instances are neither modern nor rare.

Coincidently with Mr. Frederic's death from pneumonia in England, the newspapers also report the deaths of Messrs. Kershaw in Tacoma, and McDowell in Cincinnati, and Mrs. Brown of Washington; the first of pneumonia, the second of typhoid fever, the last of an unnamed malady—all the diseases being complicated with Christian science. It is only Frederic's prominence as a journalist and fiction writer that brings his case nearer home to the multitude.

The ordinary quack is content to lay claim to some special skill or knowledge in the use of natural methods or remedies. Thus in February, 1806, one John M. Crous induced the same legislature of New York that in the following April chartered the existing county and State medical societies to authorize by special act the purchase for $1,000 and publication in the State papers of his "perfect and infallible remedy and cure for the hydrophobia or canine madness." And a wonderful remedy it was.[1]

[1] Here is the prescription, and it certainly seems adequate to put an end to hydrophobia or any other malady:

"First: Take one ounce of the jawbone of a dog, burned and pulverized, or pounded to fine dust.

"Secondly: Take the false tongue of a newly foaled colt; let that be also dried and pulverized; and,

"Thirdly: Take one scruple of verdigris, which is raised on the surface of old copper by lying in the moist earth; the coppers of George I. or II. are the purest and best. Mix these ingredients together, and if the person be an adult or full grown, take one common teaspoonful a day, and so in proportion for a child according to its age. In one hour after take the filings of the one-half a copper of the above kind, if to be had; if not, then a small increased quantity of any baser metal of the kind; this to be taken in a small quantity of water.

"The next morning, fasting (or before eating), repeat the same as before. This, if complied with after the biting of a dog, and before the symptoms of madness, will effectually prevent any appearance of disorder; but after the symptoms shall appear a physician must immediately be applied to, to administer the following, viz.:

"*Three* drachms of the verdigris of the kind before mentioned, mixed with half an ounce of calomel, to be taken at one dose. This quantity the physician need not fear to administer, as the reaction of the venom will then, diffuse through the whole system of the patient, neutralize considerably the powerful quality of the medicine; and,

"Secondly: If in four hours thereafter the patient is not completely relieved, administer four grains of pure opium or one hundred and twenty drops of liquid laudanum.

"N. B.—The patient must be careful to avoid the use of milk for several days after taking any of the foregoing medicine.

"JOHN M. CROUS."

In the following year an act (ch. 104, ll. 1807) passed, prohibiting unlicensed practice of medicine; with the proviso, however, that it should not be construed to debar any one from using, or applying for the benefit of the sick, roots or herbs the growth or product of the United States. This exception favored at once the principle of protection to the industry of home herbs and the teachings of the Thomsonian or botanic school of medicine, founded upon the simple, obvious theory that mineral remedies are injurious because, their nature being to remain in the earth, they tend to drag man down to the grave; while herbs, having by nature an upward, skyward thrust, tend, on the contrary, to the advancement of those into whose midst they penetrate.

This system, once as popular as Christian science, furnished the leading American case on manslaughter by medical malpractice, that of Commonwealth *v.* Thomson (6 Mass. 134). It there appeared that Samuel Thomson, founder of the system, undertook to cure "all fevers, whether black, gray, green, or yellow." His staple remedies were "coffee," so-called, "well my gristle," and "ram-cats." Being summoned on January 2, 1809, to attend Ezra Lovett, ill of "a cold," he ordered a fire built, put Lovett's feet on a stove of hot coals, wrapped him in a blanket, and, with a powder given in water, "puked" him—to use the simple language of the day—violently thrice within half an hour, meantime administering copiously the warm "coffee." He then put Lovett to bed, and sweated and "puked" him pretty steadily for three days, the patient growing weaker and weaker, until, poor soul! he could puke no more. Then Thomson asked "how far down the medicine had got," and, Lovett indicating his chest, the quack said that the medicine "would soon get down and unscrew his navel." On the third day the patient "lost his mind and went into convulsions," which condition lasted until the eighth day, January 10th, when he died. The "coffee" proved to be a decoction of marshrosemary and the bark of the bayberry bush; the powder was Indian tobacco or *Lobelia inflata*. There was no evidence that defendant had killed any one else; on the contrary, there was testimony of benefit in one case from his treatment. The court, therefore, did not put him to his defence; but, ruling that the commonwealth had failed to make out a case even of manslaughter, charged the jury to this effect: Deceased, beyond reasonable doubt, lost his life by defendant's unskilful treatment. But there could be no murder, unless the prisoner was wilfully regardless of his social duty and determined on mischief, of which there was no proof; on the contrary, his intent was to cure. Neither could there be manslaughter; for, although defendant's ignorance was very apparent, nevertheless, if he honestly intended to cure, he could not be guilty of that crime on account of death unexpectedly ensuing from his treatment, *unless he was engaged in an unlawful act;* and there was no law in Massachusetts forbidding any man, honestly intending to cure, from prescribing for a sick man with the latter's consent. The court cited Lord Hale as authority for the proposition that, "if a physician, whether licensed or not, gives a person a potion, without any intent of doing him any bodily hurt, but with

intent to cure or prevent a disease, and, contrary to the expectation of the physician, it kills him, he is not guilty of murder or manslaughter;" and, accordingly, laid down this law for the case:

"The death of a man, killed by voluntarily following a medical prescription, cannot be adjudged a felony in the party prescribing, unless he, however ignorant of medical science in general, had so much knowledge or probable information of the fatal tendency of the prescription that it may be reasonably presumed by the jury to be the effect of obstinate, wilful rashness, at the least, and not of an honest intention and expectation to cure."

The court further said that if the solicitor-general had proved, as he promised to do in his opening, that Thomson had killed others by his treatment, it would have been left to the jury to say whether on the whole evidence they would sustain the charge of manslaughter; which they might justly have done if they had found that defendant acted from "obstinate rashness and foolhardy presumption, although without intent to do Lovett bodily harm;" "*for it would not have been lawful for him again to administer a medicine of which he had such fatal experience.*" Upon this reasoning Thomson was acquitted; and his case having proved, as a precedent, a strong shield for manslaughtering charlatans, by establishing what has been called the humane American rule as contrasted with the strict rule of common law, it is well to state succinctly the reasons why he escaped conviction, viz.: (1) because there was no statute in Massachusetts prohibiting medical practice by the ignorant and unlicensed; (2) because there was no proof that Thomson (*a*) knew his treatment to be dangerous or (*b*) had any other intent than to cure in good faith.

In 1842 the question arose in New York, upon an application for a bill of discovery, in Marsh *v.* Davison (9 Paige 580), whether it was slanderous to have said of complainant that he was guilty of malpractise as a cancer doctor and had killed a woman in Schoharie. Davison not being licensed to practise, the court held that—inasmuch as he might be guilty of manslaughter, for that reason, if the patient died under his treatment—the words might be slanderous.

It thus appears that—even accepting the benign rule of Thomson's case, which, as we shall see presently, was ill stated—wherever a statute makes the unlicensed practice of medicine a misdemeanor, if death result from the treatment of a non-licentiate he is guilty of manslaughter at least, no matter how honest his intent. This is the rule of common law and of the New York penal code, which defines as manslaughter the killing of one human being by the act, procurement, or omission of another, without design to effect death, by a person engaged in committing or attempting to commit a misdemeanor affecting the person or property either of the person killed or of another.

In 1844 the case of Rice *v.* The State (8 Mo. 561) was decided in Missouri. Rice, a Thomsonian, undertook by the same methods used on Lovett to cure Mrs. Keithley of sciatica. She had not been so well for years as when he began to treat her, and was within six weeks of giving birth to her fourth child. Under his system she fell into premature labor and died within about ten days. He was convicted of manslaughter; but the appellate court, adopting the rule in Thomson's case, the facts being substantially the same, reversed the judgment.

In 1881 another case arose, in Iowa, State *v.* Schulz (55 Ia. 628). Schulz treated a sick woman by acupuncture and an irritating oil, according to the system of Herr Baunscheidt, who, having been much benefited by the bitings of small insects, sought to give the world, for a consideration, a simulacrum of his experience. Defendant admitted that he did not know the composition of the oil, that being Baunscheidt's secret. The patient died. Schulz claimed that if he had not been interfered with he could have helped her, and produced twenty-three witnesses to testify that Baunscheidtismus, as administered by him, had benefited them. Schulz was convicted, but the appellate court reversed the judgment, following the cases of Thomson and Rice, and expressed this conclusion: "The interests of society will be subserved by holding a physician civilly liable in damages for the consequences of his ignorance, without imposing upon him criminal liabilities when he acts with good motives and honest intentions." The adoption of this theory by the New York statute of 1844 enabled quackery, in the words of Beardesley J., to "boast its triumphant and complete establishment by law" (Bailey *v.* Mogg, 4 Den. 60). And the people of Iowa, instead of adhering to it, have passed, since the Schulz case, a law forbidding medical practice to the unlicensed.

Notwithstanding these acceptances of the rule in Thomson's case by other jurisdictions as sound law, the supreme court of Massachusetts, wherein it originated, has since held, in Commonwealth *v.* Pierce (138 Mass. 165, A.D. 1884), that the accuracy of its report was doubtful and its law open to criticism. The facts in Pierce's case were these: Defendant held himself out as a physician. There was no more law in Massachusetts to prevent him from so doing in 1884 than there had been to prevent Thomson's like pretension in 1809. Being called to a sick woman, he caused her, she consenting, to be kept for some three days swathed in flannel underclothing, saturated with kerosene. Under this treatment she died in great misery. There was evidence in the case that in some instances similar treatment by defendant had resulted favorably, but also that in one it had burned and blistered the flesh, as in the case of deceased. Defendant's counsel at trial asked the court to charge, following the rule in Thomson's case, that defendant could not be convicted unless it were proven beyond reasonable doubt that death resulted from his treatment and that he had such knowledge or probable information of the fatal tendency of his prescription as to justify the jury in presuming that death was the effect of his obstinate or wilful recklessness, and not of an honest intent and expectation to cure. This request was refused, defendant was convicted, and his conviction affirmed by the appellate court, who, by Holmes J., said that the language of Thomson's case relied upon by defendant—viz., that "to constitute manslaughter the killing must have been a consequence of some unlawful act. Now there is no law which prohibits any man from prescribing for a sick person, with his consent, if he honestly intends to cure him by his prescription"—was ambiguous and wrong, if it meant "that the killing must be the consequence of an act which is *unlawful for independent reasons apart from its likelihood to kill.*" "Such," continued the court, "may once have been the law; but for a long time it has been just as fully, and latterly, we may add, much more willingly, recognized that a man may commit murder or manslaughter by doing otherwise lawful acts recklessly, as that he may by doing acts unlawful for independent reasons, from which death accidentaliy ensues." Thomson's case, it was said, did not intend to lay down new law, but cited and meant to follow Lord Hale, whom it had taken too literally, since his lordship admitted that other persons might make themselves liable by reckless conduct (1 P. C. 472); and why not a physician as well?

As to what constitutes criminal recklessness in such cases, the court said substantially that the standard is not gauged by the actor's belief or idea of danger, but by common experience. If the thing done "is generally supposed to be universally harmless and

only a specialist would foresee that in a given case it would do damage, a person who did not foresee it and who had no warning would not be held liable for the harm. . . . The use of the thing must be dangerous according to *common experience*, at least to the extent that there is *a manifest and appreciable chance of harm from what is done, in view either of the actor's knowledge or of his conscious ignorance. . . . Common experience is necessary to the man of ordinary prudence, and a man who assumes to act as the defendant did must have it at his peril.* . . . The defendant knew he was using kerosene. The jury have found that it was applied as the result of foolhardy presumption or gross negligence, and that is enough. . . . Indeed, if the defendant had known the fatal tendency of the prescription, he would have been perilously near the line of murder." The rule laid down in this carefully reasoned case must commend itself to prudent men; for it really amounts only to this—that if one unversed and unskilled in medical science and practice undertakes, nevertheless, the cure of a patient, and in so doing uses remedies or adopts a treatment—whether positive or negative ought to make no difference—from which there is a manifest and appreciable chance of harm according to common experience, he shall be held liable for his recklessness and shall not be excused by the innocence of his intention. And certainly when part of the treatment adopted is the *exclusion of proper treatment*, this is just as harmful as if positively injurious methods were adopted. It is just as much homicide to cause death by starvation by keeping food from the victim, as to use an active poison.

How does this principle apply to "Christian science," "faith cure," or any eccentric treatment of the sick—not excluding voudoo or the "scandal cure"[1]—that by operating strongly on the mind may restore the lost equilibrium? Is the pursuit of any of these methods "practice of medicine"?

While the ordinary quack, who, as has been said, pretends only to extraordinary human skill or knowledge, is, therefore, generally held to be a practitioner of medicine, Christian scientists, who go further and pretend to procure for lucre divine intervention by their prayers, contend that in thus offering to heal the sick, although for hire, they are not practising medicine, but observing religious rites, and are therefore protected in their practices by constitutional safeguards. We are thus brought to consider what is the "practice of medicine." The answer to this query must depend in most instances upon the words of the statute and the peculiar circumstances of the case. In the New York case of Smith *v.* Lane (24 Hun, 632, A.D. 1881), plaintiff, apparently a masseur, sued for agreed fees which defendant refused to pay on the ground that plaintiff, not being licensed to practise medicine, could not recover compensation for his treatment, which, as the opinion of the court recites, "consisted entirely of manipulation with the hand. It was performed by rubbing, kneading, and pressure." The court said:

"The practice of medicine is a pursuit very generally known and understood, and so also is that of surgery. The former includes the application and use of medicines and drugs for the purpose of curing, mitigating, or alleviating bodily diseases; while the functions of the latter are limited to manual operations, usually performed by surgical instruments or appliances. . . . To allow incompetent or unqualified persons to administer or apply medical agents, or to perform surgical operations, would be highly dangerous to the health as well as the lives of the persons who might be operated upon, and there is reason to believe that lasting and serious injuries as well as the loss of life have been produced by the improper use of medical agents and surgical instruments or appliances. It was the purpose and object of the legislature by this act to prevent a continuance of deleterious practices of this nature, and to confine the uses of medicine and the operations of surgery to a class of persons who, upon examination, should be found competent and qualified to follow these professional pursuits. *No such danger could possibly arise from the treatment to which the plaintiff's occupation was confined. While it might be no benefit, it could hardly be possible that it could result in harm or injury.*

"And for that reason no necessity existed for interfering with this pursuit by any action on the part of the legislature. It may be that credulous persons would be deceived into the employment of the plaintiff, and in that manner subjected to imposition. But it was no part of the purposes of this act to prevent persons from being made the subjects of mere imposition."

Either the italicized words are superfluous or they contain an implication that if the treatment, in the court's opinion, had been capable of causing injury like improper medical treatment, the judges would have classified it in the same category.

In Eastman *v.* State (10 N. E. 97), an Indiana case, the court said, on the other hand: "It is the purpose of the statute to prevent persons, who do not possess the necessary qualifications to practise medicine or surgery from inflicting injury upon the citizens by undertaking to treat diseases, wounds, and injuries." And again: "The State has an interest in the life and health of all its citizens, and the law under examination was framed, not to bestow favors upon a particular profession, but to discharge one of the highest duties of the State—that of protecting its citizens from injury and harm." In People *v.* Phippin (70 Mich. 6), the defendant was held to have practised medicine, on proof that he held himself out as "Dr. W. W. Phippin, magnetic healer," had attempted to cure the sick, and in the case of a child's death had certified the cause to be "canker, sore mouth. Duration of disease: June 3 to July 22, 1887." In Bibber *v.* Simpson (59 Maine 181), a clairvoyant who gave remedies was said to be practising medicine. So also in Nelson *v.* Harrington (72 Wis. 591). And in New York, De Leon, who prescribed for a child, drawing its horoscope and giving some rhubarb, was convicted of illegal practice of medicine. The administration of electricity has also been held to constitute medical practice—Davison *v.* Bohlman (37 Mo. App. 576).

The Ohio statute provides that: "Any person shall be regarded as practising medicine or surgery, within the meaning of this act, who shall append the letters M.D. or M.B. to his name, or for a fee prescribe, direct, or recommend for the use of any person any drug or medicine *or other agency* for the treatment, cure, or relief of any wound, fracture, or bodily injury, infirmity, or disease." That seems very broad; but in the case of Eastman *v.* State (6 Ohio Dec. 296), it was held, in January, 1897, that a "graduate of the school of osteopathy of Kirkville, Mo.," was not practising medicine by kneading and manipulations, using only his hands and no medicines. The court cited Smith *v.* Lane, and held that the words "any other agency" were too vague and were limited by the particular words "drug or medicine."

The New York statute does not define medical practice. Such a definition was framed in the draft of the act of 1887, but stricken out because a certain senator,

[1] I knew once of a *malade imaginaire* who for years had drifted feebly from bed to lounge and back again. Physicians were in vain. One day a friend called and said that the newspapers had gotten hold of a bit of history that would interest the nations on the following Sunday. The patient leaped from the lounge, took a cab to the steamer office, and by Sunday was on the ocean. This is the "scandal cure."

who died shortly afterward, declared that it would include an eccentric healer who had saved him from the grave. The definition was yielded to save the bill.

The Nebraska medical act defines as a practitioner, any one "who shall operate on, or profess to heal, or prescribe for, or otherwise treat any physical or mental ailment of another."

Under this statute arose, in 1894, the case of State *v.* Buswell (40 Neb. 158). The defendant, charged with unlawful practice of medicine, claimed to be a Christian scientist, graduated from the Metaphysical College of Mrs. Mary B. G. Eddy, of Boston. Defendant offered testimony to cures wrought by him in cases of rheumatism, rattlesnake bite, pneumonia, and scarlet fever—the last in the case of a child, four years old. He testified that in eighteen months he had treated about one hundred persons, of whom only two had died. The accuracy of his diagnosis was not in issue. He testified that the text-books of the Christian Science Church are the Bible and Mrs. Eddy's work, "Science and Health." He denied that in a medical sense he treated physical or mental ailments, saying: "I understand with God's laws, and not mortal man's." Questioned as to the privilege of patients or parents to call in medical aid, he said: "We believe that every one has a right to express their wish, and it is always understood that if they prefer some other treatment, or some other mode, or some one else to aid them, it is their privilege. We always do that. It is taught in our text-books. *We never give any medicine; that is entirely contrary to the teaching of Christian Science.*" And his counsel said: "The defendant, and those of the same faith with him, *believe as a matter of conscience that the giving of medicine is a sin;* that it is placing faith in the power of material things, which belongs alone to Omnipotence. To the Christian scientist, it is as much a violation of the laws of God to take drugs for the alleviation of suffering or the cure of disease, as for a Methodist clergyman to take the name of his God in vain to relieve his overwrought feelings."

Being asked if he took pay from his patients, he said: "As a rule I do not. We tell them we leave the question to them and God. . . . Jesus says the laborer is worthy of his meat, and we expect that those whom we spend our lives for to remunerate us for it. *If they are not willing to part with the sacrifice themselves, it is not expected that those should reap the benefit.*" Considering that defendant described his treatment as one of prayer; this intimation that the answer to prayer would be contingent on the payment of the scientist's fee apparently seemed rather blasphemous to the court, who very aptly cited two cases from one of the science's text-books, the Bible—the former, that of Simon the sorcerer (reported in Acts viii. 18-23), to whom Peter said, "Thy money perish with thee, because thou hast thought that the gift of God may be purchased with money;" the second that of Gehazi (2 Kings v. 20-27), servant of Elisha, who finding that his master had gratuitously cured of leprosy Naaman, the rich Syrian, thus establishing a precedent for dispensary abuses, remarked, "as the Lord liveth, I will run after him, and take somewhat of him," and in the end took not only a fee but the disease. Upon these precedents the Nebraska court ruled thus:

"The exercise of the art of healing for compensation, whether exacted as a fee or expected as a gratuity, cannot be classed as an act of worship. Neither is it the performance of a religious duty, as was claimed in the district court." They further said: "The object of the statute is to protect the afflicted from the pretensions of the ignorant and avaricious, and its provisions are not limited to those who attempt to follow beaten paths and established usages." This, it will be noticed, is very different from the view of the New York law taken in the New York case of Smith *v.* Lane and the Ohio case of Eastman *v.* State (*supra*), as well as from the latest case of the kind, State *v.* Mylod (40 At. 753), decided in Rhode Island last July upon these facts: Defendant undertook to cure one Hale of malaria and one Vaughan of grippe, by apparently engaging in silent prayer and giving them pamphlets on Christian science. He received a fee of $1, but gave no medicines, made no examination or diagnosis. He testified that he did not attempt to cure disease, had no knowledge of medicine or surgery, and that his only method was "prayer and effort to encourage hopefulness for all who come to him in public or private, and whatever diseases they imagine they have." The court held, citing Smith *v.* Lane, that in the absence of diagnosis, prescription of remedies, or surgical methods there was no medical practice. They suggested that if Christian science is practice of medicine, then as a school it is entitled to recognition by the State board, and that it would be absurd to hold, under the Rhode Island statute which forbids discrimination against medical schools, that requirements could be prescribed which members of a particular school could not comply with, since that would be not to discriminate only but to prohibit. And the court distinguished the cases of clairvoyant physicians, upon the ground that therein the defendants had prescribed medicine and professed to cure diseases. There seems to be fallacy in the implication by the court that any educational requirements as a condition of medical license are prohibitory upon any persons except those who are unable to acquire an education; and it is quite proper to exclude such persons from the ranks of physicians.

The question is full of difficulty. Every one admits the power of mental impulses in nervous diseases; admits nature's healing force that so often cures without any attendance at all; and admits that it would be wrong to forbid all recourse to any aid. But this much being conceded, are we to admit also that any person should be entitled to take charge of the sick merely because he pretends to act under religious beliefs and to abstain from using those remedies and methods arrived at by study and investigation? Are we to punish the physician who fails to report yellow and scarlet fevers, diphtheria, and other contagious disorders, and allow a person who boasts his ignorance of medical and sanitary science to treat and conceal such cases? The Christian scientist, in his madness or worse, says that there is no disease but only fear or loss of relation to God, which he in his blasphemy undertakes to restore, providing he is paid for his services. What, then, would his death certificate be? Would it be that Jones was permanently scared? What would his report of a contagious disease be? That Brown has a panic, which is likely to spread?

In the case of Reynolds *v.* United States (98 U. S. 145, A.D. 1878) the supreme court of the nation applied common sense to this proposition, that the name of religion may be used to cloak either lust or imposture. Defendant, a member of the so-called Church of Jesus Christ of Latter-day Saints, being indicted for bigamy, pleaded in defence that the penalty imposed by his church upon its male members who failed to practise polygamy "when circumstances would admit" was "damnation in the life to come." No such dreadful penalty hangs over a Christian scientist who abstains from his lucrative practices. The supreme court said in Reynolds' case: "Laws are made for the government of actions, and while they cannot interfere with mere religious belief and opinions they may with *practices*." Can it be seriously contended, asked the court, that a civilized nation may not law-

fully suppress human sacrifices and the Indian custom of suttee, because their votaries claim religious sanction therefor; or polygamy for the same reason? To suffer such things, it was answered, "would be to make the professed doctrine of religious belief superior to the law of the land and in effect to permit every citizen to become a law unto himself. Government could exist only in name under such circumstances." These wise words of the court apply even to honest believers, whom we may respect, or, at least, sympathize with, even in their delusions. But if the defence of religion were allowed to the extent that the eccentrics claim, the deadly sin of lying would become even more prevalent than it is, and the dangerous classes would go over in a body to *soi-disant* religion.

There was an English case in 1868, Reg. *v.* Wagstaffe (10 Cox's Cr. Cas. 530), wherein parents were charged with manslaughter of a child because, pursuant to their religion as members of the "Peculiar People," they neglected to provide medical attendance for it, in a case of acute inflammation of the lungs; instead they anointed and prayed over it. The court charged that if they had let the child starve for want of food, the case would have been different; for every one recognizes the need of food. But it was not the same when the question was one of medical attendance, for as to that opinions differed, and he read to the jury from the general Epistle of St. James (v. 14–15) those words upon which the Roman church rests the doctrine of extreme unction, and the Mormons and "Peculiar People" rest their doctrine of healing the sick by anointing and prayer *only*: words which the learned and sensible commentator, Adam Clark, forcibly argues to be an exhortation by the apostle to use the ordinary Eastern remedy, oil, *as well as* prayer, in treating the sick. The jury acquitted. Recently in a like case, Reg. *v.* Cook, they convicted.

Beyond doubt there are very honest, intelligent, cultivated persons who believe in the efficacy of Christian science and faith cure. Among some twenty cases of death under such treatment, including cases of contagious diseases, the writer has noted the names of such persons. It is equally true that some "intelligent persons" find no "fad" too extraordinary for adoption. The writer knew of a most shrewd and cultivated woman who consulted in Sing Sing prison as to investment in stocks an "astrologer" convicted not only of illegal medical practice but of abhorrent crime. It is said that where voudooism prevails, cultivated people consult its priestesses, after the fashion of Nicodemus. And when St. John Long, prince of quacks, was convicted of manslaughter at the Old Bailey (4 Car. and P. 398) among the twenty-nine patients who testified to the excellence of his treatment were divers "ladies of quality," headed by the Marchioness of Ormond, than whom, save royalty, only a duchess could be better able to form a sound opinion in such a case.

But nothing is more false than to say that medical laws forbid the practice of Christian science, faith cure, voudoo, vitapathy, or any other "pathy" or cult. Those laws provide only, at most, that no person shall practise medicine who has not pursued a course in medical study. There is nothing in them to prevent any licentiate from practising as he pleases. There is nothing to prevent a masseur without license from washing and rubbing a man, if he confines himself to that. But there is no reason why unqualified persons should be allowed to pretend to cure disease, by their pretences deprive the sick of the benefits of science, and yet escape the just consequences of their imposture. The whole case of these people who desire to earn a livelihood by treating the sick without any adequate preparation therefor through study and investigation was summed up in the grotesque falsehood, circulated by way of petition to the New York legislature of 1885 for the repeal of the medical law, which said:

"The law deprives from practising in this State persons who are gifted with the power of healing by the laying of hands, through the presence and imparting of vital magnetic force, and otherwise. Some of these powers are natural to the practitioner and cannot be imparted or increased, *but are likely to be limited or impaired by the course of study required by medical colleges.*" Could anything be more absurd? The natural power to heal disease impaired by the acquisition of knowledge concerning disease! And yet there were those prepared to believe even that, so true is it to-day as of old that the wonderful is the unknown and the credible that which is impossible of belief.

It may be a question of policy whether Christian scientists should be prosecuted; whether cheap martyrdom might not strengthen them. But there seems no good reason, as matter of law, why they should not be punished for the evil they actually do, prohibited, if the policy seem wise, from treating the sick without adequate preparation by study of medical science, and convicted of manslaughter if death results from their interference.

59 Wall Street, November 19, 1898.

COMMON-SENSE INFANT FEEDING.

By LOUIS FISCHER, M.D.,

New York.

When nature has been unkind, and deprived the infant of its proper food—breast milk; or if the infant's mother is prevented from nursing her offspring through illness—accident (epilepsy), tuberculosis, syphilis, carcinoma; then we must give a substitute which offers nutritious qualities. At the same time we must bear in mind that the digestive functions of an infant cannot equal those of an adult.

Substitute Feeding at Birth.—An infant from its birth and until it is two months old should be nursed or fed once every two hours—no oftener. Some children will sleep—from 10 P.M. until 6 A.M.—without feeding; others will require an extra feeding about 2 A.M. The mixture is to consist of the following:

Formula No. 1.

℞ Cow's milk	200 gm.	(or about 7 oz.)
Water	600 gm.	(or about 20 oz.)
Milk sugar	30 gm.	(or 1 oz.)

The above is to be divided into eight parts, so that the quantity for each feeding consists of about 100 gm., or about 3 oz.

Formula No. 2 (for a Child Two to Four Months Old).

℞ Cow's milk	350 gm.	(or about 12 oz.)
Water	700 gm.	(or about 23 oz.)
Milk sugar	36 gm.	(or about $1\frac{1}{2}$ oz.)

One feeding after the infant is two months old every two and one-half to three hours, and no oftener.

The above quantity is to be divided into seven portions, each portion to consist of 150 gm., or about 5 oz.

Formula No. 3 (for a Child Four to Five Months Old).

℞ Cow's milk	500 gm.	(or about $16\frac{2}{3}$ oz.)
Water	500 gm.	(or about $16\frac{2}{3}$ oz.)
Milk sugar	40 gm.	(or about $1\frac{1}{3}$ oz.)

This quantity is to be divided into six portions, three bottles containing 6 oz. and three 5 oz. each.

The infant now requires one bottle of 5 oz., alternating with a bottle containing 6 oz., once every three hours—no oftener.

Formula No. 4 (for a Child Five to Nine Months Old).

℞ Cow's milk ..... 750 gm. (or about 25 oz.)
Water..... 375 gm. (or about 12½ oz.)
Milk sugar..... 50 gm. (or about 1⅔ oz.)

The above quantity is to be divided into six portions, three of 6 oz., and three of 7 oz. each.

The same rule applies here to alternate—once every three hours a six-ounce bottle, followed three hours later by a seven-ounce bottle.

Formula No. 5 (for a Child Nine to Twelve Months Old).

℞ Cow's milk ..... 1,125 gm. (or about 37½ oz.)
Water ..... 375 gm. (or about 12½ oz.)
Milk sugar ..... 50 gm. (or about 1⅔ oz.)

We now feed the baby with 8 oz. of the diluted milk at each feeding, once every four hours.

The above quantity is to be divided into six portions, each containing 8 oz.

Formula No. 6 (for a Child Over One Year of Age).

℞ Cow's milk ..... 1,500 gm. (or about 50 oz.)
Milk sugar ..... 59 gm. (or about 1⅔ oz.)

We now feed but once in four hours—using pure milk, no dilution—giving the baby 8 oz. (½ pint) at each feeding.

The above quantity is to be divided into six equal portions, containing 8 oz. each.

We therefore have, in formula No. 1, about 7 oz. of cow's milk, to be given in twenty-four hours; in formula No. 2, 12 oz. of cow's milk, in twenty-four hours; in formula No. 3, 16⅔ oz., in twenty-four hours; in formula No. 4, 25 oz., in twenty-four hours; in formula No. 5, 37½ oz., in twenty-four hours; and in formula No. 6, 50 oz. of pure cow's milk, to be given without water, in twenty-four hours.

The above formulas will serve to illustrate the quantities to be given children from birth to the first year, and more especially for those children removed from the city, where modifications of milk cannot be procured. Good, wholesome cow's milk is easily obtained throughout the whole country, for the health departments of the various States exercise a careful supervision of the milk supply. It is safer, of course, to subject each cow to the tuberculin test, but when this is not possible it is safer to use the milk of several cows, rather than feed a baby from the milk of one cow.

Sterilization.—It is necessary to sterilize everything used in connection with infant feeding. By this I mean that the cow, the pail for the milk, and the immediate surroundings (stable), and by all means the manipulator's hands, must be absolutely clean. This also applies to the bottle, the nipple, and to everything coming in contact with the milk mixture to be used for feeding. Sterilization really means destroying pathogenic bacteria, and the same applies to the pasteurization of milk foods. It also means the utmost cleanliness and prevention of contamination by the addition of filth in any form, be it through microorganisms or by the accidental introduction of dirt from the cow's udder or otherwise. We can accomplish the desired results by using good wholesome milk in the proper dilution, and dividing it into absolutely clean bottles, if we will only take the trouble to impress on the mothers or nurses in charge all these details of the preparation of the infant's food, and also that they require careful attention but once in twenty-four hours. In order to prepare formula No. 1, I would proceed in the following manner: The number of feedings, as above stated, are eight in twenty-four hours; consequently we prepare eight bottles every morning. The bottles are first to be washed with some small shot and warm water, thoroughly rinsed, and turned upside down. If they are new bottles, it is a good plan to give them one good washing; then, turning the bottles upside down, allow the water to drain off. I then insert a large stopper, consisting of absorbent cotton, well into the neck of the bottle, at least one-half to three-fourths of an inch, and take the empty bottles, cotton stoppered, place them in a large frying-pan, with a small piece of pasteboard between each bottle, and bake them in the hot oven about half an hour. This not only dries the bottles thoroughly, but, baking them as it were, sterilizes them. I next dissolve one ounce of milk sugar in the twenty ounces of water, and add seven ounces of fresh cow's milk. The milk sugar being dissolved and the milk added to the water, I pour this mixture into a saucepan and boil it for about ten minutes, and then divide it among the eight bottles, care being taken to have the bottles warm, else they will crack while the milk is being poured into them. The cotton stoppers are to be disturbed merely to pour into the bottles the requisite quantity of the milk mixture, and are immediately replaced; otherwise contamination may be possible. These eight bottles are then to be put in a cool place; an ice chest is preferable, but not contact with the ice. Each bottle is to be warmed immediately before the baby is fed.

A Word about Nipples.—Attention to this portion of the feeding-apparatus is very important, as the cause of sore mouth and tongue and gums can frequently be traced to an infected nipple. The nipples are therefore to be boiled, immediately after being used, in plain water to which a pinch of salt has been added, and allowed to soak in salt water until ready for use. Before putting a nipple on the bottle, a good plan is to soak it for fifteen or twenty minutes in plain sterilized (boiled) water, and when the cotton stopper is removed the nipple should immediately cover the bottle.

After the child has been fed, the bottle should be rinsed, and must be boiled again in water containing a little caustic soda, common washing-soda, before being used again for feeding-purposes.

If a child takes only part of one bottle, then the rest must be thrown away and a fresh bottle used for the following feeding.

I wish to emphasize the fact that we must individualize our method of feeding, and remember that while some children merely require food once in three hours, others will require feeding every hour and a half. The capacity of an infant's stomach at birth is estimated to be about one and one-half ounces. It has been found that excessive feeding over this amount may cause vomiting. The usual amount recommended for an infant at birth is about two ounces.

In formula No. 1 the amount of food given for an infant at birth, and up to two months, is about three ounces. This conforms with the views entertained by Professor Baginsky, of Berlin.

After the child is ten weeks old, the amylolytic function develops, and we can then dilute the cow's milk with some of the following mixtures, if the condition warrants it.

Fluids for Dilution of Milk in Hand Feeding.—Barley water. Take a tablespoonful of pearl barley, grind it in a coffee grinder or pound it in an ordinary mortar; add one pint of cold water, and allow it to simmer slowly for about an hour. Strain and add enough water to make one pint.

Oatmeal water. Take a tablespoonful of ordinary coarse oatmeal and add one pint of water. If it is allowed to stand for several hours before using, the oatmeal swells and can be more easily boiled. It is well to allow the oatmeal to simmer slowly for one hour, and then strain. Add enough water to make one pint.

Farina water. A tablespoonful to a pint of water boiled for from ten to twenty minutes, and strained

through coarse cheesecloth. Add enough water to make one pint.

Rice water. Take a tablespoonful of rice to a pint of water, and allow it to boil at least three-quarters of an hour or an hour; then strain, and add enough water to make one pint.

Flour ball. A small bag made of cheesecloth is to be filled with wheat flour, and suspended or immersed in a saucepan of water. This is to be boiled from six to twelve hours constantly. The flour becomes agglomerated into a hard mass, and is doughy only on the surface. It is then removed and allowed to dry, and after removal of the crust it is grated, and makes a whitish-yellow powder that is very nutritious. I usually commence feeding with a teaspoonful to ten or twelve tablespoons of water, with a pinch of salt and sugar, for one feeding. If it agrees well with the child, then I increase the quantity of the flour ball by adding a half-teaspoonful more every three days to the same quantity of water. If this agrees very well and the child seems to assimilate its food, then I usually, after one week of flour-ball feeding, substitute one ounce of cow's milk for one ounce of water, so that the formula would be one teaspoonful of flour ball, four ounces of water, one ounce of cow's milk, pinch of salt, and some lump sugar—for a child nine months old, and older. This formula I have found eminently successful in the treatment of summer diarrhœa, but I usually omit the milk.

The guide to the value of any given food is the scales. I insist upon weighing every child at least once a week, and if there is not an increase of at least four to eight ounces in the first three or four months of infant feeding, and at least several ounces weekly (roughly estimated) up to the period of dentition, then it is safer to change the method of feeding; for if there is no increase in weight, the food certainly will do no good. Another valuable point to bear in mind is the condition of the infant's stools. If the child suffers from severe constipation or diarrhœa, or seems to show a severe form of colic, then the food must be changed. This also applies to any and all severe gastric disturbance, such as vomiting, or to fermentative conditions, such as eructations or severe colic shortly after feeding. One point to note is that we must individualize and cannot set cast-iron rules, which must adapt themselves for every infant's stomach; and it is important to watch a child's condition, its sleep, its digestion, its stools, its weight, before deciding that the food selected really agrees with it.

137 Second Avenue.

MODERN ASPECTS OF PUERPERAL FEVER.[1]

By F. D. GRAY, M.D.,

surgeon to christ hospital, jersey city, n. j.

Mr. President and Fellow Members: In deciding on a theme for your consideration this evening, it occurred to me that I could select none more practical—even if somewhat trite—than the febrile complications of the puerperal state.

The fact of their lessened frequency now, as compared with past decades, speaks well for the advances of modern medicine, and especially surgery; but until this dread foe of womankind is actually exterminated, we, as general practitioners, obstetricians, and surgeons, must continue to study and discuss its nature and the best means for its suppression.

It is hardly necessary to rehearse the symptomatology of puerperal fever, for most if not all of us have, no doubt, at some time or other, had it indelibly impressed on our minds—partly by the severity of our patient's suffering, partly by our ofttimes sense of powerlessness to save, and partly perhaps by a terrible suspicion that we may not have been entirely guiltless of the cause. But if we may pass by the symptoms, we cannot lightly leave the questions of origin and treatment.

There are a few cardinal facts that have gradually impressed themselves on the minds of the profession regarding the etiology of this disease.

Puerperal fever does not originate *de novo*. It does not depend on any indiscretion of diet, neither is it caused by too brief a period in bed. The day is past when a physician of intelligence can delude himself with the idea that his patient has a fever following her confinement because she ate meat on the third day or arose from her lying-in couch previous to that sacred ninth day. In fact, the time has about passed when even the uninformed part of the laity can be satisfied by the ever-ready explanation of the charlatan that his patient has "caught cold," while he himself knows that he has undoubtedly poisoned her as certainly as if he had administered an overdose of morphine or strychnine.

I think I am safe in saying that puerperal fever is always due to one of two causes:

First, and most frequent, is the introduction of septic germs into the genital tract during, just before, or within a few days after delivery.

Second, by the decomposition of retained secundines, clots, or secretions.

The result of the former of these causes is a true septicæmia, while the latter constitutes a sapræmia. The former condition is undoubtedly more serious and less amenable to treatment than the latter, but fortunately it is without doubt more easily prevented. I have a growing belief, as I shall try to establish later on, that the introduction of dangerous germs into the parturient canal is entirely unnecessary; but I am hardly willing to assert that the retention of clots or small portions of secundines is always preventable, or that their subsequent decomposition can always be forestalled. The rare cases in which this does occur, however, are usually amenable to treatment, if promptly instituted on the first appearance of symptoms. The healthy vagina and uterine canal of the pregnant woman may safely be assumed to be in an aseptic condition previous to any digital examination, by which means germs might be introduced. Further on I shall allude to the fact that the vaginal secretions are normally not only aseptic, but distinctly antiseptic. Kroenig states that the antiseptic virtue of the normal vaginal secretion is sufficient to sterilize that cavity in the course of forty-eight to seventy-two hours; so we may fairly assume the normal parturient canal, previous to the approach of physician, midwife, or nurse, to be aseptic; consequently a woman who suffers from what is commonly termed puerperal fever must do so as a result of introduction of germs from without and resulting septicæmia, or production of putrid poisons by decomposition of organic matter within, and a consequent sapræmia.

Accepting, then, the bacterial or putrid origin of the disease, we may next investigate the varieties of such poisoning and the various modes of its introduction or production. Just here two facts stand out clearly:

First, septic germs are of various sorts.

Second, not all bacteria are septic, but many are innocent.

The air we breathe, the water we drink, and the skin which covers our bodies are all more or less infested by bacteria; but most of these might and undoubtedly do at times find lodgement in the parturient canal with impunity. There are, however, a few dangerous varieties, and one in particular which under such circum-

[1] Paper read before the Practitioners' Club of Jersey City, November 9, 1897.

stances is deadly. I refer to the streptococcus. It is this micro-organism, as we know, which is the cause of the most virulent and uncontrollable of all puerperal diseases. Besides the streptococci, there are the staphylococci, the communis coli, the gonococci, the Klebs-Loeffler, and we may include the germs of one or more of the exanthemata. Undoubtedly all of them are capable of causing infection, accompanied by elevation of temperature and inflammatory action in the uterus and adnexa; but chief among all these agents of disease and death in the puerperal condition is the streptococcus pyogenes. It is no doubt true that the Klebs-Loeffler or streptococcus erysipelatos may prove as malignant, but fortunately they are more infrequent in this relation.

Van Schaick asserts, after a series of investigations, that the gonococcus may be found in the vaginæ of twenty-six per cent. of married women—a rather startling statement, if it be true; and the fact that gonorrhœal infection as a cause of puerperal fever is comparatively rare indicates that the parturient woman must be especially protected from that bacillus. A point to which I have alluded before is that the normal vaginal secretion is decidedly germicidal. It constitutes in the majority of cases an acid medium, which is destructive or at least strongly inhibitive to the pyogenic organism, which can exist and propagate in this medium only when, in addition, there are present lacerations or abrasions of the vagina or uterus. In the presence of infection, nature appears to make an effort to come to the patient's rescue by the generation of a new germ, known as a Döderlein's—which gives an added acidity to the secretions, and it is claimed makes them more strongly germicidal than any known antiseptic that can be safely used.

To summarize the question of etiology, it is, briefly, that puerperal fever is either septicæmic or sapræmic —germ infection or putrid poisoning. Of the former, the most virulent are the infections by streptococci, either pyogenes or erysipelatos; and the lesser infections are by staphylococci, coli communis, etc., or perhaps a mixed infection; that it is always important and generally possible to differentiate between septicæmia and sapræmia, as well as between the various forms of septicæmia.

Regarding the general facts as to etiology of puerperal fever, I believe the profession is practically in accord at the present day; but as to treatment, which we will now consider, there is more room for difference of opinion. It is to be hoped, however, that a physician whom I met in a case of this sort a few years ago and who advocated no treatment at all was the last of his type, and that he has since reformed. It seems almost unbelievable that within the past five years any graduate of a reputable medical college would be either so ignorant or so vicious, but this M.D. coolly informed me, when I asked him why he had done nothing for a case of sepsis of several days' existence, that it wasn't necessary—that he often had such cases and they got along all right without his bothering.

The first point in treatment on which I want to insist sounds anomalous, and yet I regard it as by far the most vital. It is to prevent the necessity for treatment. Here is a field where we can pin our faith to the gospel of prophylaxis with the utmost confidence that we will not be disappointed. There are few lines on which preventive medicine can be practised so absolutely.

What vaccination is to variola; what modern sanitation and quarantine are to cholera; what the guarding of water supply is to typhoid fever—all this, and with even more certainty, is surgical asepis to puerperal fever. I do not mean to insist upon all the details of what may be termed fussy asepsis; some of it even, such as the routine use of vaginal douches, I firmly believe to be harmful asepsis. The previous sterilization of the vulva, the use of sterilized napkins and pads, sterilized gowns for accoucheur and nurse, are all well enough; they are refinements of the art, but in my opinion they are not essentials. The essentials as I see them are surgically clean hands and instruments. Hands and instruments are the danger points. The ease with which the not overcareful physician may introduce septic matter into the vagina may clearly be seen. He rushes from a case of scarlatina, or perhaps from lancing a foul abscess or dressing a septic wound; the washing of his hands is likely to be more thorough after his examination of the patient than before—if, indeed, he takes the trouble of a preliminary wash at all—and in go the streptococci or Klebs-Loeffler, etc. A forceps delivery becomes necessary, and his instruments are produced from a bag in which he has carried them about from case to case for months or perhaps years—and after a preliminary dip in a carbolic solution, in they also go, with their load of bacteria; and in a few days the physician is wondering at his "bad luck" at having on his hands another of those troublesome cases that occur so often in his practice—and on his hands literally he has carried the cause of trouble, and similarly conveys it to his next unfortunate obstetric case.

Not always is it an unseen germ which such a practitioner introduces, but in some cases it is actually a septic wound or sore on his own hand that kills his patient or makes her a chronic invalid. One such case at least I have in mind, the history of which I have from reliable witnesses; a physician—one, by the way, who is said to enjoy a large obstetric practice —attended a woman while he had a suppurating sore on his finger, and within ten days his patient was dead, having had typical symptoms of puerperal sepsis, accompanied by membranous patches on the vagina and cervix. Possibly the doctor had not heard of the dangers of streptococci, or possibly he was not willing to sacrifice his fee even though he sacrificed the life of his patient. I suspect though that to this day that man never fully realized the enormity of his offence.

The old saying, "An ounce of prevention is worth a pound of cure," may well in these cases read, "An ounce of prevention is worth untold pounds of cure." For prevention, as I shall shortly try to show, is almost universally possible, while cure is at best very uncertain; and even if life is saved it is usually at the expense of a vast amount of anxiety and labor on the part of the physician, and in many cases a chronic invalidism for the patient.

There are those who claim that the occurrence of a case of puerperal sepsis is clear evidence of malpractice on the part of the attending accoucheur or nurse, or both—a statement which is probably too severe; I am free to admit that this disease may in rare cases occur apparently in spite of every precaution. It is no exaggeration, however, to say that the wilful neglect of any preventive measure during the lying-in period constitutes one of the grossest types of malpractice.

I trust you will permit me to introduce a short chapter of personal experience in proof of my contention that puerperal fever is almost if not absolutely preventable. I present this not in any boastful spirit, for no doubt many if not all of my hearers could produce an equally good record. I give it rather in a spirit of humility that the whole period of my obstetrical practice does not afford so good showing.

Of my last four hundred confinement cases, approximately covering a period of between four or five years, I have had to contend with but two cases of this sort that could be called in any way serious—in both of which the patients I am happy to say recovered, after much suffering on their part and much anxiety and struggle on mine. In the one case I am still uncertain wheth-

er the patient was infected by my using an unsterilized silver catheter to relieve retention of urine on the second day, or whether it was the result of a washing of the vulva by a dirty and ignorant nurse on the same day with water from an ordinary slop-bucket applied by a common domestic sponge. I like to think, and I believe with reason, that it was the latter procedure which did the damage. The second case developed during my attendance on the first, and was no doubt infected by me in spite of thorough precautions. This leads me to say right here that I am satisfied we ought never to go to a maternity case for at least one month after having been so unfortunate as to have in our care a genuine case of puerperal fever. I believe it is Lawson Tait who said, in an article published early this year, that there are two septic poisons which it is impossible to get rid of by any antiseptic method, viz., that of puerperal sepsis and of certain virulent forms of peritonitis; they simply have to wear away, and during that period (of a month at least) the tainted person has no right to perform a laparotomy, and, I will add, attend a case of obstetrics.

To return to my statistics, the two cases mentioned occurred among the first hundred; and, as a result of increased vigilance, the last three hundred and twenty-five cases, approximately covering a period of between three and four years, have not contained a single case that may fairly be dignified by the term puerperal sepsis. Perhaps a half-dozen presented, some time after the third day, a temperature of from 100° to 101° F., accompanied by slight chill and some malaise, all of which were promptly subdued by a single or at most a second antiseptic vaginal douche, and which, from the lateness of their development and the promptness of relief by the simple means used, were undoubtedly only mild cases of sapræmia. Of the remainder, not one had a temperature above 100° F. or any symptoms of illness. I believe it is fair to assume that the uniform results of more than three hundred cases, covering a period of three years or more, may be extended to three thousand or any number of cases as well, under similar conditions; hence I feel that I have proved my assertion that puerperal fever is nearly if not quite universally preventable, if we will take the necessary precautions.

My list includes women of all walks of life—those from the lowliest and most squalid surroundings to those most favorably situated; those cared for by the most ignorant, careless, and obstinate nurses to those having the benefit of the most carefully trained attendants. In none of them did I follow the ultra refinements of previous sterilization of the genitals, or subsequent vaginal douche, except in those very few cases referred to in which the symptoms of a mild sapræmia indicated it. In no case did I cover my clothing with a sterilized gown, nor were sterilized napkins or pads applied to the vulva. In all cases I endeavored, by proper protection of the bed, to prevent its being soaked with discharges that would ferment and decompose later on, and in all did enjoin upon the nurse to prevent accumulation of lochial discharge upon the vulva by frequent ablutions with a weak carbolic solution applied with a cloth that had not been used since its last washing. From all this I am satisfied that the freedom from unfavorable results was due to two things, viz., surgically clean hands and instruments.

At the risk of being prolix, I want just here to emphasize the details necessary to accomplish this. To begin with, the safe accoucheur, just as the safe surgeon, should be chronically aseptic; spasmodic efforts upon surgically unclean hands are not worth half so much as when applied to hands that are daily familiar with soap and nail brush, nail file and antiseptic solutions, even when the immediate necessity for the same does not appear.

Then, when called to the bedside, let us remember that no detail of preparation of the hands is too trivial to observe. Soap and warm water, nail file and spud, nail brush and antiseptic solution, are to be used so thoroughly and as long as the exigencies of the occasion will permit before the first examination is made; then, too, do not delude yourself with the idea that one sterilization will suffice for the entire case. Have a basin of mild antiseptic solution near by, into which the hand can be dipped previous to each vaginal examination.

As to instruments, it is hardly necessary to say that nothing short of thorough boiling will make them safe. Before leaving this point, I want to call your attention to the immunity which strict asepsis of hands affords from trouble consequent upon frequent examinations. There seems to be a holy horror of this procedure on the part of many in the profession. This is chiefly, I think, among writers and teachers. It may be very well to instruct students in the refinements of the art, but what is the use when diagnosis can be so much better made and just as safely by the combined method, if only the attendant's hands are truly aseptic? Furthermore, it cannot be denied that the closer you watch the progress of your patient the better for her, and this certainly means fairly frequent examinations. More than this, I am a believer in the efficiency of digital dilatation of the cervix in obstinate cases and similar relaxation of the perineum from within the vagina. Much time is saved to the attendant and much suffering to the patient by these procedures; parts are relaxed and softened that otherwise would remain rigid and easily tear, and all this is accomplished with perfect safety, if your hands are aseptic.

It would be just as sensible to advocate "long-distance" surgery, owing to the fear of sepsis, as to demand "long-distance obstetrics" on the same ground. If either surgeon or accoucheur is not aseptic in his work, he will have bad results, but with proper care both are equally safe.

I dare say that in fifty per cent. of my maternity cases I employ, at one stage or another, digital dilatation of the cervix or digital relaxation of the perineum, and have done so with impunity, for more than three years at any rate. I also employ digito-vaginal examinations as often as I think the necessities of any case demand, without the slightest fear that I am recklessly exposing my patient to the probability of septic complications. The fact is, I have a suspicion that those zealous antagonists of intravaginal examinations and manipulations during labor have not practised strict asepsis in their obstetrical work, or they would not stand in such awe of the results.

Passing now from the discussion of preventive treatment, allow me to present as briefly as possible the various methods of combating the disease after its actual occurrence, for, no matter how faithfully we may preach the doctrine of prevention, there are and always will be careless doctors, midwives, and nurses, and as a result we shall at times be called to help them undo their bad work, even if we ourselves never relax our vigilance or have an oversmart nurse anticipating our arrival by examinations with finger nails in mourning.

When the light of pathology first broke over the darkness that had enshrouded puerperal fever, we were taught to place chief reliance on the antiseptic vaginal douche—using it as a routine after confinement and increasing its frequency in case of infection. Then it dawned on the minds of the profession that this procedure reached only the vestibules of the structure where the disease was too often entrenched, and the uterine douche with Chamberlain tubes, etc., held sway. It being found that in many cases the infections had invaded the depths of the mucous membrane, and also

often much deeper, as it was subsequently learned, the sharp curette was called into play and we were adjured to curette unsparingly until all the infected mucous membrane had been cut away. Later, again we were warned against this procedure, as only opening up fresh channels of infection. Still more recently the very radical obstetric surgeon advocated and performed hysterectomy in those cases in which infection had extended to the uterine substance and adnexa; and last, but let us hope not least, comes the serum treatment of this disease with Marmorek's or streptococcus antitoxin. To be candid, we must admit that probably each of the therapeutic means enumerated has its sphere of usefulness, and no doubt he will subdue most cases of puerperal fever who can most happily select from among them all the particular weapon or combination of weapons most suited to combat the particular case.

Regarding the efficiency of the antistreptococcic serum of Marmorek, I cannot speak from personal experience, for the simple reason that I have had no occasion to use it since its introduction. From my reading, however, I gather that in those instances in which it has been employed it has had about an equal number of successes and failures—the latter, no doubt, due in part or largely to the fact that it has been used in many cases indiscriminately, while it can be expected to show good results only in streptococcic infections, or at most in cases of mixed infection in which the streptococcus plays a part. For puerperal fever due to poisoning by staphylococci, coli communis, etc., or in saprophytic infection, it must in the nature of things be useless. Owing to this fact, the early differential diagnosis between the different varieties of puerperal fever becomes highly important. For this purpose the only true test, of course, is the bacteriological culture—which may be carried out by the inoculation of a culture tube with a sterilized swab moistened with the vaginal or uterine secretions; or, in case of the uterine contents, it can be done more exactly by withdrawing from it, by means of a sterilized glass suction tube, a few drops of fluid, and applying the same to the culture-tube media, and subsequently subjecting the same to microscopical examination. However, all this takes time, and in most of these cases time is vital; treatment, to be successful, must be prompt. The delay of twenty-four hours to learn the result of our culture test may mean the death of the patient. There are fortunately other approximate points of differential diagnosis. We know that streptococcic infection is likely to occur early—before the third day. Sapræmic poisoning is most likely to take place later. The former is apt to be accompanied by more intense initial symptoms, while the latter is generally milder in character. On general principles, then, a case of puerperal fever occurring early and presenting an intense type should have the benefit of the antistreptococcic serum before waiting for the result of a culture, which latter should nevertheless be made at the earliest possible moment. In fact, in order to be on the safe side and give my patient every chance, I should be inclined to use the serum treatment in all cases, for, by analogy with diphtheritic antitoxin, I am sceptical of any serious results that could arise from such a procedure, in case the condition proved not to be due to streptococci. In cases in which the Klebs-Loeffler bacillus proved to be present or in which pseudo-membranous patches appeared on the vagina or cervix, I would certainly use the diphtheritic antitoxin on the same basis.

Coming to the local treatment, there is no doubt that in a minority of cases—those of vaginal origin and depending on a mild bacterial or sapræmic infection—the time-honored (but more often dishonored) antiseptic vaginal douche is all that is required. A few cases referred to earlier seem to prove this.

Regarding the use of the curette, the consensus of recent opinion is that it should be confined to those cases of sapræmia due to retained clots or portions of secundines, and that with rare exceptions only the dull instruments should be used. The use of the sharp curette, however, seems to be safe, and is no doubt indicated in cases accompanying early abortion—previous to the third month—for then the lymph and blood channels of the uterus are smaller and less open, and usually there is also a granulation zone underneath the decidua, which serves as a barrier to further entrance of micro-organisms.

All curettage should be followed by intra-uterine irrigation and the subsequent application of Churchill's caustic tincture of iodine or of caustic solutions of silver nitrate or zinc chloride, in order to render the uterine canal non-absorptive, followed by the introduction of some self-retaining uterine drainage tube, such as Longyear's, which will permit easy and frequent intra-uterine irrigation.

A matter of practical importance to which I would allude here is the fallacy of gauze drainage in these cases. Gauze does not drain the uterine cavity perfectly, especially when introduced, as it usually is, firmly packed in, as it were. If applied at all, it should be very loose, so that the retained secretions may easily escape.

A common source of error in treating this disease is to regard the uterus as the sole seat of infection, while the fact is that in a certain proportion of cases the trouble is wholly vaginal. For this reason in all cases the vagina and vaginal portion of the cervix should be carefully inspected, and any areas of abrasion or laceration thoroughly cauterized. A practical point in the management of all confinement cases—one which strictly comes under the head of preventive treatment—is the advantage of having the patient void urine in the sitting posture, thereby facilitating drainage of secretions and discharge of clots, etc., with consequent prevention of sapræmia. This entails no risk, except in rare cases of unusual weakness or when a ruptured perineum has been immediately sutured. In all other cases it should be a routine measure.

Regarding the advisability of hysterectomy in those instances of severe infections, accompanied by metritis or inflamed adnexa, or both, there is much to be said for and against. The chances are that whichever course is pursued in those cases, the attendant is likely to wish he had chosen the other.

Pan-hysterectomy in such a case, if well advanced, can hardly succeed in removing all the infected tissues, and must add much by its shock to the already desperate condition of the patient. To make success at all certain, it must needs be done within the first twenty-four to thirty-six hours, before infection is far advanced, and he would be a bold surgeon indeed who would adopt such a procedure at that stage. If the patient should fortunately survive the acute process of the disease and present a pelvic abscess or diseased adnexa, the former may be evacuated per vaginam or along Poupart's ligament, or the latter removed by the abdominal or vaginal route.

A practical point in treatment which has been lately advocated, and which commends itself to our judgment, is the submammary injection of decinormal saline solution. It stimulates the patient, dilutes the infected blood current, and sometimes tides her over the critical period of her disease.

The foregoing therapeutic measures, together with general stimulation and suitable supportive medication, appear to me to be the basis upon which we must hope to control, if possible, this formidable foe of the puerperal woman.

Before I close, I desire to refer to two practical points of diagnosis. One is the possibility of mistak-

ing malarial infection for puerperal sepsis. A sharp chill, rise of temperature, and general malaise, occurring during the puerperium, do not always mean septic or sapræmic infection. It may be only a malarial explosion. Absence of pelvic tenderness and of a fetid odor of the lochia will usually suggest the possibility of the malarial cause, while the presence of protozoa in the blood or a few full doses of quinine in solution will settle the diagnosis; still, even in these cases when at all in doubt, or until diagnosis is established by the above means, it is of course safer to treat a malaria as sepsis than to neglect a sepsis on the theory that it may be malaria.

The other point has reference to two symptoms just mentioned, and which are usually regarded as pathognomonic of puerperal sepsis, viz., pelvic tenderness and fetid lochia. It is well to bear in mind that some of the worst cases of true septicæmia occur with a total absence of these manifestations, the poison seemingly entering the uterine sinuses and passing directly by the circulation throughout the system, without causing the usual local symptoms. These are commonly cases in which we are powerless to help.

As a final word, let me enter another protest against that sacred and time-honored instrument, the vaginal syringe in obstetrics. I believe its routine use, either before or after delivery, is bad practice and has been responsible for vastly more harm than good. It should never be employed after labor, unless there is some positive indication for its use, and then only by the physician or a capable trained nurse, after specific directions from the physician. There is no doubt in my mind that its employment by any one during the first twenty-four to thirty-six hours following confinement is absolutely dangerous, owing to the liability of injecting the uterine sinuses or forcing fluid through the patulous Fallopian tubes.

It would be well should we all subscribe to a rule which I recently read in one of the current journals, laid down by some wise obstetrician, whose name I unfortunately forget. He says that invariably when assuming charge of a maternity case, especially when he is not sure of the nurse, he inquires if there is a syringe in the house, and, if so, he carefully locks it up and takes charge of the key.

CLOSURE OF WOUNDS OF THE ABDOMINAL WALL.[1]

By ROBERT J. REED, M.D.,

WHEELING, W. VA.,

SURGEON TO CITY HOSPITAL; PRESIDENT, BALTIMORE AND OHIO ASSOCIATION OF RAILWAY SURGEONS.

The chief concern ordinarily in the treatment of flesh wounds, whether traumatic or operative, is to secure union by first intention—or, in modern phraseology, that they shall heal aseptically. A consideration of much greater importance is presented in wounds of the abdominal wall, when structures deeper than integument and adipose tissue are involved. It is the prevention of hernia. To this end simple surface healing is not sufficient; repair of the deeper layers, especially the perfect union of divided aponeuroses, is absolutely essential to the avoidance of this unfortunate sequela. Very painful is the surprise of the patient and in time extreme annoyance, and very deep is the chagrin of the surgeon, upon the discovery of a tumor in the position of a recent abdominal wound, which was believed to have healed perfectly. It may be in the location of an operative scar, the result of a section made for the removal of an intra-abdominal growth. In such an event there have been patients sufficiently unappreciative as stoutly to maintain that their last condition was worse than their first, and even question the skill of their surgeons.

Happily such results are not frequent; neither are they rare. The percentage of hernial formations following abdominal section, operative and traumatic, is difficult to determine. Statistics are unsatisfactory in connection with this question. It is doubtful if any entirely reliable will ever be compiled, for the reason that hernial development is remote from the time of operation. The majority of these patients are treated in hospitals. In the case books their histories are closed, "Discharged, cured." They become widely scattered. Weeks or months later the family physician may be consulted; abdominal supporters are advised, and with such helps they drag their lives along, many not returning to the surgeons who were primarily responsible. Clearly it is practically impossible to follow all of one's cases and to make a perfect estimate of the percentage of those which develop hernia. However, notwithstanding the fact that a large majority of cases will not suffer this misfortune by whatsoever method of closure adopted, it does occur in a minority sufficiently large to warrant the demand for a more certain method of treatment than the old-time through-and-through interrupted suture.

It is profitable to seek explanation of the occasional failure to secure perfect union when this method only is adopted. The tensile strength and competence of the abdominal wall are in its fasciæ. Together they form the fascial layer, the importance of which may be appreciated when it is considered how richly nature has provided the parietes with it. This measure of defence and security is present in every abdominal region, covering the entire epigastric, umbilical, hypogastric, and both inguinal areas. Even the lumbar regions are fortified by the strong lumbar fasciæ, the aponeuroses of the transversalis muscles. Only the anterior third of the lumbar and a small angle of the hypochondriac regions are without some portion of it. The combined bellies of the three muscles occupy and give strength to this space on either side; an area which will fall between two imaginary lines—one from the junction of the ninth rib with its cartilage and the anterior superior spinous process of the ilium; the second from the end of the twelfth rib to the highest point of the crest of the ilium, a width of scarcely three inches in a subject of medium girth. With the exception of these narrow surfaces, fascia is everywhere present in the wall.

Its strength and power of resistance are better appreciated when it is recalled that this layer, over the entire anterior portion of the abdomen, is, in fact, a combination of three tendons—firm, unyielding, white fibrous tissue, the aponeurotic terminations of the three abdominal muscles. The extent and strength of the fascial layer are evidences of its paramount importance. Moreover, it is apparent that there is no tensile strength in the other layers of the wall, integument, adipose tissue, recti muscles, without union of the fascia encasing them, or in the peritoneum.

If the fascia, then, is of such significance, it is reasonable that when divided especial care should be exercised in its closure. To cure hernia, inguinal and umbilical, the natural openings in the fascia are repaired by separate suturing in the most particular manner. To prevent hernia, should not artificial openings elsewhere in the fascia be given equal attention?

This fascial layer has active reparative powers under favorable conditions. It, however, being the aponeurotic expansion of muscles, will, as any divided tendon, retract strongly when its fibres are severed; and if the muscles are brought into unusual action by a straining effort, as in vomiting, which usually occurs

[1] Read at the meeting of the Baltimore and Ohio Association of Railway Surgeons, May 13, 1898.

after anæsthesia, the retraction will be still greater. In a thin abdominal wall a through-and-through suture will succeed as a rule in apposing the edges of the divided fascia; but in a thick wall with a heavy layer of adipose tissue there may be failure, since the through-and-through interrupted suture produces a loop of large circumference, with its lateral diameter necessarily of considerable length, making possible a separation of the fascia. On the other hand, the purse-string effect of the through-and-through suture, thrusting in from the outer and drawing up from the inner surface, may serve to interpose adipose tissue from without and muscular fibres from within between the separated edges of the fascia.

The imperfections of this suture have been recognized by many surgeons, with the result of numerous suggestions, made with the aim of procuring a better method. Tier suturing, coapting each layer separately by a line of buried sutures, has been strongly recommended. In this method opportunity has arisen for discussion and criticism of the suture material used. Unhardened sterile catgut, the most suitable for buried sutures, has been extensively advised; but when used alone it has proven insecure, since it may be absorbed before perfect union has been obtained. One writer reports thirty-five cases of imperfect results with this material, occurring in the work of a number of surgeons, covering a period of three years. It has been abandoned virtually, and the non-absorbable suture has come into more general use among those who have adopted the method of tier suturing: silk, silkworm gut, and silver, as well as the slowly absorbable kangaroo tendon and chromicized catgut.

That the sutures which are to be buried should be aseptic is an absolute requisite to a good result. Admitting that this is always possible, although there are frequent failures, there is yet a well-grounded objection to their use. There exists naturally a marked tendency to mural abscess formations in the course of the repair of abdominal wall wounds. Nothing so endangers the union of the fascia, its consequent separation, and subsequent hernia, as a suppurative process. The non-absorbable or slowly absorbable sutures are practically foreign bodies, and must necessarily act in some measure as irritants, thereby increasing the danger of suppuration. At the International Congress in Geneva, 1896, in the discussion of this very subject, the following was one of the conclusions reached: "That in the repair of the abdominal incision, suppuration is due, not to the presence of bacteria, but to foreign bodies or to strangulation by tight sutures." This is a statement from high authority, and is worthy of credence. The buried non-absorbable and slowly absorbable sutures must be convicted under this ruling, and will probably come more and more into disfavor as the truth of this conclusion is verified in the experiences of surgeons now advocating this procedure.

Many ingenious methods of closure have been devised, based upon the principle involved in the tier suture, but avoiding its objectionable feature — the suture not buried, but so placed as to be removed when union is effected. But one of these, which seems the least open to criticism, will be referred to. It is the figure-of-eight suture, suggested and advocated in Dennis' "System of Surgery." Silkworm gut is used, and the suture is thus described: "Beginning on the left side, for instance, we pass first through the skin and fat in the order named, then across to the right side, where it passes downward through the fascia, muscle, and peritoneum; it enters at a corresponding point under the peritoneum of the left side, then through the muscle and fascia of this side. The suture is then recrossed to the right side, and is brought out through the fat and skin to the surface."

This figure-of-eight suture is doubtless practicable in a thin abdominal wall, but in one with a thick layer of fat it is unsatisfactory, failing perfectly to coapt the fascia. In fact, the author who has been quoted advises that in such cases it is better to leave out the skin and fat, permitting them to close by granulation, applying the suture only to the fascia, muscle, and peritoneum, "including the fascia in the outer loop of the figure-of-eight, the muscle and peritoneum in the inner." It is hard to understand how this suture can without difficulty and pain be removed, if this suggestion is adopted, since it must, at least in some measure, be buried and hidden in granulation tissue. At any rate, a granulating surface is undesirable. It means frequent dressings, retarded convalescence, and leaves an unsightly scar. Hence, if in thick abdominal walls, the very ones demanding tier suturing, the figure-of-eight suture is unsuitable, it is unlikely that it will come into popular use, though ardently advised by this eminent surgical authority. Again, it is somewhat complicated in the technique of its introduction, and requires twice as much time as the simple interrupted suture.

With the view of protecting against hernia, it is advocated by some surgeons that in an operative incision near the median line it should be made through a rectus muscle and parallel to its fibres, rather than through the linea alba, in the belief that firmer and more reliable union may be secured in this way. But it is clearly a fact that muscular tissue is elastic and yields to moderate pressure. Union between parallel fibres is not strong. It is not firm before their division, gentle force with the blunt finger separating them. If power of resistance, therefore, rests in this muscle, it is by the perfect restoration of the fascial layer, which forms its sheath, making the repair of the fascia even in this procedure an essential step.

In view of the fact that the favorite through-and-through interrupted suture is so nearly satisfactory and is defective chiefly in one particular, its occasional failure to appose the fascia, it would seem a rational practice to keep the old suture, but correct its shortcomings.

It is not essential that the through-and-through interrupted suture should include the peritoneum. It is unquestionably better that it should not. By its omission, two lines of stitch holes are avoided; but especially is it desirable to escape the irritation to the peritoneum, which is occasioned by the presence of that portion of the suture between the stitch holes. When tied, it is embedded in the coat and to some extend wounds it, thereby encouraging inflammatory adhesion with the intestine, a condition which it is very important should not develop.

The edges of the peritoneal layer should be united separately and before the interrupted sutures are placed. Aiming to avoid a buried suture and seeking one easily removed, a silkworm gut of good length is selected. It is carried through the integument one-half inch below the termination of the skin incision, and down to the end of the incision in the peritoneum. The suture is anchored by an artery clamp, made to catch it a little distance from its end, permitting about two inches of it to remain free. The peritoneal incision is now closed by the silkworm gut, with a running stitch somewhat after the fashion of the basting-stitch, picking up the edge upon one side, crossing and securing the edge upon the opposite side half an inch further along, and so continuing back and forth to the end, where the suture is passed up through the integument half an inch above the beginning of the incision. By drawing forcibly upon the suture until it corresponds almost to a straight line, the peritoneal edges are perfectly apposed. This apposition is maintained by catching the silkworm gut with another

clamp just as it emerges from the skin. Should considerable length remain to the suture, it should not be cut away, but retained for a later service in the fascia.

The through-and-through sutures are then placed after the usual manner, care being taken to include every layer to the peritoneum. When they are in position and before they are tied, there comes the most important step, in my opinion, in the closure of abdominal-wall wounds—uniting the fascia. The interrupted sutures are collected together upon either side of the incision and held apart, exposing the edges of the fascial layer, which are then apposed in precisely the same manner as was the peritoneum. The remainder of the silkworm gut used in the peritoneum can be employed. If not sufficient length remains, a second suture can be tied to the first, close to the second clamp. Simply the edge of the fascia upon one side is included in the running suture, the same upon the opposite side half an inch beyond, and so on throughout the length of the wound. It is made to emerge at the end of the incision, and after being drawn taut, thereby perfectly apposing the edges of the fascia, it is tied to the protruding end of the peritoneal suture, when both clamps are removed. If a diminutive pad of gauze be placed under the silkworm gut at either end where it rests upon the skin, it will be prevented from embedding itself in the integument and occasioning discomfort in case of great abdominal tension. The repair of the incision is then completed by tying the interrupted sutures. This fascia suture is efficient and sufficient, since it is to approximate and not to support, being perfectly reinforced by the through-and-through suture, which relieves it from all strain. At the same time the interrupted sutures are removed, and with the same ease, this long peritoneal and fascial suture is withdrawn, after being cut at one end but at two points, the half inch of exposed suture being removed.

Although this simple method is particularly adapted to the closure of the operative abdominal incision, I wish to end this paper by emphasizing the importance, in my judgment, of its use in all traumatic wounds of the abdominal wall, sufficiently deep or so situated as to involve the fascial layer. In the treatment of lacerated, incised, and punctured wounds of the wall, such as are frequently encountered in railway and general surgery, it is certainly the part of wisdom to observe all possible precaution to avoid subsequent hernia. The surest safeguard is found in the fascia stitch, so speedily and easily taken, prior to the tying of the interrupted sutures.

73 Twelfth Street.

The Action of Certain Drugs and Mineral Waters on the Secretion and Composition of Bile in the Human Being.—Dr. William Bain (*British Medical Journal*, June 25th) made the following observations on a patient with a fistula of the gall bladder: (1) The total quantity of bile secreted in twenty-four hours is about 775 c.c., and contains 15.8 gm. of solid constituents. (2) The quantity secreted in the daytime is larger than at night. (3) The sulphocyanate of potassium of the saliva does not come from the bile salts. (4) The following substances increase both the quantity and solid elements of the bile: The mineral waters of Harrogate, of Carlsbad, of Kissingen, and of Spa; likewise euonymin, sodium benzoate, and sodium salicylate. (5) Podophyllin and iridin increase the solid constituents without perceptibly changing the quantity of bile. (6) Podophyllotoxin and the strong water of Montpellier Springs in Harrogate diminish to a slight degree both the quantity and the solid elements of the bile. (7) Hot water and soda water in large amounts do not appear to increase the secretion of bile. (8) Sodium salicylate increases the excretion of uric acid in the urine.

Progress of Medical Science.

Knee Bursæ.—Dr. N. C. Morse (*The Railway Surgeon*, September), in an article entitled "Traumatic Bursitis of the Knee," states that, according to Gray, the normal bursæ of the knee-joint are distributed as follows: Anterior, 3: (1) the prepatellar (found between the integument or skin and the patella); (2) between the upper part of the tuberosity of the tibia and the ligamentum patellæ; (3) between the lower part of the tuberosity of the tibia and the integument, at or about the insertion of the ligamentum patellæ. To these should be added: (1) One beneath the tendon of the quadriceps extensor, at or about its insertion to the upper and anterior surface of the patella; (2) the subcrureus bursa. Upon the outer side, 4: (1) one beneath the outer head of the gastrocnemius; (2) one above and (3) one beneath the external lateral ligament; (4) one beneath the tendon of the popliteus. Inner and posterior surfaces, 5: (1) one beneath the inner head of the gastrocnemius; (2) one beneath the insertions of the tendons of the sartorius, gracilis, and semitendinosus; (3) one above and (4) one beneath the tendon of the semimembranosus; (5) one between the tendons of the semimembranosus and of the semitendinosus.

Growing-Pains.—Dr. Bennie says that "growing-pains" have been diagnosticated by him less frequently as the years rolled by, and that cases which have been classified together under this name are the following: Myalgia from fatigue: this is the commonest variety, usually about the knees and ankles after unusual exertion. They are probably due to autoinfection brought about by excessive production of effete materials in the blood and their inefficient elimination. Elevating the limbs and rubbing with the palm of the hand in a direction toward the heart, relieving venous stasis and facilitating a supply of healthy blood to the exhausted muscles, promptly quiets the pain. Rheumatism: This is second, if not first, in frequency. There are slight pain in the joints, little or no swelling, and very mild fever, and hence the true cause is recognized; but rheumatic endocarditis frequently develops in these cases. Diseases of joints and bones of the lower extremities: Cases of hip-joint disease and suppurative epiphysitis of the upper end of the fibula, diagnosed by the laity and allowed to go on untreated, are related under this heading. Fevers, accompanied by pains in the limbs, in one instance proving to be the inception of typhoid fever, constitute this class. Adenitis: Here, again, the mother still supposes that the lad of sixteen years suffered from "growing-pains," but he was treated for gonorrhœa and a sympathetic bubo. The malady "growing-pains," with its frequent concomitant growing-fever, like its congener, disorders of dentition, as a separate morbid entity exists principally as an article of faith. The complaint still maintains, however, a strong hold on the lay mind, and forms an extremely common lay diagnosis, which is often the cause of much suffering and even death.—*Archives of Pediatrics.*

Syphilis and its Relation to Pregnancy.—J. A. Quimet writes (*American Medico-Surgical Bulletin*) of the effects of parental syphilis on pregnancy, and concludes that syphilis is a powerful cause of abortion, the abortion being due to lesion of the fœtus itself or of its appendages. It occurs mainly about the seventh month. The father alone, being syphilitic, can transmit the syphilis to the product of conception. The latter is more liable to occur the nearer the moment of conception is to the beginning of syphilis. The mother may give birth to a syphilitic child while remaining free from syphilis. When the father and

mother are both syphilitic, the child rarely escapes infection. The mother, if syphilitic before pregnancy, is more liable to give birth to a healthy child the more ancient the syphilis. The nearer the syphilis approaches the termination of pregnancy, the greater chance the child has to escape infection. The child born of a syphilitic mother may come into the world presenting lesions manifestly syphilitic, or be born apparently healthy and become syphilitic only after some months or even years. Syphilis imparts no particular characteristic to the course of confinement. Mercurial treatment should be instituted at the beginning of pregnancy.

Action of Sudden Cold upon the System.—It is a curious fact, that after exposure of the body to an intense dry heat or to a heated vapor, as in the Turkish or Russian baths, when the general temperature is somewhat raised and the surface is bathed in perspiration, a cold plunge, which checks the action of the skin almost immediately, is not injurious and is decidedly agreeable. This presents a striking contrast to the effects of sudden cold upon a system heated and exhausted by long-continued exertion. In the latter instance, when the perspiration is suddenly checked, serious disorders of nutrition, inflammations, etc., are very liable to occur. The explanation of this, so far as we can present any, seems to be the following: When the skin acts to keep down the temperature of the body in simple exposure to external heat, there is no modification in nutrition, and the tendency to an elevation of the animal temperature comes from causes entirely external. It is a practical observation that no bad effects are produced, under these circumstances, by suddenly changing the external conditions; but when the animal temperature is raised by a modification of the internal nutritive processes, as in prolonged muscular effort, these changes should not be suddenly arrested; and a suppression of the compensative action of the skin is apt to produce disturbances in nutrition, very often resulting in inflammation. — Dr. Austin Flint, "Text-Book of Human Physiology," page 521.

On the Amount of Fat in the Milk of Nursing Women under Varying Conditions.—Dr. Gersoni has made two thousand analyses of the milk of three hundred and ten nursing women (*Wratsch*, 25, 1898), to determine the proportion of fat contained in normal milk, and its fluctuation under varying circumstances. As the result of his labor the following data are presented: (1) The average per cent. of fat in the milk of a nursing woman for the entire period of lactation is about 3.48. (2) This per cent. varies greatly in different women and also in the same woman, the average amount being between 0.6 and 10 per cent. (3) During the first days of the nursing-period the milk is poor in fat, averaging about 3.03 per cent.; the amount of fat then gradually increases to about 3.8 per cent.; it remains almost stationary from the fourth week to the fourth month, when it again shows a tendency to increase. The milk of young women, of primiparæ, and of delicate women is richer in fat than is that of those more advanced in years, of multiparæ, or of robust women. (4) The quantity of fat is increased by moderate muscular exercise, by strong and frequent nursing, during the menstrual period, and also in fever. (5) A low meat diet has but very slight effect on the amount of fat. (6) A low or high percentage of fat in the milk is not of itself sufficient to cause gastro-intestinal disturbance; on the other hand, a sudden increase in the amount of fat may derange the child's digestion.

Rectal Injections.—The value of flushing the colon with properly sterilized water—hot, tepid, or cold, according to the special indications present—will be readily admitted in a long list of formidable diseases, some of which may be mentioned as follows: Habitual constipation, with or without mental depression or active cerebral manifestations due to auto-infection, being so common, might be permitted to head the list; all occult nervous affections, associated or not with the uric-acid diathesis, would naturally attract our notice, as it is well known that disordered innervation is generally conducive to the absorption of poisonous products from the alimentary tract. They are also serviceable in disease dependent upon pelvic congestion, such as uterine displacements, ovarian pains, and hemorrhoids, for they contribute materially, though indirectly, to relieve the original cause, viz., hepatic insufficiency. In appendicitis, perityphlitis, and abscess, for which the amœba coli communis is now held responsible, they are invaluable. Mild and even severe cases of dysentery and diarrhœa are often brought to a favorable termination without enemata, but it is safe to say that, with appropriate diet, all cases would be decidedly benefited, and many fatalities avoided, by the adoption of simple means. Enemata should find a place in the treatment of other disorders of this character, notably in the collapse of cholera morbus, yellow fever, and cholera, as well as in the conduct of cases of pleurisy or typhoid fever.—*American Therapist.*

The Smegma Bacillus.—Dr. J. L. Miller (*Medicine*, July) summarizes as follows: (1) Over the entire surface of the body and exposed mucous membrane, and especially on the genitalia, bacilli are found which resemble morphologically and in tinctorial qualities the bacillus tuberculosis. (2) From the external genitalia they frequently gain access to the urine, especially in women, and may be a source of error in the examination of the urine for tubercle bacilli. (3) The smegma bacillus presents wide variations in size and form, thus rendering morphological differentiation frequently impossible. (4) While most smegma bacilli are more readily decolorized by any of the solutions commonly employed, occasionally they possess equal or even greater resistance than the tubercle bacillus. (5) Methods of decolorization, when acids are employed alone, are especially fallacious; acid alcohol or dilute alcohols, unless long continued, are equally unreliable. Better, but not free from error, is the use of absolute alcohol for at least five minutes; in ammoniacal urine, however, such prolonged use of alcohol may also remove the stain from the tubercle bacillus. (6) Attempts to remove the fat or fatty acids from the bacilli by ether, chloroform, or other solvents fail to furnish us with a means of differentiation. (7) We must rely on means of excluding the smegma bacillus from the urine. It has never been demonstrated in the bladder, and apparently seldom invades the deep urethra; therefore, by cleansing the external meatus and withdrawing the urine with a catheter, we can exclude this possible source of error.

A Case of Poisoning from Camphor.—Dr. A. Berkholz reports the case of a young woman who took about fifteen grams of camphor suspended in water, probably with the intent of producing an abortion (*Petersburgische med. Wochenschrift*, No. 51, 1898). There were no immediate symptoms. After about two hours there were severe headache, vomiting, convulsions, and a comatose state; the pulse was very full and strong, and respiration rapid. The patient became highly excited, screamed, sang, and tossed about; the sensorium was completely benumbed. After repeated stomach washings and the administration of chloral and bromides, improvement set in and the patient recovered in a few days. The lethal dose of camphor

is placed at from two and one-half to seven grams. The writer believes that recovery in this case was due partly to the fact that after swallowing this exceedingly large dose of camphor the patient indulged in a hearty meal, consisting chiefly of carbohydrates, and that glyco-camphoric acid, which is non-toxic, was formed in the intestinal tract. He recommends large doses of sugar as an antidote in camphor poisoning.

Cassareep: A New Remedy for the Treatment of Corneal Ulcers and Other Infectious Diseases of the Eye.—In the *Philadelphia Medical Journal*, October 29, 1898, Dr. S. D. Risley, in an original article on the properties of this new remedy, discusses minutely its origin, chemistry, physical properties, and therapy. To Dr. H. B. Chandler, of Boston, he gives the credit for calling attention to what promises to be a useful addition to our means of treating dangerous and often rebellious forms of eye diseases. The writer emphasizes a few points with regard to the employment of cassareep. He has at no time used it stronger than in a ten-per-cent. ointment. It causes no irritation, however; there seems therefore no objection to employing it in much stronger preparations. The ointment was applied freely between the lids, and the eye subjected to massage so as to distribute it thoroughly into the retrotarsal folds, and, in the corneal cases, a protecting bandage was applied. When the patients were in the hospital this was repeated three times daily; in the out-door cases, morning and evening. No other treatment was employed except the use of atropine and a wash of boric acid. In a few minutes after the application of the ointment in new cases, the discomfort was much diminished, and the improvement was usually rapid, as compared with other modes of treatment. In a case of ophthalmia neonatorum the eye was thoroughly cleansed, the ointment of cassareep applied, and a supply given, to be used three times daily at home, after the usual wash. In two days the purulent discharge had entirely ceased.

Paralysis of the Ulnar Nerve Due to a Cicatrix; Liberation of the Nerve; Recovery.—Dr. Julie (*Bull. et Mém. de la Soc. de Chir. de Paris*, t. xxiii., p. 565) reports a case of ulnar-nerve paralysis which is interesting because of the late appearance of the symptoms. The patient, a man, twenty-four years of age at the time of operation, had received, four years previous, an incised wound, inflicted with a sickle, on the postero-internal aspect of the arm, four fingers' breadth above the internal epicondyle. The wound suppurated and healed by secondary intention. There were no motor disturbances, and the light disturbance of sensation in the area of distribution of the ulnar nerve disappeared in a short time, so that two years later the patient was accepted as a dragoon in the army. During the following year the hand began to get thinner; sensation was diminished, so that finally he could not hold the bridle reins of his horse; there was almost complete paralysis of the hand, with marked atrophy of the interossei, the adductor pollicis, and hypothenar group of muscles. At the seat of injury and in the course of the ulnar nerve there was a swelling, the size of a nut and of fibrous consistence. Extirpation of the cicatrix under cocaine anæsthesia was followed by complete recovery after three months.

Two Cardinal Points in the Treatment of Acute Urethritis.—Dr. P. G. Unna (*Monatshefte f. praktische Dermat.*, xxvii., 1) sees an important ground for the uncertain prognosis of specific urethritis, in the fact that the usual irrigation method is employed during the day only. During the night the secretion accumulates in the urethra, owing to the diminished amount of micturition and the unfavorable effect of the bed temperature on the discharge. He advises the early use of the irrigation, which should be employed every two hours, day and night (even if it is necessary to use an alarm clock), so long as there appears a morning discharge. After this the injection should be employed every three hours, day and night, for a whole week. During the following week, if the condition is not changed, the interval between the irrigations should be increased until finally once a day suffices. The author reports very gratifying results from this method during the last few years.

Acute Infectious Myelitis Following Influenza.—Drs. Apostoli and Plauet (*Rev. de Méd.*, July) conclude as follows: (1) During the course of an influenza there may occur numerous nervous disturbances and manifestations which depend upon either a myelitis or a peripheral neuritis. (2) The "grippe" myelitis belongs in the category of acute infectious myelitis, just as does the acute syphilitic myelitis. An anatomical lesion is not found; the spinal cord seems to be affected by the action of the bacteria or their toxins. (3) The acute myelitis of the grippe may run its course with the clinical picture of a systemic disease—Charcot's amyotrophic lateral sclerosis. (4) In contradistinction to the latter, the acute myelitis of influenza as well as the acute syphilitic myelitis may heal entirely. (5) In the acute infectious myelitis we are dealing with dynamic disturbances, whereas in the systemic disease there exists a destructive process.

Studies of the Gonococcus and Gonorrhœal Vulvo-Vaginitis of Children.—Of the available culture media for the gonococcus the writer preferred that of Heiman (serum agar) and that of Kiefer (serum of ascites and pepto-glycerin-agar). The gonococcus is aerobic; it thrives best at from 36°–37° C. If the gonococcus is allowed to grow at the ordinary room temperature in serum agar it soon perishes. At the body temperature its existence is very variable, death occurring within from one to six weeks. In order to differentiate the gonococcus from the diplococcus, which is also stained by the Gram method, the writer resorts to the culture process in a variety of media. The results of the inoculation of the gonococci into the conjunctiva of new-born puppies were so varied in the different cases that the writer could not advise this method as at all diagnostic. Injection into a joint, however, always gave a constant reaction. The irritating material is present in the protoplasm of the gonococcus, for a filtered culture gave a negative result. Injection into the peritoneum of mice and guinea-pigs was soon followed by death of these animals. Post-mortem examination always showed tumefaction of the spleen but no local affection. The poisonous properties are destroyed either by drying, pulverization, or by heating up to 120° C. The writer has seen in six years seventy cases of vulvo-vaginitis in very young girls; of these sixty-five were gonorrhœal. In forty-two of these cases the microscopical examination showed positively the presence of the gonococcus in forty of them. In the remaining twenty-eight cases cultures in serum agar were made; three of these, by cover-glass preparations, gave a negative result; the remainder (twenty-five) were positive. Four of the five non-gonorrhœal cases ran a much shorter course than did those of the gonorrhœal type. There was only a single case which simulated the gonorrhœal type in its clinical aspect without showing the presence of the gonococcus. The writer supposed that the child had a chronic gonorrhœa with an acute exacerbation. Forty-seven of the cases were from two to six years old. Only two cases were shown to be the result of direct infection; fourteen cases were infected at the hospital; fifteen at home; and in twenty-

nine the origin of the infection could not be traced. A small epidemic was caused in one hospital by an infected thermometer. As the disease remains localized in children, the prognosis is much more favorable in them than in adults.—Lyder Nicolaysen, *Christiania Norsk Magazin f. Lägevid. Ergänzungsheft*, 1898.

Bolognini's Sign in Measles.—Dr. Bolognini has described as an early symptom in measles a peculiar rubbing or crackling sensation imparted to the flat hand placed upon the abdomen of the patient, whose legs are held fully extended. With the abdominal muscles thus on the stretch and the flat hands on either side of the abdomen, gradual, gentle, yet increasing pressure is made with the tips of the middle three fingers, alternately upon the right and left sides. The light rubbing or grating sensation is ascribed by Dr. Bolognini to the rubbing together of the visceral and parietal peritonei, which, he thinks, are the seat of an erythematous eruption, similar to that which exists on the skin at a later date. Sometimes this symptom is localized in certain areas of the abdomen, at other times it is general; the symptom is found early, before the development of the cutaneous eruption, and exists for some time. Recently Dr. A. Köppen-Norden (*Münchener med. Wochenschrift*, 1898, S. 897) had an opportunity to study this symptom in an epidemic of measles affecting three hundred and sixteen children. He agrees with Dr. Bolognini in that the symptom is frequently present, but believes the sensation of crepitation imparted to the fingers is due to minute particles of air in the intestine itself. The intestine, he claims, is the seat of a catarrhal inflammation, and contains more or less fluid and air bubbles. He says that the crepitant sensation passes gradually into a wave of larger calibre and finally assumes the character of ordinary intestinal rumbling. Many of the children examined by the writer had diarrhœa.

Purulent Discharge from the Nose; Clinical Significance and Differential Diagnosis.—Dr. George E. Shambaugh, in an article on the above subject, concludes as follows: (1) Purulent discharge from the nose is a common symptom of intranasal disease. (2) Its presence may be detected by the patient, but often he complains only of secondary symptoms produced by the pus. (3) Older writers described all these cases as "purulent rhinitis," etc., and never suspected what we now know to be true, that in the majority of cases the pus has its origin in one of the accessory cavities of the nose. (4) Pus in the nose may come from (I.) disease in the nose itself; (II.) suppuration in the accessory sinuses, or (III.) suppuration in the post-nasal space. (5) The diseases in the nose are: (*a*) purulent rhinitis—found in children in acute infectious fever, in acute rhinitis, and in gonorrhœal infection; (*b*) ulceration—either traumatic (as the erosion in the anterior nares; idiopathic perforation; ulceration due to the action of chemical agents, foreign bodies, larvæ of insects; and perichondritis), or tuberculous or syphilitic. (6) The diagnosis of diseases in the nose producing purulent discharge is not especially difficult when we keep in mind the associated general condition and study carefully the nature of the ulcer itself. (7) The accessory sinuses of the nose form two groups. The first group, including the maxillary and frontal sinuses and the anterior ethmoid cells, opens into the middle meatus of the nose. The second group, including the sphenoid and posterior ethmoid cells, opens into the olfactory space between the middle turbinated and the septum. (8) A differential diagnosis of diseases of these cavities is one of the most difficult problems in rhinology. It requires a knowledge of the whole field of the technique of intranasal examination and a thorough knowledge of the complicated anatomy of the nose and its accessory sinuses. (9) The diagnosis of a complicated case of accessory-sinus trouble is not made at one sitting, but only after repeated examinations lasting over a considerable period of time.—*Medical Standard*, September.

Serpents and their Venom.—In an interesting article in the Cincinnati *Lancet-Clinic* of September 3d, under the above title, Dr. B. Merrill Rickets, in treating of the results of the bites of the venomous serpents of this country, arrives at the following conclusions: (1) The copperhead, coral, and rattlesnake are the only serpents in the United States which possess fangs at the base of which is a sack containing a poisonous fluid. (2) The result of inoculation depends upon the dose, and the size of the human being or animal. (3) Most of the authentic cases of death by these serpents have been among children. (4) No authentic death, as the result of the bite of either one of these snakes, has been found in the adult man by myself. (5) If death does not result within a few hours, it is not the venom, but other agencies, that produce it. (6) The bite of the cobra is not so deadly as is generally supposed. (7) Overstimulation from alcohol and other agencies is, I believe, oftener the cause of death than is the virus inoculation. (8) The effect upon the body is more severe if the virus be injected into blood-vessels. (9) There seems to be no subject which is surrounded by so much uncertainty and exaggeration.

The Relative Value of Iodine Salts in the Treatment of Syphilis.—(1) All the iodides possess marked antisyphilitic properties. (2) Iodide of potassium is, as a general rule, the most active, but iodide of rubidium is often better tolerated, and seems to be of equal value. (3) When iodide of potassium is not well tolerated, recourse should be had at once to iodide of sodium, which usually proves an efficient substitute. (4) Iodide of strontium has no advantage, and should be avoided in syphilitic headache. (5) Iodide of ammonium ought to be reserved for certain severe cases of syphilis in which iodide of potassium has failed or produced but little effect; it is particularly serviceable in tertiary eruptions. (6) Iodide of lithium or of calcium acts more slowly and less surely than the above-mentioned preparations.—Briquet, *Jour. des Mal. Cut. et Syph.*

Typhoid Pneumonia.—The term typhoid pneumonia is commonly used to designate cases with adynamic symptoms, and it is to be distinguished from those cases in which typhoid fever begins with a definite pneumonia, the so-called pneumono-typhus of foreign writers.—Osler.

The term typhoid pneumonia is one in common use by many who have no definite notion of its meaning, and, like the term typho-malaria, has occasioned confusion. In the first place, the case may begin as a lobar pneumonia, the intestinal symptoms appearing at the end of the first week or later, at which time also the spots may appear, establishing the diagnosis, while the usual crisis of pneumonia fails to make its appearance. Again, a pneumonia may supervene in the second or third week of typhoid fever as a complication in which the true relation is less difficult to determine. Finally, there may be a true pneumonia, to which stupor, a dry tongue, and general adynamia may be added, without the distinctive lesions of typhoid fever. This is true typhoid pneumonia, which it may not always be possible to separate from the typhoid fever beginning with a pneumonia. Each form of pneumonia may be caused by the typhoid bacillus or by the pneumococcus.—Tyson.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, November 26, 1898.

THE NATIONAL QUARANTINE CONVENTION.

IT is quite evident from the resolutions adopted at the meeting of the National Quarantine Convention held last week at Memphis, Tenn., that the question of establishing some form of national quarantine will be duly advocated during the coming session of Congress. The stand to be taken will be not so much the actual necessity of the measure as the adoption of practical methods for the imperative end. The medical profession for years has discussed the subject from many points of view and has been educating public opinion in the right direction as to the necessity of change in present methods, and there is no argument against the opposers of the scheme which has not been definitely answered even to the satisfaction of the various legislators who in their turn have had the matter in hand.

The main trouble in determining the application of the general principles involved has centred in a want of reasonable agreement as to plans of detail working urged by rival medical bodies. It is still to be demonstrated whether or not the differences of opinion on minor points of organization of the proposed national board are not as radical and as pronounced as ever. If the history of last year's legislation is to be repeated, the struggle may go on indefinitely. The Spooner and the Caffrey bills, although both governed by the same general principle of national control of quarantine, were the two measures which ranged themselves in fierce and determined opposition against any compromise or agreement that would reconcile clashing and belligerent interests.

The resolutions of the recent convention give some indication, so far as can be seen on the surface, of a position of compromise between the rival parties of last year. The recommendations are eminently proper in their way, and it only remains to prove how they can be practically carried out to meet all the general and detail requirements of the proposed new bureau. So far as the convention itself was concerned, there was a general unanimity of opinion regarding the fundamental principles involved, which was expressed in the following:

"*Resolved*, That there be established a national bureau of public health in the department of the treasury of the United States; that the administration of all the public health functions now exercised by authority of the United States be placed in charge of this bureau; that the sanitary authorities and commercial interests of the several States of the Union be brought into immediate relations with the bureau and be given a due share in the power and responsibilities of the control board, through the agency of an advisory council, consisting of one member from each State, to be appointed by the authorities of the several States."

While it is eminently proper that the new bureau should thoroughly represent the varied interests of all parties involved, there is a threatened danger of cumbersomeness of action if, as is contemplated, each State is given the power to interfere with the purely executive functions of the board. However, it is too soon to discuss this phase of the question, in view of the fact that the present proposal is a mere preliminary of what will appear later.

ALOPECIA AREATA.

ONE of the most interestingly tantalizing affections of the outer surface of the human body is that form of baldness to which Celsus gave his name so many years ago. Effort upon effort has been expended in attempts to demonstrate the etiology, not alone that the rational treatment might follow, since in time in the majority of instances recovery ensues under one or another of the thousands of hair tonics recommended, but from a scientific desire to do away with the uncertainty surrounding the matter and establish definitely the belief of one investigator in the neurotic, or that of another in the parasitic theory. When authorities disagree, it is the privilege of the outsider to form his own conclusions, and thus there have arisen several rather widely differing beliefs in regard to the matter.

Both the subject of alopecia who finds himself gradually losing hair until his surface comes to resemble that of the Mexican hairless dog, and the physician who is intrusted with the problem of how to readorn the sufferer with a presentable hirsute covering, know, as none others can, the serious side of the question. Despair may drive the patient into insanity and the doctor almost to suicide. For a long time French dermatologists have maintained that *la pelade* belongs in the group of contagious diseases, and in England this view has had among its strongest supporters Hutchinson and Crocker, while Aldersmith, the appearance of whose recent work on ringworm and alopecia we have had occasion to note, remains a firm opponent. In this country opinion has been divided, and many have clung to the nerve-origin theory, finding it impossible to reconcile instances of rapid loss of hair from the entire body, or universal alopecia, with the invasion of the skin by a micro-organism; the inability to discover a parasite similar to that producing ringworm baldness; and the fact that certain supposed instances of contagion and epidemic prevalence of alopecia have been found to depend in reality upon the ringworm fungus itself, which had caused a misleading form of bald ringworm. Nor have all observers been led away from their beliefs by the recent discoveries of Sabouraud, in France, who would

make of alopecia areata and seborrhœa oleosa essentially identical processes, depending upon the same micro-bacillus, alopecia being in reality an acute local seborrhœa. While it is not beyond the realms of possibility, one hesitates to accept a single micro-organism as the cause of two so clinically dissimilar processes. It is naturally asked why the one is so common while the other is relatively rare, and, as Aldersmith says, seborrhœa is rarely seen in ordinary alopecia areata, and he puts the question, Why should the patches so often be symmetrical?

The simple way of looking at the matter would seem to be to accept two forms—one depending upon nerve changes and including those instances which follow injury to definite nerves and general shocks; the other due to a parasite, whose identity is as yet not positively proven. Then one must bear in mind that there is a form of trichophyton disease which is capable of producing rounded areas of smooth baldness not to be distinguished by the eye from alopecia, and that this form occurs more commonly on the adult scalp than has been supposed.

Sabouraud makes one therapeutic suggestion as the result of his very extensive and remarkable investigations—the employment of sulphur, incorporated with such fatty substances as will mix readily with the fats of the skin.

Indeed, parasiticides have always, we might say, seemed to produce better results than applications having no antiseptic properties. Just as is the case in ringworm, chrysarobin has been for a long time a useful remedy. Corrosive sublimate has been recommended as an injection, five drops of a two or five per cent. solution at a time (Moty); and recently Panichi, of Florence, has advocated making isolated punctures about the circumference of the patch, every four or six days, with a hypodermic needle steeped in a mixture of carbolic acid and tincture of cantharides, while the same mixture (one part of carbolic and two parts of cantharides) is to be painted over the bald surfaces on the intervening days. Formic aldehyde, in forty-per-cent. solution, or formaldehyde, likewise called by the trade names of formalin and formol, which has been successfully used by some in the treatment of ringworm of the scalp, has also been tested—as it naturally would come to be in this affection—and some patients have recovered under its employment in a comparatively brief time. Unless suitably diluted, it is too irritating for the skin of most persons; but in the proportion of one to four it may be used in the form of a liquid application or as an ointment, especially one made with lanolin. Whenever practicable, the application of such powerful remedies should be made by the physician himself.

In one of the most recent skin publications, the last edition of Hyde's work, considerable stress is laid upon general hygienic management and internal therapy. Among other good suggestions is one that the patient should wear a wig for its moral effect when the hypochondriasis peculiar to the involvement of extended areas on the scalp begins to be manifest.

We spoke above of the affection driving the patient to the verge of insanity, and this feature gives to it the importance of being a much more grave disorder than many might accord it. Though the hair of the insane is popularly supposed to be abundant, coarse, and wiry, no doubt asylum physicians are familiar with those instances in which there is almost constant dread that the hair, though perhaps only somewhat thinned, will be entirely lost.

THE "CHINK KILLER."

A LAW is urgently needed to apply to the small boy of this town with his slingshot. Many persons have been injured by the stones thrown, and when one thinks f the size or number capable of being projected by some of the weapons sold in toy shops, the wonder is that fatal casualties are not reported. Chinamen and Hebrew peddlers are the greatest sufferers. But last fall it was unsafe for a cyclist to ride through many of our streets and avenues during recess time, and the police seemingly ignored the dangerous practice.

THE TREATMENT OF PNEUMONIA IN CHILDREN.

THE symposium convened by the chairman of the pædiatric section has done practitioners a great service, in that it has presented the modern treatment of this disease so clearly that there can be no misconception. There existed a consensus of opinion upon the importance of absolute quiet, best obtained by complete isolation from other children; upon the need of careful nursing and abstaining from meddlesome attention which interferes with rest; upon the value of ventilation to afford the child an ample supply of natural oxygen. There seemed to be unanimity also upon the harmfulness of active medication, especially with opium, nauseants, and antipyretics; also upon the necessity for care in the resort to stimulants. The hot poultice and cough mixture were inveighed against as relics of barbaric therapeutics.

Two of the speakers pithily expressed the object of the treatment of the pneumonia of children to be "to treat the child and not the disease"—to enhance the resisting power of the patient's organism by removing all debilitating influences and strengthening cardiac action.

Upon only one point was there a diversity of opinion. All the speakers referred with more or less approval to baths, the temperature of which ranged from 70° to 100° F.; and one speaker advised the wet sheet cooled by rubbing ice over it. This diversity in temperature and method of applying water is explained by the fact that all but one of the speakers advocated the remedial agent for the reduction of high temperature. The latter advised the mildest baths, the lowest temperature of which was 80° F., claiming that in pneumonia the resistance to temperature reduction is so diminished that great caution should be exercised with regard to low bath temperatures. He insisted that it is the chief object of the baths to neutralize the effect of toxæmia and stimulate the heart. Another

speaker, on the other hand, warned against all baths, warm or cold, when the heart action is feeble, stating that he regarded 70° F. as a warm bath. This may account for his warning, for a bath of 70° F. for five to ten minutes, whether it be regarded as warm or cold, would be a heroic measure for a child suffering from pneumonia.

The happy mean advocated by a majority of the speakers would seem the safest and wisest proceeding.

The section is to be congratulated upon the felicitous presentation of every aspect of this important subject.

News of the Week.

Dr. Louis Bauer, of St. Louis, died in this city on November 5th, at the age of eighty-four years. He was born in Stettin. He was obliged to leave Germany because of his political principles, and went first to London, where he obtained the license of the Royal College of Surgeons in 1852. Soon afterward he came to this country, and began to practise in Brooklyn, where he remained for fifteen years, removing to St. Louis in 1869. He was one of the pioneers in orthopædic surgery in this country, and was also known as a medical educator, having been instrumental in establishing the Long Island College Hospital Medical School and the St. Louis College of Physicians and Surgeons. He was dean of the latter school up to within a few years. He was editor for some time of the *St. Louis Clinique.*

Dr. Vincent Gomez, recently of Brooklyn, has been appointed mayor of Gibara in Cuba, by General Wood.

"The Medical and Surgical Review of Reviews" is the name of a new journal published in London, under the editorial management of Dr. Nathan E. Boyd. The first number, which bears the date of October, 1898, is well gotten up and contains numerous careful abstracts of the leading articles in the current British and some foreign journals.

The Latest Tuberculosis Antitoxin is one announced as discovered by Dr. J. Denys, professor of pathological anatomy and bacteriology at the University of Louvain. The discoverer, of course, claims that it is effective.

The Plague Outbreak in Vienna is over, the last patient having recovered. Dr. Rudolph Poch, who treated those attacked, shutting himself up in the pavilion with them, has received from the Emperor of Austria the Knight's Cross of the Francis Joseph Order, in recognition of his bravery and devotion.

Preparing for an Attack of the Antivivisectionists.—At a recent meeting of the joint committee on vivisection of the scientific societies of this city, the following resolution was adopted:

"*Resolved*, That the secretary be authorized to call the attention of the prominent medical and scientific journals of the country to the importance of the meeting of the American Humane Society, to be held in this city in December *proximo*, and to request that editorial notice be taken of the danger that the influence likely to be exerted at that meeting may cause the vivisection bill now pending in the senate to be called up and passed."

The physicians throughout the country may aid greatly in the defeat of this oppressive measure by writing to their respective senators and representatives in regard to the matter, and urging upon them the desirability of voting against the bill when it comes up in either the senate or the house.

The Death of Dr. Philip Arthur Malleson.—At a meeting of the Harlem Medical Association, held November 14, 1898, it was unanimously—

"*Resolved*, That the members of this association deeply deplore the sudden and untimely death of their fellow-member and president, Dr. Philip Arthur Malleson;

"*Resolved*, That we bear him in fond remembrance for his kindly demeanor and sense of justice in his office, his geniality to his friends, his sympathy for the sufferers intrusted to his care, and for his attainments as a physician, which were of a high order;

"*Resolved*, That we tender our respectful and sincere condolences to his family; and be it further

"*Resolved*, That we cause this expression of our regard and esteem to be published in the medical journals of this city.

"Emil Mayer, William Westerfield, W. H. Stewart, *Committee.*"

The Plague in Russia.—Much concern is felt at the breaking out of the bubonic plague in a village in Samarcand, in Russian Turkestan, for it is feared that it may be imported thence into European Russia. The military authorities have established a close sanitory cordon around the infected village, suspected cases are promptly isolated upon the appearance of the slightest symptoms, and the clothing and furniture of those dying of the disease are burned.

The Anti-Cigarette Law in Tennessee.—The supreme court sitting at Nashville has made a decision concerning the validity of the anticigarette law passed by the Tennessee legislature last year. The court has decided that cigarettes are not legitimate articles of commerce, and therefore are not within the provisions of the federal constitution regarding trade. The cigarette manufacturers will probably carry the case to the United States supreme court.

Famine threatens the inhabitants of Astrakhan in the valley of the Volga, or rather already exists in that region. The Russian government has so far, however, prevented any widespread suffering by the distribution of large quantities of wheat brought from Siberia, and by the employment of many of these peasants in the construction of irrigation canals.

The Newark Eye and Ear Infirmary was recently the recipient of a gift from Mr. J. A. Coles of $1,000, in memory of his father, the late Dr. Abraham Coles. The donor stipulates that the "principal is to be kept permanently invested by the trustees of the infirmary,

and to be known as the Dr. Abraham Coles' surgical fund, the interest only to be used for the purchase of instruments of the best and most approved workmanship."

The Medical Society of the County of Kings.—The cornerstone of the new building of this society was laid in Brooklyn on November 10th. The building will be of three stories in the colonial style, facing Grant Square.

The Recent Yellow-Fever Visitation.—The Marine Hospital service has issued a statement, showing the total number of yellow-fever cases in the United States during the season just closed as 2,456, with 115 deaths. In Louisiana there were 1,470 cases, with 51 deaths; mortality, 3.47 per cent. In Mississippi, 985 cases, with 63 deaths—a mortality of 6.40 per cent. In New York, 1 death, that of Colonel Waring; and 1 death from alleged yellow fever in Washington. The mortality was very low, and the mildness of type of the disease in no way justified the senseless panic which it raised among the State officers and others in Mississippi.

The Pasteur Institute at Lille, in France, has received a donation of 250,000 francs ($50,000) from its director, Dr. Calmette. According to the stipulation of the donor, the money is to be loaned for the defraying of building expenses till the municipal council votes the sums required for that purpose. The money is then to be employed in the purchase of material for new researches, or for scholarships for young men who wish to make original researches in the laboratory. The sum given to the institute represents the profits accruing to the donor from the application of one of his discoveries in a large distillery at Seclin. Dr. Calmette is made of different stuff from the once respected Behring.

The Fordyce Barker Memorial Bed.—Mrs. E. L. Barker, the widow of Dr. Fordyce Barker, died recently in Connecticut, leaving in her will a bequest of $5,000 to St. Luke's Hospital in this city, to endow a free bed in that institution in memory of her husband and son.

Dr. Mary H. Murray has been appointed, by the board of health of New York City, medical inspector of the twelve public schools in the third ward of the borough of Queens.

The Connecticut Medical Law.—The members of the three medical examining boards of Connecticut, appointed under the new law, have agreed that all examinations of candidates in that State must be written in English, and that at least seventy-five per cent. of the answers must be correct, to enable a candidate to pass. Conditions will be allowed, if not more than two branches are below seventy-five, and if the general marking is not below fifty. About forty per cent. of the candidates this year failed to pass the examinations.

A British Plague Commission.—The British government has appointed a commission of scientific experts to India to investigate and report on the disease. The commission will consist of Drs. Thomas R. Fraser, of Edinburgh; Wright, of Netley; and Ruffer, of the Egyptian sanitary commission. They will be accompanied by two officers of the Indian civil service, who have had personal experience of the plague. An inquiry will be made into the origin of the various outbreaks of plague and the manner in which the disease is communicated. The commission will also make a comparative study of the various orrhotherapeutic measures that have been proposed and tried in India and elsewhere. The members of the commission have sailed for India, and it is expected that they will begin their labors in Bombay about the end of the present month.

The Sixth International Otological Congress will be held in London, on August 8, 9, 10, 11, and 12, 1899, under the presidency of Dr. Urban Pritchard, professor of otology at King's College, London. The meetings will be held at the Examination Hall of the Royal Colleges of Physicians and Surgeons, Victoria Embankment. The subject chosen for special discussion is "Indications for Opening the Mastoid in Chronic Suppurative Otitis Media." A British organization committee has been formed, the treasurer being Mr. A. E. Cumberbatch, 80 Portland Place, London, W.; and the honorable secretary, Mr. Cresswell Baber, 46 Brunswick Square, Brighton. The International Otological Congress, which assembles every four years, met last in Florence, where a very successful gathering was held under the presidency of Professor Grazzi.

Preparing Infants for Slaughter.—It will not be many years before the town of Keighley will be the scene of a small-pox epidemic that will surpass that at Gloucester in the Jenner centennial year. The place is one of the many strongholds of the antivaccination cranks in England, and the inhabitants are availing themselves to the full of the "conscientious objection" clause in the recent vaccination act. In one day 690 parents applied for exemption certificates for 1,670 children, and on another day 800 exemptions were granted. Altogether over 3,700 exemptions were granted. Fortunately the absurd vaccination law, which is worse than no law, since it is ridiculous, applies only to England, and not to Scotland or Ireland.

Innocence ?—A diploma mill in the West has been seeking to place its advertisement with a number of our contemporaries. We have seen the ad. printed as such in but one journal, but several with much apparent indignation have commented editorially upon the impudence of the advertiser, and, to show what a brazen-faced impostor the diploma manufacturer is, they print his advertisement, address and all!

Osteopathy.—The following lucid exposition of the principles upon which this medical "system" is based has been found somewhere by the editor of the *Medical Standard*. We commend it as a mnemonic exercise. "Osteopathy has been technically defined as: 'That science which consists of such exact, exhaustive, and

verifiable knowledge of the structure and functions of the human mechanism, anatomical, physiological, and psychological, including chemistry and physics of its known elements, as has made discoverable certain organic laws and remediable resources, within the body itself, by which nature under the scientific treatment peculiar to osteopathic practice, apart from all ordinary methods of extraneous, artificial, or medicinal stimulation, and in harmonious accord with its own mechanical principle, molecular activities, and metabolic processes, may recover from displacements, disorganizations, derangements, and consequent disease, and regain its normal equilibrium of form and function in health and strength.'"

The Happy Result of a Mistaken Diagnosis.—A young physician in a neighboring city, who was looking forward to the joys and sorrows of matrimony, was recently taken ill, and a physician decided that he had appendicitis and that it would be necessary to have an operation performed. His condition became worse, and it was finally determined that the marriage should take place at once. This was done, and then it was found that the case was not one of appendicitis and an operation would not be necessary. The patient was thus made twice happy over one mistake.

St. John's Guild.—At the annual meeting of St. John's Guild, held in this city a few days ago, it was decided to construct another floating hospital, in order to accommodate the hundreds of babies and their mothers who have often to be deprived of the benefits of an excursion for want of room. The report of the floating hospital committee showed that the following work was done during the season which opened on July 6th and closed on September 10th: 60,144 children and their mothers treated on floating hospital; 11,403 baths given on floating hospital; 2,507 children and their mothers treated at Sea Side Hospital; 17,350 days of hospital treatment; 216 children treated at Children's City Hospital; 6,501 hospital days; 1,959 children attended by special relief department, and 6,464 visits made. The daily average attendance on the floating hospital was 1,273, and on one occasion as many as 2,000 women and children were carried in a single day. Throughout the season there was never an accident or a mishap of any kind.

The Centennial of the Lying-in Hospital.—Next year it is purposed to celebrate the one hundredth anniversary of the establishment of the New York Lying-in Hospital. The hospital was opened in a building in Cedar Street in the summer of 1799, De Witt Clinton and Alexander Hamilton being among the founders. Work in the erection of a new building, the gift of Mr. J. Pierpont Morgan, will soon be begun, and it is expected to be completed in time for the centenary of the hospital.

Koch's Latest Error.—Dr. Koch's tendency to jump at conclusions on insufficient evidence is well shown in his assertion that "black-water fever" is merely quinine poisoning. Apparently because he never found the malarial parasite in such cases, therefore they are not malarial. Sometimes his patients denied that they had taken quinine, but "these statements are, for obvious reasons, unreliable." Koch refrained from telling his audience all his reasons for coming to so remarkable a conclusion, but he assured them that they were completely conclusive, and went on to say: "I am convinced that when this view has gained more ground, and when the tropical doctors learn to use quinine somewhat more cautiously, and perhaps to use other medicaments—arsenic or methylene blue, for instance—in suitable cases, black-water fever will vanish altogether from the category of the tropical diseases proper." The rarity of hæmoglobinuric fever in India would alone be enough to prove the impossibility of this view, even if one could bring one's self to believe that the large number of able medical men practising in the tropics could by any chance have overlooked so striking a connection as that between quinine poisoning and hæmoglobinuria would be. —*Indian Medical Gazette.*

The Anglo-American Medical Society held its annual meeting in Paris last month. This organization embraces members located and engaged in active practice in all the principal cities and health resorts of Europe and Northern Africa, and was founded on a social basis, "to serve as a bond of union between British and American practitioners established on the continent of Europe and Northern Africa." No one is eligible to membership who does not possess a French qualification. The honorary presidents for Great Britain and Ireland are Lord Lister, Dr. Samuel Wilks, F.R.S., and T. W. Nunn, F.R.C.S.; for the United States, Drs. J. S. Billings, S. Weir Mitchell, W. M. Polk, A. Jacobi, and E. L. Keyes.

The Cincinnati Presbyterian Hospital was opened on November 1st. This model structure will replace the old hospital, which was in reality nothing more than a large house converted into a hospital building, and lacked most of the conveniences necessary for operative work. The new building is the gift of Mr. and Mrs. Alexander McDonald, and, while small, is very complete in its appointments. It is a four-story building of brick and stone. On the first floor are all rooms necessary for an out-patient department and a chapel. Two free wards, male and female, occupy the entire second floor, and will accommodate about twenty-five patients. The third and fourth floors are devoted to private rooms which have been endowed by different people, and the operating-room on the third floor is quite a feature of the building. It is finished in marble and mosaic, and furnished with a fine case of instruments. The exercises of dedication consisted of a Scriptural reading by Mr. McDonald; a prayer by Rev. Peter Robertson; a dedication hymn by Mrs. Alice Griswold Huston; remarks by Messrs. Bartholomew, McKibben, and Baker; a description of the building by President William H. Taylor, and benediction by the Rev. Mr. James. Governor Bushnell was present at the dedication and at the reception which followed. The profession of Cincinnati was represented by a full attendance of the prominent physicians.

NEW YORK ACADEMY OF MEDICINE.

Anniversary Meeting, November 17, 1898.

EDWARD D. JANEWAY, M.D., PRESIDENT.

Anniversary Discourse: Landmarks in the History of Pathology.—PROF. WILLIAM H. WELCH, M.D., LL.D., of Johns Hopkins University, delivered this address He said that when the Academy of Medicine was founded, fifty-two years ago, an unexampled era of scientific investigation and progress had begun. It was just forty-three years ago since Dr. John Watson delivered his justly celebrated discourse before this academy on "The Medical Profession in Ancient Times." After showing that what was termed Hippocratic medicine included the work and writings of a number of men, the lecturer turned to the consideration of that other great father of medicine—Galen. He said that Galen's system was founded upon an elaboration of the Hippocratic humoral doctrine, and was the essence of the later humoral pathology. Galen was the greatest of ancient anatomists, and he, and not Harvey, was the founder of experimental pathology. But in the absence of morbid anatomy he could not make fruitful application of the principle which long afterward was elaborated by Morgagni. Nevertheless he clearly stated that it was his custom to examine the part affected in disease to determine the reason for the impairment of function, and from such information to draw conclusions regarding treatment. He was not permitted to dissect the human body, and his conclusions from his anatomical studies on the lower animals were not particularly happy. Until the revival of learning in the fifteenth century the minds of physicians were bound by the fetters of Galen's doctrines; yet, under the circumstances, this thraldom was not an evil. Early in the sixteenth century appeared that turbulent genius, Paracelsus. There was in this man something of the prophets of old, together with a yearning to extract the secrets of nature. He introduced into medicine new and revolutionary ideas, and his alchemy was the foreshadowing of modern chemistry. Rejecting anatomy as worthless, the beginning and end of his striving were the cure of disease, and for practical medicine his therapeutic innovations were of much significance. He conceived disease to be something entering the body as a seed or germ—a conception of special interest in our day. The real glory of medicine in the sixteenth century was the development of the study of human anatomy, and with this was associated the name of Vesalius. It was the anatomists of the sixteenth century who led medicine into the paths of true science. Although the authority of Galen was undermined by the demonstration by Vesalius that he had made certain important errors, the complete overthrow of his authority did not take place until the time of Harvey. A work published in 1506 was the first one containing systematic observations in morbid anatomy. The physicians of this period seem to have met with obstacles in securing autopsies. In 1627 was published to the world the greatest event in the history of medicine—the discovery of the circulation of the blood. It was a triumph of the experimental method, yet one of the most singular of the many delusions of the opponents of vivisection was that Harvey had not been led to his discovery of the circulation of the blood by his experiments on animals. The influence of this discovery on pathological and practical medicine was before long manifest in new and better conceptions of disease. One of the early effects of the discovery was the introduction of physical conceptions in medicine, and then, for the first time, the physicians began to count the pulse, measure the temperature of the body, and use the balance in physiological experiments. One of the most interesting phenomena toward the close of the seventeenth century was the introduction of the study of microscopical anatomy by such men as Malpighi. They made use of the simple microscope, and yet with even this instrument were able to make such discoveries as those of the spermatozoa and the blood corpuscles. Malpighi was the great representative of this school. It was curious, the speaker said, that this period of development of microscopical anatomy was so short; it was limited by the powers of the microscope of that time, and disappeared soon, only to be resurrected in the present century. The speaker next referred to Sydenham as the most honored name connected with English clinical medicine. His writings, he said, were by no means free from theories and doctrines, but they did not in the least obscure the pure practical observations of disease met with throughout all of his works. He did not construct any system of medicine, but the minds of physicians were still desirous of systems. The rise of the systemists characterized the first half of the eighteenth century. The legitimate successor of Vesalius and Harvey in medicine was Haller whose work, published about the middle of the eighteenth century, was the foundation of modern physiology. He introduced the great conception of the irritability of the tissues. Here really for the first time was recognized the fundamental property of living tissues—a vital phenomenon which could be studied. Malpighi was the great founder of pathological anatomy. Post-mortem examinations began to be made as far back as the fifteenth, and even the fourteenth, century; they were done in a very unsystematic manner, and the records of them show that these investigators had no very clear understanding of the relation of these observations to pathological medicine. But Malpighi approached the subject in an original way, and with entirely different results. He was searching for the real seats and causes of disease. He treated systematically of the diseases of the different regions of the body, one after another. His work, therefore, marked the beginning of the physical basis of scientific pathology. From the time of Malpighi the development of this side of pathology had been continuous, and the influence of his writings was almost immediate. Toward the end of the eighteenth century one found the name of John Hunter. Hunter was a pathological physiologist as well as a pathological anatomist; he was searching not only for the alterations in structure of diseased organs, but also for the changes in function. He was particularly interested in the study of the blood in morbid conditions —sometimes spoken of as "hæmopathology." He was impressed especially with what he called "the vitality" of the blood. He observed, for example, that the blood taken fresh from human beings or from animals, even when mixed with putrid material, remained fresh and uncontaminated, and he was, therefore, led to believe that there was something in living things which resisted putrefaction and decomposition. It was now known that that phenomenon was due to the presence of the so-called bactericidal substances in the blood. A nephew of John Hunter, Matthew Bailey, wrote one of the most attractive books in pathological anatomy. He was the first to illustrate morbid anatomy. Just at the end of the last century the great Bichat entered upon his career. His great works were all practically written within four years. He was a vitalist, and believed that physical and chemical forces took no part whatever in vital phenomena. Aside from his theories and speculations he gave wonderfully vivid descriptions of the tissues of the body. He was the founder

of general anatomy, and he brought the study of disease processes one step nearer the goal; *i.e.*, from the organs to the tissues. He made a great impress upon his contemporaries, and immediately after him sprang up the great French school. The first three decades of the present century were unquestionably the most splendid in French medicine, but about this time the study of pathology passed largely from the French to the Vienna school, and then there came on the scene Rokitansky, the greatest descriptive pathological anatomist who had ever lived. His experience was simply enormous. It was said that at the time of his retirement from the chair of pathology, at the age of seventy years, he had in his possession the protocols of one hundred thousand autopsies. The interpretation of his facts were often erroneous, and his system was simply humoral. It was early and severely criticised by Virchow, and it was worthy of note that soon thereafter Rokitansky discarded it. About this time came the first fruitful applications of the microscope through Johannes Müller, in his study of tubercle. This was the period of the specific cancer cell, the specific tubercle cell, etc., and these erroneous views caused the microscope to be brought into a disrepute from which it had hardly yet recovered. In the early part of this century the study of medicine in Germany was by no means edifying. It was then in the thraldom of the so-called natural philosophy. Virchow laid the foundations of the "cellular pathology," which certainly was to be ranked as next in importance in the development of scientific pathology to the discovery of the circulation of the blood, and, so far as furnishing an incentive to further work, it was even more important than the great discovery of Harvey. Cellular pathology was not a dogma, a doctrine, or a theory, but a great principle which admitted of endless development. Whether or not the last word had been spoken was not certain; at present there was no unit of life known beyond the cell. We were so imbued with the spirit and the principles of cellular pathology that it was almost impossible for us to put ourselves back, in imagination, to a period when this did not exist, and we could hardly do justice to the ideas which prevailed before cellular pathology was known. Virchow's great contribution to the cell doctrine was, of course, not the discovery of the cell, as that had been made before, but the demonstration that all cells sprang from pre-existing cells—that living matter always came from living matter. Since the introduction of cellular pathology there had never been an attack upon it which had been successful. Repeatedly pathologists and various other investigators had thought that they had made discoveries which were calculated to cast doubt upon the validity of this great principle in pathology, but the foundations of cellular pathology had apparently only been strengthened by later discoveries. The great step which had been made since the introduction of cellular pathology—*i.e.*, that which brought us back to a knowledge of the causes of disease—we owed to Pasteur and Jenner. In closing, Dr. Welch said that his hearers had traversed with him a long road from Hippocrates to the present day, although they had lingered at only a few of the great landmarks in the history of pathology. It was evident that the past had been one of progress, even if slow and, at times, apparently interrupted. Each important step forward had been followed by great benefits to practical medicine, and, therefore, to mankind. There had been periods when physicians had thought that the laws of life and disease could be discovered by contemplation and philosophical speculation divorced from experience; but medicine, both scientific and practical, needed scientific methods just as much as did chemistry and physics. The use of the experimental method in a most important field—animal experimentation—had for several years been threatened by the fanatical assaults of ignorance and so-called humanity in so false a way that it was nothing short of inhumanity. We should see to it that the experimental method was preserved and handed on to our posterity intact. To accomplish this, medical and scientific men, who alone could fully appreciate the threatened danger, must present a united front; and if they did this, they might feel assured that they would not be deprived of one of the great levers of scientific progress. The true end of all medicine, whether it be called scientific or practical, was the prevention and cure of disease. To this end those who worked in the laboratory, as well as those at the bedside, could contribute, and there was just as wide a scope for the application of scientific methods in the one case as in the other. Pathology and practical medicine were drawing closer together to the immense advantage of both. Each had its own problems and methods, and it was important that each should preserve its autonomy. The ultimate goal of practical medicine was to become an applied science. To some this goal seemed unattainable, but already in certain important directions medical practice could justly claim to be an applied science. This idea should be kept ever in view, and should be striven for with all our might. Every step toward it was a benefit to mankind in enabling medicine to fulfil its true mission of relieving pain and suffering.

SECTION ON MEDICINE.

Stated Meeting, November 15, 1898.

LOUIS FAUGÈRES BISHOP, M.D., CHAIRMAN.

The Non-Medicinal Treatment of Habitual Constipation.—DR. GEORGE ROE LOCKWOOD sent a communication on this subject, which, in his absence, was read by the secretary. He asserted that the well-known laxative drugs give only temporary benefit and set up a train of symptoms which often indicated serious damage to the intestinal tract. The better method of treating constipation was, therefore, that which comprised attention to diet, exercise, and general hygiene. From an extensive experience he had come to the conviction that a daily stool was necessary to health, and yet it did seem as though there were a few individuals who normally had a stool only once in two or three days. It was well to make a rough estimate of the quantity of fæcal matter voided, and thus determine whether or not the constipation was real or only apparent.

The Use of Saline and Vegetable Cathartics.—The salines, of which the Carlsbad water might be taken as the type, usually depended for their efficiency on sulphate of magnesium or sodium. One effect of these remedies was greatly to reduce the production of hydrochloric acid and of the digestive ferments; another was the production of atony of the wall of the stomach. These results were sometimes noticeable within six weeks after the beginning of a course of salines. The drastic purgatives, such as aloes, rhubarb, podophyllin, cascara, and the like, not only depressed the secretory power of the stomach and weakened the tone of its muscular walls, but, in addition, exerted a congesting effect on the mucosa. From the congested vessels serum exuded, and a watery stool resulted. The result was comparable to a cold in the head. The contraindications to the use of saline and vegetable cathartics were: (1) All the conditions characterized by diminished secretory power; (2) all conditions of impaired muscular power of the stomach and intestine; (3) all conditions of inflammation of the stomach or of the large or small intestine; and (4) in children,

owing to the proneness in them to inflammation of the intestinal mucosa. Regarding enemas, it should be remembered that, as the rectum and colon were endowed with marked powers of absorption, there was a tendency for the ptomains to be absorbed more easily when enemas were used, because of the softening and partial liquefaction of the fæcal masses.

Dietetic Treatment.—The chief articles of diet especially suitable for those suffering from constipation were the coarse vegetables, coarse breads, and cereals; the sugars, as secretion excitors; buttermilk, fats, and organic acids, as peristaltic excitors. Coarse vegetables, such as spinach, turnips, and sprouts, should constitute a large portion of the diet, and to avoid irritation of the stomach it was well to have these prepared in purée form. To these should be added the cereals. The breads should be coarse, porous, and one day old. Whenever inflammation existed, bulky foods must be excluded; they were also contraindicated in cases of muscular insufficiency of the stomach, when associated with gastroptosis, as the bulk of the food mechanically overloaded the weakened stomach. A point in the diet which was frequently overlooked was the necessity for excluding all constipating food. For instance, one glass of claret would neutralize the effect of an entire meal of otherwise carefully selected food. Similarly, if tea was taken at all, it should be well made and never strong. It was not known whether the action of sugars was due to the fermentation undergone, or whether they acted like saline cathartics by exciting increased exudation through the intestinal wall. The sugars were best given in the form of honey or milk sugar. A teaspoonful of honey in half a glass of warm milk, on rising in the morning, was an excellent corrective of constipation. Lactose should be used instead of ordinary sugar in tea and coffee. Another excellent remedy was made up of two parts of prunes and one of figs. Raw fruit the speaker did not approve of. Huckleberries and cranberries were to be studiously avoided. Among the liquids that might be taken were buttermilk, kumyss, and cider. To get the laxative effect of buttermilk, three glasses of it should be taken daily. Kumyss had a similar action, increased somewhat by the stimulating effect of the contained carbonic-acid gas. White wine might be allowed in moderation. Fats were administered with difficulty. One-eighth to one-half pound of butter might be given daily. Cream rarely agreed. In debilitated subjects cod-liver oil was advantageous. The effect of taking water with meals was still a mooted point. Undoubtedly a glass of cold water on rising in the morning was of great service in increasing peristalsis, but the speaker believed that during meals little water should be drank. In general, the drier the diet the greater the mechanical stimulation of the intestinal wall.

Exercise and Hydrotherapy.—The abdominal wall might be strengthened by massage, abdominal gymnastics, electricity, and the wearing of an abdominal support. Massage was contraindicated in all inflammatory and spastic conditions. Abdominal gymnastics he had found more serviceable. General exercise, especially bicycling and golf, were of great service in overcoming constipation, and should be resorted to, together with local exercise, such as raising and lowering the legs to and from the vertical position. Faradization had proved a grievous disappointment to him in the treatment of constipation. Artificial abdominal supports were indicated in downward displacement of the stomach or colon, and in weakness of the abdominal walls. They should be worn continuously through the day. He strongly recommended the spinal douche as an important adjuvant to the other treatment. It was most efficacious when given before breakfast. While the patient sat in hot water, the spine was sponged at first with hot water, and then a pitcher of cold water was poured on the back from a considerable height. This should be followed by brisk friction. Another plan was for the patient alternately to sponge the abdomen with hot and cold water. Sedative remedies were indicated in conditions of intestinal spasm—a more frequent condition than was commonly believed. In this class of cases purgatives, massage, and bulky articles of diet must be excluded. The primary cause was usually hyperacidity of the gastric contents. An efficient remedy in these cases was the Neptune girdle, made of two thicknesses of flannel, large enough to cover the abdomen, which were to be wrung out of hot water, covered with oiled silk, and applied to the abdomen at night by means of a binder.

Kussmaul's Oil Irrigations.—Oil irrigations had been first employed by Kussmaul. Dr. Lockwood said that his own results with this treatment had been so brilliant that he was inclined to attach much importance to this method. A rectal tube of large calibre, with a large lateral opening, should be selected and inserted in the rectum a distance of from six to eight inches. Through this from six to eight ounces of cotton-seed oil (free from rancidity) was to be injected. This oil would be found as satisfactory as olive oil, and much less expensive. The patient received the injection while in the Sims position, with the hips elevated on two pillows, and with the muscles well relaxed. The position should be maintained for ten minutes; then the dorsal decubitus should be assumed for ten minutes; and, finally, the patient should lie on the right side for another period of ten minutes. By this postural treatment the oil reached the entire length of the colon. The injection was given preferably at bedtime. No immediate effect was to be expected. There would be usually a normal movement, without straining, for five or six successive mornings. The oil seemed to act by commingling intimately with the fæces, and thus preventing any further drying process. The treatment should be repeated whenever the effect of the previous injection had subsided—ordinarily every five days was sufficient. One great advantage of this treatment was that it may be used in atonic, spastic, and inflammatory conditions alike. In conclusion, the author insisted upon the importance of making a careful physical examination at the outset of the treatment of constipation. Almost always a physical examination of the colon was demanded. The colon should be flushed out with decinormal saline solution, and the washwater examined. If mucus was present, indicative of intestinal catarrh, bulky foods should be avoided. Massage, electricity, and cold abdominal irrigations were contraindicated, while oil irrigations might be used with benefit. If colitis could be excluded, either atony or spasm was probably present. The former was shown by the facility with which water entered into the gut and by the diminished expulsive force. Examination of the rectum should be made for hemorrhoids, rectal ulcers, stricture, or fissure, as any rectal malformation might lead to reflex intestinal spasm and to constipation. Abnormalities in the position of the colon could be easily appreciated by inflation with air, and their presence called for the use of the Bodenhamer abdominal support. If the patient was nervous, he should be instructed to lie down at least one hour in the middle of the day. The writer firmly believed that careful and systematic treatment along the lines indicated in the paper would be followed by successful and more or less permanent results in a very large majority of patients. In a very small percentage of cases an additional medicinal laxative might be required, but such a percentage he believed to be very trifling—in two years such a case had not come to his notice.

Constipation as a Cause of Anæmia and Chlorosis.—Dr. Judson Daland, of Philadelphia, read a brief paper with this title. He said that he had been deeply interested in this subject for three or four years past—indeed, the profession in general had been aroused by the masterly article of Sir Andrew Clark. The main point to be determined in this study was as to whether the fæces remained in the colon longer than usual and whether the normal quantity of fæces was evacuated. Colonic washings showed that hardened masses of fæces often remained in the colon for days, or even weeks, notwithstanding the fact that the patient's bowels moved regularly. In many cases digestion was influenced by constipation, but more important still were the putrefactive changes produced. In one class of cases there would be a continuous absorption of poisonous products formed in the intestine, associated with marked indicanuria, a moderate grade of anæmia, and obstinate headache. In another group of cases the constipation would so influence the blood as to produce, both on microscopical and clinical examination, the picture of progressive pernicious anæmia. In one typical case of this last group, Dr. Maisch had demonstrated by chemical analysis the presence of indol, skatol, cadaverin, and putrescin. There was, therefore, every probability that these poisons, by their circulation in the blood, resulted in ordinary anæmia, in chlorosis, or even in a condition simulating closely that of pernicious anæmia. It was not improbable that in the future the physician would be able to state that some particular poison, such as neurin, was the cause of the constipation in a given case. This poisonous state of the blood complicated many diseases, such, for example, as typhoid fever. The recognition of this truth had much to do with the comfort of the patient, as well as with the successful termination of the case.

The Use of Enteroclysms.—The speaker then dwelt upon the importance of using enteroclysms, not merely for the purposes of diagnosis, but for treatment. His attention, he said, had been first directed to this subject by the work done in New York Harbor in connection with the treatment of Asiatic cholera. It had been demonstrated at that time that a certain quantity of liquid passed the ileo-cæcal valve, and could be utilized for cleansing that portion of the intestinal canal. A long soft-rubber tube, a little smaller than the stomach tube, was introduced into the rectum, and to this was attached a fountain syringe placed at a height of four feet above the patient. Good results could be obtained by allowing the patient to assume a comfortable position on the back. Saline solution at a temperature of 100° F. was used for the irrigation. The liquid having been introduced and allowed to remain for a few minutes, the patient was urged to evacuate the fluid, and this was facilitated by movements of the legs or by moving about the room. Oftentimes considerable pain would be experienced when the fluid was first introduced, owing to the presence of gas in the bowel; but if the fluid was allowed to remain for a few minutes before the injection was continued, much of this gas would be discharged.

Constipation Largely Due to Ignorance and Careless Habits.—Dr. Beverley Robinson said that much of the constipation in the world was the result either of the ignorance or carelessness of mothers regarding their children, and particularly their daughters. Another cause of constipation, in New York City at least, was the absence of proper public accommodations for those desiring to attend to the wants of nature. Paris was far ahead of our city in this respect. He was inclined to believe that the morality of New York as well as the health of its citizens would be improved by attention to this matter, for he was under the impression that a rather poorly dressed person would not be admitted to a hotel to answer a call of nature, and would therefore be compelled to go to a grog shop. While Dr. Lockwood had spoken disparagingly of the use of medicines in the treatment of constipation in order to emphasize the great importance of other measures, it could not be denied that in every-day practice the physician was constantly forced to use medicines for these cases, if only for the purpose of securing a sufficiently rapid result to gain the patient's confidence. Without any wish on his part to disparage all that had been done in the way of showing that chlorosis and constipation were closely related, it must be plain to all that chlorosis not rarely existed without constipation, and there were hundreds of cases of constipation without any associated chlorosis. Nevertheless it was well, particularly in the treatment of anæmic, city-bred girls, to bear in mind this relation between constipation and anæmia. It did not seem to him to have been sufficiently insisted upon that there was hardly any more constipating diet than milk, taken undiluted. If milk must be taken, it should be diluted with water or lime-water.

Do Not Overlook the Stomach.—Dr. W. W. Van Valzah said that he heartily agreed with all that had been stated in the paper regarding the different kinds of diet, but he could not indorse the very general directions on other matters. In the past winter he had made thirty analyses of the stomach contents in cases in which there were no symptoms referable to that organ, yet in many of these it was found that the stomach was not secreting its juices at all. The chief symptoms had been intestinal, the most prominent one being diarrhœa. This experience had led him to suspect that the gastric glands often refused to work in persons of fifty years of age or over.

The Choice of Remedies.—With hyperchlorhydria and glandular over-action one almost always found constipation, and in this class of cases he knew of nothing better than Carlsbad salts. Of course, if given for a long time they were injurious, but it was an exceedingly valuable remedy when administered for about three weeks. The next best remedy for these cases was the milk of magnesia, as it was more palatable than the calcined magnesia. If the muscular power of the stomach was diminished, the bowel would often be sluggish also. In these weakened muscular conditions he was very chary of the use of laxatives. Here he was in the habit of using an injection of oil or water, or else gluten suppositories. The habit could be easily broken if they were used properly. Of course, if there were hemorrhoids the suppositories were not admissible, because they would add to the irritation. He could see no possible objection to taking water freely. If it were drank slowly, and half an hour or more before a meal, he did not see how it would interfere with digestion. Both children and adults reared in the city were prone to take too little water. It should be remembered that a common cause of constipation in women was retroversion of the uterus. Among the drugs which he used, he had still great confidence in rhubarb. He did not think it did a particle of harm if used in moderation.

How to Give Cascara.—Cascara was another good drug. If he found that the liver, bowel, and stomach were working well, and that the constipation was simply the result of defective expulsive power, or to spasm (as indicated by ribbon stools), he used cascara. An excellent method of using cascara was to give it at night only; if given two or three times a day, it pushed the food along too rapidly. Another point in the treatment of constipation was the selection of a convenient time for going to stool, and the giving of the laxative at such a time as would secure its action at the accustomed hour for going to stool. The aim should be not to get a loose stool, but a formed one.

The remedy should be kept up in the same dosage for ten days or two weeks, preferably the fluid extract of cascara being used. The dose should then be lessened, and given, not every night, but every second or third night.

Rule about Fruits.—As to the use of fruits, if they did not appreciably increase the burning or the quantity of flatus, and did not produce diarrhœa, they might be given with good results in almost any quantity; if they did produce such symptoms, they must be entirely withheld.

Infantile Constipation.—Dr. L. Emmett Holt said that the conditions found in young children were such as to make the treatment of constipation in these little patients proportionately easy and satisfactory. He always insisted upon a careful scrutiny of the whole of the child's daily life. The nurse was often to blame for the constipation in the infant. In infants under six months of age constipation was often due to the use of modified milk in too small percentages, so that too little residue was left. Under such circumstances the indication was to increase the total solids. The bad cases of chronic constipation in children of five or six years of age that he had seen had been almostwithout exception in children who were exceedingly healthy and robust. He could heartily recommend cascara as being probably the most valuable drug in the treatment of cases in which there was loss of expulsive power. Still better than drugs, in his opinion, were suppositories.

The Effect of Mental Excitement.—Dr. F. W. Jackson divided cases of constipation into (1) those due to diseased states of the system, and (2) those due to abnormal habits or abnormal nervous conditions. In the cases in which the stools consisted of small scybalous masses, he would think not only of calomel and water, as Dr. Van Valzah had said, as appropriate remedies, but of mental excitement and undue business strain as probable etiological factors. The most obstinate cases of constipation could be at least improved by regularity in evacuating the bowel and in selecting the most convenient time in the twenty-four hours for this purpose.

Dress Reform and Constipation.—Dr. S. A. Knopf said that tight lacing and faulty methods of dress were responsible for much constipation among women. He advocated the adoption of the Jenness-Miller reform dress. Abdominal massage, to be carried out properly, must be done with the patient on a hard surface; and, while it was useful, he would not think of treating constipation by it unaided, at first, by medicine. The massage must be continued for a long time, and the patient must be taught after it was stopped how to exercise so as to improve the tone of the abdominal muscles. He had not been able to rely upon cascara alone, and did not approve of giving it for any length of time. The Winternitz method of passing cold and hot water alternately through a coiled tube applied to the stomach had given good results in certain cases.

Dr. Daland, in closing the discussion, said that he had meant to say that constipation was only one of the causes of chlorosis. He had also made use of the term "chlorosis," not in the strict sense of "green sickness," but as indicating a severe type of anæmia. The use of coarse and bulky food had been almost uniformly unsatisfactory in the treatment of the cases of constipation that he had considered. The old idea of giving calomel in full doses, followed by a saline, seemed to him erroneous; it was far better to give a number of minute doses. He believed that the reason that this method of administration proved so successful was that with the increased flow of bile there were increased peristalsis, improved intestinal digestion, and diminished fermentation. The latter effect was to be expected, in view of the high rank of bile among the intestinal antiseptics.

OUR LONDON LETTER.

(From our Special Correspondent.)

DIPHTHERIA OR RHINITIS?—SYRINGOMYELIA—CHYLURIA—GRAFTING NASAL BONES—MYXŒDEMA—LUPUS—GUMMA OF TONGUE—REPRINTS—WATER QUESTION—HAROLD FREDERIC'S DEATH—HOSPITAL CHANGES—WHITMARSH.

London, November 4, 1898.

Fibrinous rhinitis, as described by Schüller in 1871, is a subacute or chronic affection characterized by a fibrous or membranous exudation on the nasal membrane. A good deal of interest attaches to this condition, in regard to its relation to diphtheria. It has been until recently considered distinct, but latterly some observers have come to consider it as mild diphtheria, basing their conclusion on bacteriological investigation. The relation of the two was discussed at the last meeting of the Medico-Chirurgical Society, when a paper on the subject, written by Dr. Lambert Lack, was presented. It stated that no less than two and one-half per cent. of all the children attending Dr. Lack's hospital practice were affected by the disease, and it contained an analysis of the symptoms in thirty-six cases. Certainly the affection is not uncommon, and there may be no symptoms, though, as Dr. Lack enumerates those most frequently met with, he would appear to expect some indications of the condition. He found them chiefly local, such as nasal obstruction and discharge, excoriations, and occasionally epistaxis. Sometimes a peculiar sore throat was seen. Bacteriological examinations in thirty-three cases showed the true Klebs-Loeffler bacillus in all, sometimes mixed with pyogenic cocci, sarcinæ, etc. It was usually of the large variety, its identity being proved by its morphology and growth on various media; it was of full virulence on animals, produced virulent toxins, and was neutralized by antitoxins. It could live for several months on culture media, and crowded out other organisms. In only one case could a previous history of diphtheria be traced. But the rhinitis is very infectious, and the bacillus was found in the throats of healthy persons who had been near the patients. Statistics of a comparative investigation were presented. The conclusion of the author is that the fibrinous rhinitis is a mild form of diphtheria, the difference in the clinical manifestations depending apparently on some differences in the organisms associated with the bacillus, the presence of which in the absence of clinical symptoms was not to be regarded as of great diagnostic value.

Dr. Macfadyen remarked that it was puzzling to find this bacillus present in these cases and in some normal throats. It had been shown that the bacilli from cases of diphtheria varied in virulence. During convalescence they also changed in form, becoming shorter and stouter. By artificial means the virulence of a culture could be intensified or diminished. The condition of the tissues and the presence and virulence of other organisms might have an important influence.

Dr. T. D. Lister said he had examined the nasal mucus of one hundred and twenty-five children at his hospital. Of these sixty-nine had some discharge, watery, muco-purulent, or hemorrhagic. All the hemorrhagic cases gave pure cultures of the Klebs-Loeffler bacillus. Altogether there were sixty-one children in whom the bacillus was found—thirty-seven with discharge and twenty-four without. In no case did diphtheria result from contact with these chidren He had examined two cases post mortem. In one there was a creamy exudation on the nasal mucous membrane; in the other nothing.

Dr. E. W. Goodall remarked on the well-known fact that the bacillus might be met with in scarlet fever and various other conditions, even in healthy persons. But the evidence of its causal relation to diphtheria was too strong to be given up, and Dr. Todd found the bacillus in fifty-one cases out of seven hundred to eight hundred cases of scarlet fever. He thought that any case of sore throat in which the bacillus was found should be isolated and treated as diphtheria.

Mr. Lyster mentioned the circumstance of a boy who was thought to have a cold, went home from his school, and never had anything more than a slight discharge, but fatal diphtheria followed in his family.

Among the cases shown at the Clinical Society's meeting, I may mention one of syringomyelia in a woman of twenty-eight, who when young had never been able to get about like healthy children, being always apt to fall, had had painless whitlows at seven, and whose back had been noticed to be twisted at ten. Now she has spastic paraplegia with increased reflexes, wasting of muscles round the shoulder, diminished electric excitability, wasting muscles of the right hand, loss of sensation to painful impressions above the waist, except in the face. There are marked lateral curvature and vertical nystagmus on lateral deviation. Her general health is said to be good.

There was a boy of sixteen, with chyluria of three years' standing—the milky urine appearing only after sleep, whether by night or day. The clear urine sometimes contained albumin, but at other times was normal. The blood had been repeatedly examined at night, but no filariæ had been detected.

A youth, eight years ago, lost through an accident a large part of the nasal bones. In January last Mr. Cheyne exposed the periosteum on the right side of the nose, removed the femur of a rabbit, split it into pieces, laid them on the periosteum, and replaced the flap of skin. The wound healed without suppuration, and the result now shown to the society is excellent.

A girl of seven, with myxœdema, was shown by Dr. Bertram Abrahams. She could not walk until five years old, and at six and a half rapidly grew stout, and in twelve weeks became helpless. Treated with thyroid extract, her weight fell from forty-four to thirty-three pounds in thirty days, and she got about and went to school. On discontinuance of treatment, the symptoms returned. She has a curious induration of the calf muscles, which was attributed to deposit of mucin.

A case of lupus in a woman of forty-seven, shown by Mr. Pearce Gould, had benefited under thyroid colloid. There was a history of enlarged glands from childhood. One foot had been amputated for tuberculous disease. The glands of the neck broke down in 1897, and ulceration extended to the face. This healed, but in September the patient was admitted for an ulcer reaching from the eyelids to the mouth. Colloid tablets were given, and in three weeks it had healed. One tabloid a day is now being given, the scar tissue is supple, and the pain has ceased.

Dr. Pringle thought this the best treatment, though relapse is likely unless it be kept up.

Dr. Whitfield would have described this case as scrofuloderma, which he considered more amenable to treatment, whether by serum or thyroid, than typical lupus.

A girl of seventeen, with gumma of the tongue, shown by Mr. Symonds, was the subject of congenital syphilis. She had previously had eye symptoms and gummata on the forearm. The gummata appeared while the patient was undergoing vigorous mercurial treatment.

The unauthorized reprint from the *British Medical Journal*, mentioned in my last, has been withdrawn by the advertiser, who also apologizes for his indiscretion and says he had no intention of committing an unjustifiable action. It is well that companies and interested persons generally should clearly understand that comments on their wares in the journals are copyright.

On Tuesday the county council finally determined to promote bills in the next session of Parliament for taking over the water supply of London and to obtain additional supplies from Wales.

The inquiry into the death of Harold Frederic, the novelist, has been adjourned further until next week, as the jury expressed a wish to have the whole case summed up. Mrs. Mills, who calls herself a "Christian scientist," again appeared and asked for a room to which she might retire to "realize" on the "realization of God's power"—a request which naturally caused contemptuous amusement. She told the jury she was "a healer—a willing channel for the goodness of Jesus;" that there "is no death, because God is life;" that she "did not concern herself with results," and other remarks of the same kind. She had been paid in cash, she said, for this patient, but checks were acceptable to her sect.

Dr. Goodhart has resigned his office at Guy's Hospital, after twenty-one years' good service. Dr. Newton Pitt succeeds to the physiciancy. The governors have followed the example of the London, and resolved that in future the assistants on the staff shall after seven years' service have the full title. Many think that assistant physician or assistant surgeon is a misnomer, and should no longer be continued, at any rate after a year or two of duty satisfactorily discharged.

Dr. Crawford, an Oxford man, has been appointed assistant physician to King's College Hospital.

Dr. Murrell takes the place of Dr. Donkin, who has resigned from the Westminster Hospital.

The death sentence on Dr. Whitmarsh has, as was expected, been commuted.

THE DISINFECTION OF TYPHOID STOOLS.

To the Editor of the Medical Record.

Sir: There is a point in regard to the spread of typhoid by flies that cannot be too thoroughly emphasized, inasmuch as the methods ordinarily employed, and even recommended by high authority, in the army and elsewhere, show that it has not been taken into the account at all. The writer has been able to secure abundant clinical and microscopical evidence that covering the excretions from typhoid patients with earth is no protection whatever against flies. Such a mixture of earth and excrement is simply a veritable culture bed for the propagation of the typhoid bacillus, and it attracts species of flies that live outdoors and are much more migratory than is the ordinary house fly, thus spreading the disease far and wide. What is needed is something that will make such material absolutely sterile, so that there will be nothing for the flies to carry, no matter how numerous they may be. Carbolic acid is a poor disinfectant for such a purpose, for the reason that it is very volatile and soon evaporates, perhaps before penetrating the entire mass, unless used very strong and in large quantity. Ordinary lime likewise soon loses any germicidal power unless employed in large quantities. On the other hand, so small a quantity as a pound or two of sulphate of copper, dissolved in a barrel of water, will prove decidedly efficient, for when soaked into the soil and excrement in this way it stays there, producing permanent sterility as far as it extends. Earth thus treated becomes a good disinfectant, and the copper sulphate is readily portable and easily handled.

M. A. Veeder, M.D.

Lyons, N. Y.

A NEW ANÆSTHETIC ON THE BASIS OF THE SCHLEICH PRINCIPLE.

To the Editor of the Medical Record.

Sir: Referring to my letter of April 23d (*cf.* Medical Record, 1898, vol. liii., p. 607, "Correspondence"), in which I stated that on the basis of physiologic research I had given up the petrolic ether in Schleich's mixtures for general anæsthesia, using instead the molecular solution of chloroform and ether, briefly called M.S., I now beg to send you this additional information.

M.S., as explained in said letter, is a solution in molecular proportion of 119.5 gm. of chemically pure chloroform and 74 gm. of absolute ether; or, expressed in volume, of 43.25 per cent. of chloroform and 56.75 per cent. of ether. Its boiling point is 52° C.= 125.6° F.

I have made use of M.S. in all my cases of general anæsthesia since the early part of the year up to the middle of October, with very gratifying results. Nevertheless M.S. was not that anæsthetic I had been looking for, its boiling-point being too high. Therefore I urged my friend, H. P. Weidig, Ph.D., to take up again his experiments with M.S. and find the proper third not injurious narcotic substance, which, added to M.S., would reduce its boiling-point to 38°–42° Cels. (100.4°–107.6° F.).

Dr. Weidig succeeded in obtaining the desired reduction by adding ethyl chloride (boiling point, 15° C.=59° F.) to M.S. (With regard to the effect of ethyl chloride in general anæsthesia in the human subject, see "Aus der Innsbrucker chirurgischen Klinik des Prof. Dr. v. Hacker: Ueber Narkose mit Aethylchlorid," by Dr. Alfr. Ludwig; *Beitr. z. klin. Chir.*, vol. xix., p. 639, and Dr. G. Lotheissen, *Archiv f. klin. Chirurgie*, vol. lvii., p. 865.)

Eighteen per cent. volume of ethyl chloride, plus eighty-two per cent. volume of M.S., has a boiling point of 38° C. (100.4° F.); seventeen per cent. volume of ethyl chloride, plus eighty-three per cent. volume of M.S., has a boiling point of 40° C. (104° F.); sixteen per cent. volume of ethyl chloride, plus eighty-four per cent. volume of M.S., has a boiling point of 42° C. (107.6° F.).

In view of the slight difference in the amount of ethyl chloride required to produce the three boiling-points, I have discarded the first and third mixtures and use the second one only, viz., eighty-three per cent. volume M.S. plus seventeen per cent. volume ethyl chloride, boiling-point 40° (104° F.), thus employing one and the same solution for all cases.

It is a clear, transparent fluid of very agreeable odor and a specific gravity of 1.045. According to Dr. Weidig's experiments ethyl chloride is held very firmly in solution with M.S., for on evaporating 1,000 c.c. for five hours at a constant temperature of 40° C. (104° F.), 22 c.c. (2.2 per cent. volume) with a specific gravity of 1.262 was left. The specific gravity of chloroform is 1.490. This fact shows plainly that up to the last moment a "solution of components" discharges and not a final rest of chloroform, as is the case in Schleich's mixtures. Dr. Weidig and I intend to publish these experiments *in extenso* at an early date.

This preparation will doubtless, in some form or other, soon enter the regular channels of the wholesale drug trade, and will be best put up in four-ounce bottles for physicians' use and in pints for hospitals. Three to four ounces is the amount generally used for an operation lasting about an hour to an hour and a half.

I have been using this anæsthetic since October 15th, and, as far as I can judge after so short a period, consider it a great improvement on Schleich's mixtures as well as on M.S. One of the principal advantages that have been observed so far is the little disturbance it causes to the general system of the patient, especially to the stomach; vomiting seems to be a comparatively rare occurrence after its inhalation; nor is there any struggling during the induction of anæsthesia. The patients are easily brought under the influence of the anæsthetic and wake up rapidly, points of interest noted in the use of the Schleich mixture No. 1. The lungs and kidneys seem to remain unaffected.

The administration of the new anæsthetic will have to be by the drop method. I cannot say as yet which mask would best be used, whether the Esmarch chloroform mask covered with oiled muslin or with Mosetig batiste, with a proper cut out in the centre for receiving the anæsthetic, or the paper-and-towel cone, open on both sides and filled with a piece of gauze. I am inclined to believe the latter will prove preferable.

I hope you will publish these preliminary remarks for the benefit of the colleagues who are interested in the further investigation into the important question of improving general anæsthesia, on the basis of the principle introduced by Schleich, viz., a reduction of the dangers of general anæsthesia by adapting the boiling point of the narcotic to the temperature of the body.

Willy Meyer, M.D.

New York, November 12, 1898.

ORRHOTHERAPY OF FOWL DIPHTHERIA.

To the Editorof the Medical Record.

Sir: In an editorial of the Medical Record of July 16, 1898, you give Dr. Stevenson, London, Ontario, credit for discovering or rather the application of the serum treatment for roup or fowl diphtheria. I will state that I believe the priority of this is not due to Dr. Stevenson but to me. The first article that I know of from Dr. Stevenson was published in the *Reliable Poultry Journal*, April, 1898. Prior to that time I had written two articles, both similar to Dr. Stevenson's, which were published in the *American Fancier* on May 5, 1897, and March 23, 1898.

William L. Pyle, M.D.

400 Bergen Avenue, Jersey City, N. J.

A WORD UPON THE "SURGICAL NURSES" SENT OUT BY THE ACADEMY OF MEDICINE.

To the Editor of the Medical Record.

Sir: I am recently in receipt of the usual question blank sent out by the New York Academy of Medicine, and asking if a given nurse has been satisfactory. For some reason this blank is issued with red lines drawn through the names of all the medical men, members of the committee on nursing, and is signed by R. MacHaffie, whose name does not appear upon the surgical register of this city.

I infer that charge of this department is now relegated to other than medical hands. If this be so, perhaps a word of gentle advice may not be amiss, based upon a rather unfortunate experience with nurses from this same bureau of the academy.

It has been my ill luck in several of those few instances in which I have telephoned to this bureau for a surgically trained nurse for an emergency operation to get one that proved not to deserve the written recommendations which, doubtless, she showed when she registered there.

In one instance such a nurse horribly burned a patient in a half-dozen places, by hot bottles placed about her. The burns took weeks longer to heal than did the operation wound. The academy committee on nursing dismissed this nurse from the list in consequence.

In a second instance, quite recently, the "surgically trained" nurse was unfamiliar with the names of several common instruments; and the various tools which should be taken apart in order to be properly cleaned —such as artery forceps—were found upon being examined at home after her cleansing to have blood still in their locks, etc.

In a third instance, about a year ago, the "surgical" nurse sent by this bureau dumped my entire kit of instruments into a large bowl of 1–1000 bichloride solution. After snatching them out I asked an explanation. She placidly replied that where she was trained they always soaked the instruments in bichloride. This same lady did not know the names of any of the instruments except scalpels. She handed me the trays therefore, and from them I myself picked out what was wanted.

Upon inquiry she stated that part of her training had been in Ireland (or Scotland, I forget which) and part in San Francisco.

I do not doubt that each of these nurses was a true Christian, and was possessed of a fair amount of medical training; but it is calculated to shake one's confidence in the academy's bureau to find them selected as exponents of surgery—and of asepsis! One becomes, doubtless unjustly, distrustful of the entire list. And I beg to say that my own experience herein is not by any means a solitary one, as I know by comments from other surgeons.

It is obvious that some of the doctors who recommend the nurses registered there should be more careful in signing credentials. And in two respects it would seem that the management might improve the state of affairs.

1st. The nurses should be divided into, let us say, at least four groups—surgical, medical, gynæcological, obstetrical. And if a nurse claims (for example) to be a surgical nurse, she should only be so registered, provided some well-known surgeon has recommended her after personal experience of her work.

This would require, however, that some physician, familiar with the names of prominent surgical specialists, should be in charge of the bureau, as has been the case until of late. But as matters now stand, we have no real guarantee. The nurse may understand asepsis, or, on the other hand, the physician (not surgeon) recommending her may be wrong in thinking she does.

2d. I think we should adopt at the academy a home-rule policy in this matter. There are here in Greater New York an abundance of superbly trained surgical nurses. We know our own training-schools, and the thorough work that most of them do. We do not know the quality of training in a thousand and one schools outside. Some are, doubtless good, some unspeakable. Why should we not give the preference to our own New York trained nurses?

It seems to the writer that the academy bureau should be instructed to send out, in response to a request for a nurse, always one from some well-known training-school of New York City, unless the supply is, perchance, exhausted temporarily, when an outsider may be sent.

In all of the three disappointing instances I have mentioned in this letter the nurses were, I believe, outsiders.

The foregoing suggestions are made, Mr. Editor, in no carping spirit, but solely with the idea of improving the quality of care and of asepsis upon which surgeons should feel they may depend when the academy sends them a "surgical" nurse; and in order that there may in these regards be fewer mistakes made in the future than there have been in the past.

ROBERT H. M. DAWBARN, M.D.

Hemorrhage in Typhoid Fever.—After a hemorrhage has taken place the blood as a rule is not all expelled, and part remains in the colon or at the ileocæcal valve. Blood is a fruitful soil for the development of bacterial growth, and if allowed to remain aids in the further development of the poison. Do you think any harm will come to the patient by these

clots being washed out? Instead of giving opium or any other drug to bind up the bowels and secretions, I have been in the habit for the past few years of following an entirely opposite course. I give something to move the bowels, generally a saline, and wash out the colon with ice-water. By this plan I clear out the alimentary canal, carry off the clots of blood and whatever ther substance there may be, relax all tension upon the bowel; and I have not had much secondary hemorrhage to contend with.—Dr. H. G. McCormick, *The Therapeutic Gazette*, July 15th.

—Dr. J. W. Frieser, *Münchener med. Wochenschrift*, August 30th.

Treatment of Uræmic Attacks.—Use hypodermoclysis provided the symptoms are not pressing and there is no trouble with absorption because of œdema; when the danger is pressing, or œdema is present, even in a very slight degree, use intravenous injection. In a large proportion of cases the patient should be bled, particularly if nervous excitement or convulsions are present or threatened, because this will relieve cerebral congestion, and aid in the elimination of toxins and in the absorption of the fluid from the subcutaneous tissues; or if intravenous injections are used, it will make room, so to speak, for the artificial serum. I believe this is of importance, unless the circulation is evidently very feeble from profound debility and anæmia. Again, it is of great importance to aid sweating by the use of the hot pack, using care that heat stroke is not produced; but this again should not be used unless the patient fails to sweat, nor if he has a feeble heart.—Dr. H. A. Hare, *The Therapeutic Gazette*, July 15th.

Obstinate Vomiting.—

Use as a dusting-powder.
—Oppenheimer.

In Subacute Bronchitis increasing doses of a reliable emulsion of cod-liver oil are often curative when other drugs have failed.—Hare.

Acute Conjunctivitis.—The most efficient treatment is to have the eye exposed every two hours to a steam atomizer, having a five-per-cent. solution of carbolic acid in the cup. This when mixed with the steam issues forth as about two-and-one-half-per-cent. solution, and is easily borne. Let the patient sit with his eye directly in front of the steam jet for a quarter of an hour at a time.—Blake.

Diphtheria.—

℞ Tinct. of myrrh..... 4 parts.
Glycerin..... 8 "
Distilled water..... 200 "

This is given freely—every hour during the day and every two hours at night—infants up to the age of two years taking a large teaspoonful, older children double the quantity, and adults three times as much. Continue this until the membrane has disappeared.—Dr. Stroll, *Allgemeine medicinische Central-Zeitung.*

Prevention of Gastro-Intestinal Troubles.—A very valuable point in the prevention of gastro-intestinal complaints of breast-fed children is to keep the nipples and breasts thoroughly sweet and clean. The milk drippings or oozings find lodgement in the rugæ of the nipples, and furnish a soil for bacteria and a medium for tyrotoxicon to enter the child's organism. —*Georgia Journal of Medicine and Surgery*, June.

Cold in Renal Disease.—Cold irrigation is absolutely contraindicated in renal disease; so are cold enemata.—Kemp.

Treatment of Scarlatina with the Full Bath.—Dr. D. S. Hanson (*Cleveland Medical Journal*, June) says the theory of the action of the full bath at 90° F. can be explained only by considering a number of things accomplished: (1) It reduces temperature, which is probably the most important part of its action. (2) It favors elimination, yet its effects are so quickly apparent that this feature can be beneficial only to a minor degree. (3) It stimulates the circulation and strengthens the heart's action, thereby relieving the capillary stasis, in the skin more particularly, but probably in the internal organs as well. This change can be most beautifully seen by observing the relief of the congested conjunctivæ noticeable when we find a dark scarlet skin with marked nervous phenomena, often stupor and unconsciousness. (4) It inhibits in some manner the action of the toxins upon the circulatory, respiratory, and reflex nerve centres. By the repetition of the bath as indicated, until nature comes to the rescue, nerve exhaustion can be limited and convalescence hastened.

Acute Gastro-Enteric Infections, when accompanied by vomiting, purulent dejecta, pains, etc.:

Acute Angina of Infants.—

℞ Acid. carbol. cryst ..... gr. xv.
Glycerini ..... ʒ iss.
Ol. thymi..... gtt. ij.
Aquæ ..... ʒ xvi.
M. S. Irrigate pharynx.
—Marfan.

General Tonic.—

℞ Strychninæ sulphatis ..... gr. $\frac{1}{60}$
Acidi phosphorici diluti ..... ♏ v.
Ferri phosphatis..... gr. i.
Quininæ bisulphatis..... gr. i.
Glycerini ..... ʒ ss.
Elixir aurantii.....q.s. ad ʒ ss.
M. et ft. sol. S. Take before each meal.
—Winslow Anderson.

Typhoid Fever.—

℞ Spts. terebinth. rect ..... ʒ i.
Spts. juniper..... ʒ ss.
Fluid ext. hamamel..... ʒ ij.
Pulv. acaciæ..... ʒ iss.
Aquæ..... .....q.s. ad ℥ vi.
M. S. Dessertspoonful every four hours while awake.
—J. Sanderson Christison.

Pulmonary Tuberculosis.—

℞ Ammonii sulphoichthyolatis,
Creosoti carbonat.....āā 15 gm.
Glycerini puri..... 30 "
Aq. menth. pip ..... 10 "
M. S. Twenty drops after each meal, increased to thirty drops, in a little wine or water containing lemon juice; children, ten drops gradually increased to twenty.
—H. Goldman, *Wiener klin. Woch.*, September.

Insomnia.—A Russian remedy is to have a dog sleep in the room, and preferably in the same bed. It may be through a sense of companionship, or one of security, or it may act suggestively; at any rate, it is said at times to prove of value when other means fail.

Migraine.—An apparatus like a double-hernia truss or bandage is applied so that the pads make decided pressure over the temporal regions. Numerous successes are reported.—Sargon, *Deuts. med. Woch.*, No. 35.

Bronchitis with Bronchorrhœa.—

℞ Ex. belladonnæ..... 0.01 cgm.
Ext. daturæ ..... 0.05 "
Pulv. camphoræ ..... q.s.
For one pill. One to three daily.

Uterine Cancer.—

℞ Acidi salicylici..... 0.40 cgm.
Sodii salicylat ..... 12 gm.
Tinct. eucalypti ..... 24 gm.
Aq. destil..... 180 gm.
M. S. Three tablespoonfuls to a pint of water as an injection every three or four hours.

Urea in Cirrhosis.—There is a benign form of cirrhosis of the liver with ascites, in which urea acts as a diuretic and removes the fluid. In severe forms little is to be hoped from the remedy, even when as much as an ounce is given daily.—Dion.

Blennorrhagic Dysuria.—

℞ Sodii salicylat. ..... 10 gm.
Ext. belladonnæ ..... 0.30 cgm.
Tinct. aurantii cort. amar ..... 5 gm.
Aquæ ..... 195 gm.
M. S. Teaspoonful every two to three hours.

—Gerbert.

Anal Fissure.—

℞ Europhen 0.10
Butyr. cacao 3
M. ft. supposit. S. Introduce into rectum after using a cleansing enema.

—*La Presse Méd.*

Chapped Hands.—

℞ Menthol 1
Salol 2
Olive oil 3
Lanolin 80
M. S. Apply twice daily.

—Ritterband.

Pruritus.—

℞ Plumbi acet. neutr 0.1
Cocain. muriat. 0.15
Vaselini alb. 3

—*Allgemeine mediz. Central-Zeitung*, September.

Subcutaneous Injection for Hæmoptysis.—

℞ Ergotin 5
Morph. muriat 0.04
Antipyrini 1.5
Sparteinæ sulph. 0.2
Atropinæ sulph 0.002
Aquæ destill. ..... q.s. ad 10
M. S. One hypodermatic every half or quarter hour up to five.

—Capitan.

Hæmoptysis.—

℞ Ergotin (Bonjean) 2
Acidi gallici 0.5
Syr. terebinth (Fr. Cod.) 120
M. S. Tablespoonful every half-hour.

—Capitan.

Hæmoptysis in Children.—

℞ Ferri sesquichlor 0.4–1
Syr. cinnamomi 30
Aq. destill 100
M. S. Tablespoonful every half-hour.

Or:

℞ Syr. ipecacuanhæ 30
Pulv. ipecacuanhæ 0.3
M. S. Teaspoonful every five minutes until emesis ensues.

Or:

℞ Ergotin 1
Syr. rhatan 10
Aquæ destill 100
M. S. One tablespoonful every hour.

—Cadet de Gassicourt.

Antigalactic.—

℞ Atropinæ sulph 0.003
Magnes. sulph. 90
Infus. gentian 240
M. S. Tablespoonful every two hours.

—Bloom.

Diabetic Albuminuria.—

℞ Sodii arseniatis 0.05
Potassii iodidi 5
Aquæ destill. 300
M. S. Tablespoonful before each meal.

Or:

℞ Extr. quininæ (P. G.) 0.05
Quininæ sulph 0.1
Pulv. nuc. vomic 0.02
M. ft. pil. S. To be taken with meals.

—Conard.

Enema for Tuberculous Peritonitis.—

℞ Creosoti 0.5–2
Tinct. opii ..... gtt. vi.
Ol. jecoris aselli 100–150

—Holz.

Struma.—

℞ Potassii iodidi 0.2
Æther 5
Tr. sapon. viridis 30
M. S. Apply before retiring.

—*Allgemeine medizinische Central-Zeitung.*

Bronchial Asthma.—

℞ Morphinæ sulphatis 0.075
Strychninæ sulphatis 0.01
Hyoscinæ hydrobromatis 0.003
Aquæ destillatæ 10
M. S. One to three hypodermatics in twenty-four hours.

—Sols.

Galactorrhœa.—

℞ Potassii iodidi 1
Iodi puri 1
Syrupi 30
Aquæ 200
M. S. Tablespoonful every hour.

—Audhoui.

Diarrhœa of Phthisis.—

℞ Iodoform 2
Tannin 4
M. div. in part. æq. No. xl. S. Two to four powders daily.

—Renzi.

Constipation of Phthisis.—

℞ Iodoformi 2
Naphthalin 2–4
M. div. in part. æq. No. xl. S. Two to four powders daily.

—Renzi.

Enuresis.—

℞ Sol. atrop. sulph. (two per cent.) 5.6
Sol. strych. muriat. (two per cent.) 0.25
Syr. aurantii 30
M. S. Five drops at 9 P.M. and increase gradually up to sixty drops.

—McAlister.

Angina Pectoris.—Restricted diet, forbidding articles which cause fermentation. Potassium or sodium iodide, gr. x.–xv., thrice daily.—Osler.

Varicose Ulcers of the Leg.—Fifty parts of chloride of sodium and five parts of pulverized menthol. Both substances should be in the form of an impalpable powder, and intimately admixed.—Simonelli.

Hemorrhagic Nephritis.—

℞ Salol 0.05
Pyoktanini cærulei 0.1
For one capsule. Give eight daily.

—Dr. A. Kramer, *St. Petersburg med. Woch.*

Local Treatment of Pertussis.—

℞ Quininæ sulph. 4
Resorcin. 1
Sacch. lact. pulv 25
M. S. Apply locally with powder insufflator five or six times a day.

—Leuriaux.

Carcinoma of the Rectum.—

℞ Eucainæ muriat 0.03
Morphinæ muriat 0.01
Aquæ destill. 20
M. S. Use half or the entire amount for an enema.

—Rosenheim.

Enteritis of Children.—

℞ Tannin 0.6
Acidi lact. 2
Aquæ destill. 60
Syr. simplicis 30
M. S. Teaspoonful before each meal.

—Variot.

Pertussis.—

℞ Hydrochlorate of phenocoll..... gr. xviii.–℥ iss.
M. div. in chart. No. xii. S. One powder three times a day.

—KOBERT.

Or:

℞ Tinct. bellad..... 10
Tinct. valerian,
Tinct. digitalis..... āā 5
M. S. Five to sixty drops according to age.

—ROGER.

Or:

℞ Pulv. fol. belladon..... 0.05
Sacchari..... 0.25
M. ft. pulv. S. Two to eight powders daily.

—SANDRAS.

Convulsions of Pertussis.—

℞ Extr. belladonnæ..... 0.1
Potassii bromidi..... 10
Syr. aurantii cort.....q.s. ad 200
M. S. Teaspoonful morning and evening for young children; older children, dessertspoonful twice a day.

—*Jour. de Méd. de Paris*, 1898.

Anthelmintic.—

℞ Acidi salicylici..... 0.5
Ext. filic. maris æther..... 0.75
Gummi arabici..... 7.5
Syr. simplicis..... 50
Ol. cinnamomi..... gtt. x.
Aquæ destill..... 100
M. S. To be taken before breakfast.

—M. T. GUIDA.

Ocular Neuralgia.—

℞ Quininæ hydrochlor..... 0.10
Morph. muriat..... 0.05
Aquæ destill..... 10
M. S. Instill five to ten drops into the eye.

—MARKOFF.

Local Treatment of Rheumatism.—

℞ Methyl salicyl..... 12
Vaselin liquid..... 20

Or:

℞ Acidi salicylic..... 4
Vaselin.....q.s. ad 20

Or:

℞ Acidi salicyl..... 4
Sodii salicyl..... 3
Extr. belladon..... 1
Vaselin..... 25
M. S. Apply locally.

—LEMOINE.

Vomiting of Pelvic Origin.—

℞ Menthol..... 0.3
Elixir pepsin..... 30
Tinct. opii..... 10
M. S. Ten to twenty drops before meals.

—LUTAUD.

Asthmatic Attacks.—

℞ Tinct. stramonii..... 3
Ammon. carbon.,
Magnesii carbon.....āā 1.5
Sodii bicarb..... 5
Pulv. rhei..... 0.5
Chloroformi..... gtt. x.
Aquæ menthæ piper..... 100
M. S. Tablespoonful in a wineglassful of water t.i.d.

—MURRAY.

Intestinal Antisepsis.—

℞ Alpha-naphtholi..... 4
Phenacetini..... 1–2
M. ft. pulv. div. in part. æq. No. v. S. One powder every three to four hours.

Or·

℞ Alpha-naphtholi..... 2
Olei ricini..... 30
Olei menthæ piper..... gtt. i.
M. S. To be taken in two doses at an interval of one hour.

—MAXIMOVITSCH.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 19, 1898:

	Cases.	Deaths.
Tuberculosis	192	142
Typhoid fever	75	11
Scarlet fever	100	7
Measles	149	5
Diphtheria	136	28
Laryngeal diphtheria (croup)	15	8
Cerebro-spinal meningitis	0	1

Suicide and Sex.—Dr. Alexander Haig (*British Medical Journal*, September 10th) in a discussion on suicide at the annual meeting of the British Medical Association, treats of "suicide as a result of error of diet." He believes that mental depression and melancholia are due to defective circulation in the brain; and that this is due to the blood being rendered impure by the presence of uric acid, and that this uric-acidæmia or collæmia is the result of error in diet, and can be controlled or removed by altering it. He says: "The great preponderance of suicide in males may be due to several factors: (1) Men are more exposed to weather than women and exposure may be equivalent to living in a colder climate, which we have already mentioned. (2) Men eat, I believe, more, often much more, meat than women. (3) Women excrete, as I have shown, large quantities of uric acid every month at or just after the monthly period, so that, other things being equal, they will have less retention and accumulation than men; this monthly plus excretion accounts for the fact that when they do commit suicide it is often at the monthly period. Again, women suffer much less than men from gout on the one hand and stone and gravel on the other. In just the same way life fluctuations explain why women suffer more than men from fifteen to twenty years of age. The uric acid stored or retained in the rapid nutrition of girls about thirteen or fourteen years, which comes to an end about sixteen or seventeen years, passes through the blood about and after these latter ages, and accounts for the blood and circulation changes which end in chlorosis, headaches, depression, epilepsy, and suicide. The opposite side of this picture is the rapid nutrition and retention of uric acid at thirteen years, with the acute rheumatism it produces; in such girls we often get a complete alternation of rheumatism and anæmia, with headache, epilepsy, depression, and suicide as more occasional coresults."

Dangers of Hypnotism.—Dr. J. Milne Bramwell (*British Medical Journal*, September 10th), in a discussion on the phenomena of hynotism and the theories as to its nature, refers to the dangers of this procedure in the following words: "As far as my experience goes, the employment of hypnotism by medical men who are acquainted with the subject is absolutely devoid of danger. I have seen no unpleasant symptom, even of the most trivial nature, produced by the induction of hypnosis. Further, I have never seen any evil after-effects, either mental or physical; and, if such were likely to occur, surely some of my patients would have presented them. I have hypnotized hundreds of persons of both sexes, and of all ages from early childhood upward, occasionally repeating the process almost daily for months. Some of these were actually insane, while in many the mental condition was far from stable. In a considerable proportion recovery took place after

hypnotic treatment and many years have passed without relapse. This view as to the alleged dangers of hypnotism is largely shared by others. For example, Professor Forel says: 'Liébeault, Bernheim, Wetterstrand, van Eeden, de Jong, Moll, I myself, and the other followers of the Nancy school, declare categorically that although we have seen many thousands of hypnotized persons, we have never observed a single case of mental or bodily harm caused by hypnosis; but on the contrary, have seen many cases of illness relieved or cured by it.'" He concludes his discussion as follows: "If Braid and Myers have done much toward giving us a clearer idea of the hypnotic state, they have also added to the difficulties of explaining it. A conception of hypnosis which limited its manifestations to simple automatic movements was comparatively easy to explain. The hypnotic subject who, while he has not lost the physical and mental powers of his waking condition, has acquired new and far-reaching ones, presents a very different problem. How he acquired these powers and why hypnotic methods should evoke them are questions by no means easy to answer. But normal life contains many problems, both physiological and psychological, which are yet unsolved, and some, such as causal connection between mental and physical states, which are apparently insoluble; and while this is so it would be unreasonable to expect a complete explanation of that still more complex state, the hypnotic. Further observation, however, is always giving us clearer insight, if not into the central problem itself, at all events into the phenomena which characterize it. What increased practical advantage this may give us in curing disease, alleviating pain, or improving moral states, time alone will show."

Birmingham Waterworks and their Model Village.—At Birmingham, England, a colossal enterprise to supply that town with water is now being proceeded with. Birmingham has a population of about six hundred thousand and is in the midst of a densely crowded district, and the difficulties in the way of procuring a pure water supply have for some time been approaching a crisis. The city fathers of Birmingham have resolved to undertake the enormous project of getting the water for the town from the lakes of Wales, a distance of perhaps two hundred miles. The work has now been commenced for some time. In connection with the work and for the accommodation of the workers a model village has been erected, an account of which recently appeared in an English journal; the details are worthy of note to those interested in great works. The houses are built of wood and the village is approached by a suspension bridge. The advantage of this is that "strangers" have to state their business before they can find a way into the place. If they are seeking work, a night must be spent in the corporation "doss house," on the opposite side of the bridge. Here they must sleep and have a bath; during the night their clothes are disinfected and in the morning the applicant has to appear before the resident medical officer. If everything is satisfactory, a permit is given to cross over, and by this means a clean bill of health is maintained. The village itself is laid out in streets, the house blocks being specially designed, as the case may be, for the accommodation of single families or for the housing of a limited number of unmarried men lodging with a married couple. In the latter case each lodger has his own separate cubicle and locker, and enjoys the use of a living-room in common with the other inmates of the house. The villagers number some fifteen hundred navvies and others, employed on the work, with their wives and families. Baths and wash-houses have also been built and a large public assembly room, besides a canteen and general store, a post-office, and police station. A medical officer and a staff of trained nurses are associated with the infirmary hospital down near the work and the isolation hospital upon the hillside, away from the abodes of man.

Migration of Ascarides Lumbricoides.—In the *Deutsche medicinische Wochenschrift*, No. 23, is related by Martens an instance of impaction of an ascaris, seventeen centimetres long, at the point of junction of the hepatic and cystic ducts. In another instance rapid disappearance of severe icterus followed the expulsion with the fæces of two ascarides, one of which presented a strangulation, which led to the belief that it had been the cause of obstruction in the ductus choledochus.

Inflammable Hair Washes.—The dangers of using liquids containing petroleum spirits, benzolene, etc., for cleansing the hair, have been again emphasized by another death from burns in England.

Stoke's Dictum.—"There is no single nervous symptom which may not, and does not, occur independently of an appreciable lesion of the brain, nerves, or spinal cord."

Oliver Wendell Holmes says: "Science is a first-rate piece of furniture for a man's upper chamber if he has common sense on the ground floor; but if a man has not got plenty of good common sense, the more science he has the worse for his patient."

Consumption of Milk.—Mr. Henry Kew, in the journal of the Royal Agricultural Society for 1892, computed that in Great Britain the average quantity of milk consumed per head in 1890 was sixty quarts. Sir James Blyth now states that from similar data and other information he has no hesitation in assessing the consumption of milk seven years later at eighty quarts per head for every man, woman, and child in the kingdom in 1897, which, if it reach the public at the low price of 3*d.* (six cents) per quart, is equivalent to a total payment for milk of no less than forty million sterling (two hundred million dollars), a sum, roughly speaking, equal to the whole wheat bill of the United Kingdom.—*London Times.*

The Handwriting of Medical Men.—Some time ago the question of the handwriting of prescribers was made the subject of some remarks in the general press in England, but British doctors appear not to be the only ones whose prescriptions are occasionally of a hieroglyphic character. *La Médecine Moderne* has recently had something to say on the subject. After sympathizing with the pharmacists, whose difficult task it is to decipher these illegible documents, the writer adds that the matter has attracted the attention of no less a person than the dean of the medical faculty of Paris. Professor Brouardel is concerned as to the dangers to the public likely to be caused by the execrable handwriting of many physicians. In a recent interview he is reported to have stated that he would take the earliest opportunity of bringing the matter to the notice of the professors of the faculty. What that body can do in the matter, however, is not very clear. We do not think that among ourselves the evil is of sufficient magnitude to call for any extraordinary measures of reform, such as the intervention of the General Medical Council. That the handwriting of many members of the profession is anything but legible is unfortunately too well known to us, from our editorial experience. Indeed, we are sometimes tempted to say in our haste that some of our correspondents regard writing as Talleyrand defined language—as a means of concealing thought. On this subject it is needless to say much, but if writers only realized that their

handwriting is often a bar to the insertion of communications, and still more often a cause of avoidable errors, especially in names, quantities, and so forth, they would, we think, take a little more trouble about this small matter than they do.—*British Medical Journal.*

The Prince of Wales is still wearing the apparatus which the medical experts have designed for him, and will probably continue to do so for several weeks.

The Doctor and the Monument Maker.—A physician, passing by a stonemason's yard, bawled out to him: "Good morning, Mr. W——. Hard at work, I see. You finish your gravestones as far as 'In memory of,' and then you wait, I suppose, to see who wants a monument next?" "Why, yes," replied the old man, resting for a moment on his mallet; "unless somebody is ill and you are doctoring him, and then I keep right on."

Responsibility in Mental Disease.—An eminent writer upon this subject remarks: "When one considers the reckless way in which persons, whatever the defects of their mental and bodily constitution, often get married, without sense of responsibility for the miseries which they entail upon those who will be the heirs of their infirmities, without regard, in fact, to anything but their own gratification, one is driven to think either that man is not the pre-eminently reasoning and moral animal which he claims to be, or there is in him an instinct which is deeper than knowledge. He has persuaded himself, rightly or wrongly, that there is in the feeling of love between the sexes something of so sacred and mysterious a character as to justify disregard to consequences in marriage. We have only to look at the large part which love fills in novels, poetry, and painting, and to consider what a justification of unreason in life it is held to be to realize what a hold it has on him in his present state of development, and what a repugnance there would be to quench its glow by cold words of reason. At bottom, however, there is nothing particularly holy about it; on the contrary, it is a passion which man shares with other animals, and, when its essential nature and function are regarded, we shall nowhere find stronger evidence of a community of nature between man and animals. It would not be a very absurd thing if an ingenious person, considering curiously what a solemn undertaking marriage is, and what serious responsibilities it entails, were to maintain that men and women should enter into it soberly and rather sadly, under a grave sense of responsibility as upon an uncertain voyage, and should reserve their rejoicings for the journey's end, when, having acted well their parts, they might fairly claim a *nunc plaudite.*"

Cinchona Industry of Java.—The British consul at Batavia, in his last report on the trade of Java, mentions an important development in the cinchona industry of the island. Java produces about two-thirds of the world's supply of cinchona, and it has for years been regularly shipped to Holland, where it has been sold by public auction. The large quinine manufactories, which are mostly situated in Germany, supply themselves with the raw material in the Dutch market; and of late years the manufacturers have combined to keep the prices at such a low level as to render the cinchona cultivation unprofitable, although the manufacturers of quinine have been earning large dividends. To meet this combination it was resolved to establish a quinine factory in Java; and this has been done at Bandong, where the first Java quinine has been produced. This is described as of excellent quality and equal in all respects to the best European brands. Some of the planters were tempted early last year by the rise of prices in Europe, consequent on the establishment of the factory at Bandong, to consign their cinchona to Europe rather than to their own factory, but now the latter is being well supported with the local raw material. Some large shipments of Bandong quinine have been made to London and smaller ones to other parts of the world, and the future of Java quinine will depend on the result of these ventures. Last year the total production of cinchona in the island was over eight and one-half million pounds avoirdupois.—*London Times.*

Stammering is sometimes met with as early as two years old in neurotic children; in these cases it is generally temporary. Persistent stammering rarely begins before the commencement of the second dentition, and is commoner in girls than in boys.—JOHN THOMPSON.

The Wheat Supply.—Sir William Blyth says: "The recent address of the president of the British Association was noteworthy for its insistence upon the application of science to agriculture, so as to increase the productiveness of wheat-growing areas, if, as he said, we were not ultimately to be squeezed out of existence by races to whom wheaten bread is not the staff of life. Notwithstanding Sir William Crookes' warning as to diminishing productiveness of wheat areas, I cannot help thinking that even in the event of prolonged scarcity of corn the British nation would be the last to feel the pinch, because of its preponderating wealth and by reason of the number of health-sustaining substitutes now in constant use."—*London Times.*

Legal Views on Syphilis.—In an action for divorce in a Pennsylvania court, infection having occurred before marriage through the medium of a kiss, the judge stated in his charge that he could imagine no more direct and palpable case of cruelty to a wife by a husband, for which the Pennsylvania statute allows divorce—"the wife," according to the judge's words, "after marriage having been kept constantly in a diseased condition from the same source, until she had passed into the secondary condition of the disease and had approached on the tertiary stage thereof, having endured for upward of five years the constant presence of one of the vilest, most shocking, and dangerous diseases with which the human body can be afflicted." There are here an implied state of repeated infections and a rather late beginning of what is usually termed the tertiary period.

Modesty among Philadelphia physicians seems to be so rare a thing that a medical publication of that city regards it of sufficient importance for comment that a surgeon who recently operated upon a somewhat distinguished patient withheld his name from the papers.

The Death Rate among the Troops in France, Algiers, and the Colonies.—Apropos of the much-mooted question of an unnecessarily large death rate in our army during the late war, it is of interest to note the statistics of the mortality among the French troops, recently published by M. Noël, in the *Revue Scientifique* of August 27, 1897. He summarizes his interesting article as follow: (1) The death rate among the officers of the land forces is 5 per 1,000; and in the marine infantry and artillery, 22 per 1,000. (2) The mortality of the troops in France amounts to 6.08; in Algiers, 12.27; and in the colonies, to 42.95 per cent. (3) In proportion to the severity of the training of troops, there is a rise in the death rate; this is true not only of the regular soldiers, but also of the *temporaires.* (4) In the armies of the colonies four-fifths of the total number of deaths is due to the endemic-epi-

demic diseases; in France, only half this number. (5) In the colonies malaria, enterocolitis, and liver affections are the chief causes of death; while in France, typhoid fever and grippe carry off the larger number. (6) Since the introduction of vaccination, small-pox is an insignificant factor. (7) The death rate from diphtheria is probably unimportant, on account of the introduction of serum therapy. (8) In France, pulmonary tuberculosis causes 1.09 deaths per 1,000; and in the colonies, 1.2. (9) The number of suicides in the colonial armies is about 2.5 in 1,000, while in France it is only 0.2 per 1,000. When we compare these statistics of an army at peace and those of the mortality rate among our own soldiers, which was something like two per cent., including those who fell in battle as well as those who succumbed to disease, it is only fair to ask whether the great outcry against the excessive death rate in our own armies is wholly warranted.

Hints to Authors.—Certainly it is excellent discipline for an author to feel that he must say all he has to say in the fewest possible words, or his reader is sure to skip them; and in the plainest possible words, or his reader will certainly misunderstand them. Generally, also, a downright fact may be told in a plain way; and we want downright facts at present more than anything else.—RUSKIN.

An Aid to Digestion.—Chomel knew what he was talking about when he said that a man digests as much with his legs as with his stomach, for we know that exercise facilitates nutrition, increases the elimination of waste products, promotes appetite, and under proper conditions is an aid to digestion.—*Journal of Medicine and Science.*

Professor Albert has changed the phraseology of the golden rule to read: "Castrate others as ye would that others should castrate you."

Gift of Baroness Hirsch.—Baroness Hirsch has placed Tudor House, Hampstead Heath, which she purchased at the cost of $80,000, in the hands of trustees, to be maintained as a convalescent home for Jewish consumptives.

Health Reports.—The following statistics concerning small-pox, yellow fever, and cholera have been received in the office of the supervising surgeon-general of the Marine Hospital service during the week ending November 19, 1898:

SMALL-POX—UNITED STATES.

		Cases.	Deaths.
Alabama, Mobile*	October 27th to November 5th	1	1
California, San Francisco†	November 7th	1	
Michigan, Ecorse Township	November 9th	Present.	
N. Carolina, Edgecombe‡	November 12th	10	
Ohio, Cleveland	November 14th	1	
Virginia, Norfolk§	October 8th	1	

* Disease imported from Dwight, Ala., where small-pox was reported on September 12th.
† Employee on s.s. *Mariposa.* ‡ Imported from Norfolk.
§ Seven cases now in city pesthouse.

SMALL-POX—FOREIGN.

Belgium, Antwerp	October 15th to 22d	5	3
Russia, Moscow	October 8th to 15th	9	2
Odessa	October 15th to 22d	2	1

Vera Cruz	October 28th to November 3d	..	11
Vera Cruz	November 3d to 10th	..	8

CHOLERA.

India, Madras*	October 1st to 7th	21

* On October 10th a Calcutta *Gazette* "extraordinary" was issued, giving official notice that Calcutta was free from cholera.

Swedish Physicians. — The doctors of Sweden never send bills to their patients. If you have occasion to call a physician you will find him not only skilful in his profession, but a highly educated and honorable gentleman. You will also have a proof of the honesty of the Swedes and their friendly confidence in each other. What you shall pay your physician is left entirely to your own choice. The rich may pay him liberally, whether they have need of his services or not, if he has once been retained by them. The poor may pay him a small sum, and the very poor pay him nothing. Yet he visits the poor as faithfully as he does the rich. A similar custom prevailed up to the middle of the present century in some of the most remote portions of the Highlands of Scotland. There the doctor collected his entire year's bills on a certain market day in summer, getting perhaps five or ten pounds from the larger farmers, but only as many shillings from the poorer crofters.—*Medical Age*, September.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

A PLEA FOR EARLIER RECOGNITION AND PROMPTER ACTION IN MALIGNANT DISEASE.[1]

BY JOSEPH D. BRYANT, M.D.,

NEW YORK.

THE selection of this somewhat well-worn topic for consideration this evening is largely owing to the fact that during the last few weeks far too many of those affected with the inevitable outcome of advanced malignant attack, dependent chiefly on lay and professional procrastination, have come under my immediate observation for relief. And when it is stated further that, in an instance of an operable case of cancer of the breast with axillary involvement, a highly reputable surgeon had deferred action for a month on the ground that "it would make no difference," it appears to the reader that much additional force is given to the need of urgent expression, directed to securing prompt and thorough action.

In another case in point, a patient with marked involvement of the lower jaw, due to malignant submaxillary gland extension, the sequel of epithelioma of the lip, was presented for relief, with the history of early submaxillary involvement and the admonition to the patient from the physician, "Call and see me" should further increase ensue. The patient, left to his own observation and tortured with fears of malignant involvement, accounting for evident increase by biassed lay reasons, finally presented himself four months later, in the condition already stated, and acknowledged that he would have come before had he not feared to be informed of the correctness of his worst anticipations. Surely this patient's chances could have been much enhanced and the patient rescued from the outcome of his own delusions, had wise professional vigilance and action been exercised.

The constant and active presence of a persistent and untiring enemy of human life and happiness justifies the consideration at any time of means best suited to lessen the evil effects and to defeat the fatal outcome of its presence.

This expression is not intended as an apology for the title or for what is to follow, but rather as a quasi admission that what may be said will savor of a somewhat later period than yesterday. The seekers after truth, like those in search of the baser things, can, not infrequently, gain much from that which was left behind, by working over again in a newer method the leavings of ineffective or careless effort.

It seems to me that the Practitioners' Society is just the place in which to consider the practical features of the title of this brief communication. Surely here, if anywhere, the consideration should have special significance, not only because of the active lines of the professional endeavor of its members, but also from the freshness of their experience in numerous individual instances.

That malignant disease is slowly and continuously increasing in the human family appears to admit of no denial; and that the increase seems to be one of the penalties of a membership in the ranks of advancing civilization can hardly be gainsaid. For the cruder the race, the freer it is from this infliction: the more refined it is, the greater appears to be the weight of the malignant burden.

In 1889 England lost 18,654 of her people from cancer, this number being 3.6 per cent. of the entire death rate for that year. In 1893 London alone lost 3,412 of her population from this cause, a percentage of 3.73 of the total death rate for the year. And during the ten years preceding 1895, the death rate from cancer increased 0.87 per cent.

In Berlin in 1892 "cancer and tumors" destroyed 1,138 of the population, a rate of 3.48 per cent. of the total deaths for that year. In the same city in 1877 the deaths from these causes are recorded at 2.10 per cent., showing an apparent increase of 1.38 per cent. in fifteen years.

In Vienna the deaths from cancer in 1890 were 4.96 per cent. of the total death rate for that time, and during the preceding eight years the death rate from the same cause had increased 0.84 per cent.

In Paris, in 1893, cancer caused 4.61 per cent. of the total death rate.

I will not trouble you longer with foreign evidences of a marked and increasing death rate from this infliction, but, instead, will recall similar testimony of the outcome in this regard in our more immediate presence. The average death rate from cancer in New York City during the ten years prior to 1895 was 2.17 per cent. of the total mortality of that period, showing an increase of 0.35 per cent. in the preceding ten years.

Permit me to add, in brief, in connection with other important cities of the United States, that in 1895 Philadelphia showed an increasing rate of 0.26 per cent.; Boston, 0.54 per cent.; Baltimore, 0.64 per cent.; New Orleans, 0.52 per cent.; and San Francisco, 0.84 per cent. during the preceding ten years.

It may not be uninteresting to note the fact that the deaths from cancer in fifty of the large cities of the United States is 16.34 greater per 100,000 living than in the remaining portion of the country. It is proper to say, however, that a part of this difference can be justly attributed to the comparatively greater completeness of the mortality records of city districts and to the presence in the city of those who seek the advantages it offers for relief.

It may not be unimportant at this time to note the fact that certain parts of the body exhibit a comparative increase in the frequency of malignant attacks, while others remain stationary and even suffer less than before in this respect. It appears that there has been a large increase of malignant manifestation in the upper organs of the digestive system of men—in the mouth, the tongue, the pharynx, and the fauces—while in women the contrary is observed. The generative and mammary organs of women—the commonest seat of malignant disease in the sex—show but a slight increase in this regard, while the intestines, rectum, liver, and bladder of the female exhibit a marked increase.

It is not impossible that much of the difference is

[1] Read before the Practitioners' Society of New York, November, 1898.

dependent on improved diagnosis in the latter instances. At all events, it now appears that those parts of the body possessed of especial physiological significance, and which are exposed to the evil effects of perverted appetite and mischievous habits, are foremost in the field of malignant development. In 1,000 deaths from cancer in New York City in 1893, the tongue was the seat of disease in 18, the œsophagus in 19, the stomach in 253, the intestines in 39, the rectum in 42, the uterus in 196, and the breast in 91 instances.

The remaining portion of this paper will be largely of an interrogatory character, and will be presented in logical sequence.

(1) Do surgical measures afford relief?

(2) Does thoroughness of operation favor subsequent immunity?

(3) Do early recognition and prompt action in malignant disease contribute to effective surgical effort?

(4) Will not earlier recognition and prompter action of all concerned in malignant disease increase the present rate of cure; and, if so, how can these desiderata be attained?

Inasmuch as the stomach, uterus, and female breast are the most frequent seats of malignancy, and since each is amenable to operative practice, they will be regarded at this time and without extended allusion as representative illustrations of the need of greater vigilance and action along the entire line of malignant advance.

Do surgical measures afford relief? As it seems to me, it is needless at the present day and age to address a question like this to an intelligent mind. For, in view of the certain outcome of unhindered development, as witnessed along the line of every medical effort, no other than an affirmative answer can follow, and, too, so promptly on the heels of the query as to constitute, without punctuation, a part of the leading expression.

However, according to Gross, Aldekop, Henry, and Winiwarter, with cancer in the breast the average duration of life without operation is 27.15 months; with operation along the older lines of action, thirty-nine months—making a difference in favor of operation of 11.85 months, or substantially one year, and with all of the advantages the respite implies.

This interrogatory can be regarded as rather euphonic than otherwise in this connection.

Does thoroughness of operation favor subsequent immunity? For the purposes of this paper, as wide removal of the seats of present and of prospective malignancy as possible may be regarded as constituting thoroughness of operation. In the edition of 1870 of his "Pathology," Sir James Paget uttered the following: "I am not aware of a single clear instance of recovery—of such recovery, that is, that the patient should live for more than ten years free from disease." Surely an expression of this sombre character and from such a source afforded but little encouragement to the afflicted and scarcely any support to operative adherents. It needs no words of mine to express the fact that this doleful declaration was prompted, no doubt, by the recognition of the sad outcome of the delayed and inadequate efforts that characterized the time of its utterance.

Gross, writing in 1880, dispelled much of the gloom caused by the experience of Paget; since he showed then that 9.05 per cent. of all cases of cancer of the breast were cured for ten years by improved operative technique. Later the same author reported 11.83 per cent. of cures, which list included cases up to 1885. Bull, in 1894, reported plus twenty-six per cent. of cures, based, the same as Gross' last report, on the three-year limit. Halsted reports by the same time measure a rate of cure of about fifty-two per cent.

There appears to be no doubt of the fact that to wide and thorough removal of the present and prospective seats of the disease much of this increased gain is due. It seems to the reader, so far as the breast is concerned, that progressive surgeons have now nearly reached the limit of expectancy in this regard, unless other precautionary and technical issues are raised and enforced that will increase materially the present record of cures.

Do early recognition and prompt action in malignant disease contribute to effective surgical effort? That malignant disease extends from a selected site chiefly by infiltration of contiguous tissues and by the lymph channels to lymph nodes, to fascia, etc., is conclusively proven by microscopical demonstration and clinical observation. The lymph nodes are the signal stations of the advancing enemy, and at varying intervals manifest by both gross and microscopical characters the arrival there of the subtle foe.

There can be hardly a well-founded doubt of the fact that the comparative functional activity of diseased parts regulates correspondingly through the various channels the dissemination of the infecting agents. Therefore, in view of these facts, the anticipation of malignant dissemination by means of operative practice demands not only early recognition of the danger, but prompt ablation of the source of infection and the destruction, so far as possible, of the lines of communication to the neighboring points of attack.

The tendency to implicate the contiguous tissues rapidly is too well recognized to require comment. The process appears to involve the skin sooner than it does the glands and deeper tissues. Of this, however, there can be no certainty in individual cases, as the glands are frequently invaded without appreciable physical manifestation of involvement on palpation. In fact, it is within the experience of many observers that the axillary glands have become involved in mammary cancer without appreciable increase in their size, as estimated even after removal.

According to Winiwarter and others, axillary-gland involvement takes place on the average in fifteen months. Gross expressed the fact that axillary infection happens within six months in one-fourth of the cases. The reader recalls a case of his own in which a mammary cancer, the size of a walnut, of two months' recognized presence, was attended by numerous infected axillary glands, not appreciable on palpation. In those instances in which the axillary glands were infected, the supraclavicular also were involved in 6.25 per cent., the infraclavicular in + 1 per cent., and the cervical in + 0.7 per cent. of the cases.

According to Gross, a greater or less fixity of a diseased mamma to the underlying tissues takes place in from six to eight months after involvement of the overlying fascia and skin, in the majority of instances. In these cases the pectoral muscles are involved in one of every fourteen, the intercostal muscles in one of every seventy-four, and the ribs in one of every thirty-six cases, approximately.

The importance of the foregoing facts, as bearing on the relation between promptness and completeness of surgical action and the final outcome in mammary malignancy, is self-evident. As relating to this question, permit me again to refer to Gross, who analyzed one hundred and thirty-six cases of amputation of the breast for carcinoma, in which recurrence took place; in forty-three of these cases the lymph nodes were not apparently affected at the time of operation; the average duration of life in these cases was 52.7 months from the recognized beginning of the disease. In the remaining ninety-three cases, in which the glands were involved at the time of operation, the average duration of life was only 39.3 months from the first appearance of the disease—an average difference of more than a year.

The results of operative effort in malignant disease of the uterus are advancing apace with that of the breast; and here as elsewhere, the beneficent results dependent on early diagnosis, prompt and effective treatment, supplemented by improved technique, are emphatically evident. It needs not further time or any figures to impress the facts that in the stomach, as in the preceding organs considered, as early a diagnosis as is possible and as prompt surgical effort as is practicable should always be had.

There is much more of convincing significance that can be said bearing on this phase of the question, but, since the fact seems to be proven already, it is as unwise as it is needless to add further words, and, too, with the risk of obscuring the leading proposition.

Let us now pass to the consideration of the fourth and final interrogatory.

Will not prompter and more effective action of all concerned along the lines of anticipation and established treatment increase the present comparatively high rate of cure; and, if so, how can these desiderata be acquired? All that has been said by the reader thus far is of a diminutive amount compared with that which can be uttered conclusive of the facts that the earlier the discovery of the presence of malignant disease, and the prompter the wide removal of its present and prospective points of attack is practised, the less is the danger of the effort and the greater will be the rate of subsequent immunity.

The desiderata can be acquired in the fullest degree only by the co-operation of all concerned; the patient should be impressed with the necessity of informing the physician of the presence of a tumor or other abnormality on the moment of its discovery. Personal indifference, unwise pride, and the fear of uncanny knowledge are the chief impediments to co-operation on the part of this factor in the attainment.

The physician ought promptly to ascertain the nature of the abnormal manifestation, and this, too, without undue reliance and hair-splitting differences regarding the history of development. Free incision in the instance of tumor for determinative purposes, followed at once by complete ablation, if practicable, and supplemented thereafter by periodical examination, should be the rule of action in malignant cases.

Deterring influences closely allied in their effects to ignorance, self-assumption, complaisance, and sickly sentiment on the part of all concerned—each too often robs the patient of the lasting benefits of prompt and intelligent surgical action.

RECENT ADVANCES IN THE NORMAL AND PATHOLOGICAL HISTOLOGY OF THE CENTRAL NERVOUS SYSTEM.[1]

By FREDERICK RANDOLPH BAILEY, M.D.,

ASSISTANT IN NORMAL HISTOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY, NEW YORK.

Should some neurological Rip Van Winkle awake today after his twenty years of oblivion, and should he find his way into one of our larger medical libraries, and have there placed before him any of the more recent works upon his favorite subject, he would stand no less amazed than did the real Rip when, after his long sleep, he found himself once more in his native village. He would look in vain for the faces of the once familiar words, and he would put his hands to his head in bewilderment at the new and unknown terms, in a few of which he might recognize some faint lines of resemblance to past friends. And if he is an astute observer he realizes that the science of neurology has made tremendous strides in those past twenty years, for each new name but indicates some new thought—the genesis of the term but succeeds the genesis of the idea.

The history of the advances which have marked the evolution of our knowledge in all those branches of medical science which necessitate the use of the microscope is the history of advances in operative technique. In histology, in pathology, in bacteriology, each new era of progress has been but the successor to some new method of investigation. *Par excellence* may this be said of the development of our knowledge of the normal and pathological histology of the nervous system. Each new discovery in neurological technique has opened up new paths of investigation, and has invariably led forward to important progress in knowledge. The climax of investigation along the lines of a given method is reached and research is on the wane, when some new "way" is announced and the whole neurological world is again in a bustle of activity to carry to exhaustion the possibilities of this new method of work.

Aside from those discoveries in general operative technique which mark epochs of advance in histology and its allied sciences—such discoveries as fixation

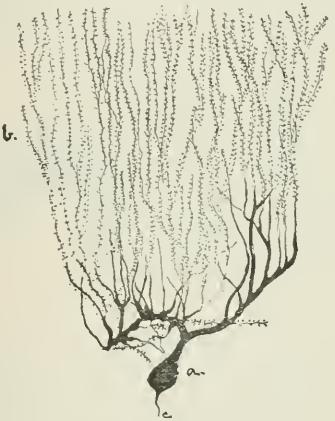

Fig. 1.

and hardening of tissues, staining, section cutting, etc. —three discoveries in method mark three distinct eras in the development of our knowledge of the architecture of the central nervous system.

(1) The method of Weigert. This may be called the "nerve-fibre method." It stains only the medullary sheath, and therefore differentiates the medullated nerve fibre only. Following the discovery of the method of Weigert, came a long line of valuable investigations upon the courses of the various fibre tracts of the brain and cord. As, however, the fibre leaves the cell in a non-medullated condition, this method gave no insight into the relations existing between the nerve fibre and the nerve cell, nor did it give any indication of the minute structure of the nerve cell.

(2) The method of Golgi. As the method of Weigert is the nerve-fibre method, so the method of Golgi is the "nerve-cell method." It stains homogeneously the nerve cell *in toto*—that is, the nerve cell and all its processes up to the point of acquisition of the medullary sheath, beyond which point it does not stain. This method gives us, as it were, a neuron "silhouette." It pictures the entire nervous system as made up of a great number of superimposed units. These units or nervous elements are seen to be anatomically independent of one another; each unit constituting a complete nervous mechanism, capable of

[1] Fellows Prize Essay for 1898 of the Medical Society of New Jersey.

receiving a nervous impulse, of acting upon it, and of transmitting it.

The technique of the method of Golgi is extremely simple. Briefly it consists in:

(1) Hardening in a solution of potassium bichromate.

(2) Transferring to a solution of silver nitrate.

(3) Embedding, section cutting, and mounting as usual.

Treated by this method, the nerve cell presents a striking picture (see Fig. 1).

The cell body (*a*) appears jet black by transmitted light, and shows no evidence of any internal structure. Passing off from the cell body proper are seen innumerable branches crossing and interlacing with one another, but never anastomosing. These (*b*) are known as the protoplasmic processes, are stained like the cell body, black, and are seen to be studded with little excrescences having knobbed ends and known as "gemmules" (Fig. 2). These protoplasmic processes divide and subdivide, becoming rapidly smaller as a result. From some part of the cell body or from one of the larger protoplasmic processes a process of a quite different nature is seen to pass off. This is rather straight, sends off but few branches, these few at right angles and not perceptibly diminishing the diameter of the process. This process is known as the axis-cylinder process (Fig. 1, *c*), and is destined to become the axis cylinder of a nerve fibre. By this

Fig. 2.

Fig. 3.

method are also stained the cells and fibres of the type of connective tissue peculiar to the nervous system, the neuroglia.

As a result of investigations upon the structure of the central nervous system by means of the method of Golgi, certain facts of extreme importance have been ascertained. These are:

(*a*) That the nerve cell and the nerve fibre are not, as we had so long believed, two separate elements in the structure of the nervous system; that no nerve fibre exists that is anything other than an outstretched arm, as it were, of a nerve cell; and, conversely, that there is no nerve cell but is continuous by one of its prolongations with a nerve fibre; that if, applying the same method, we look to embryology for light on the subject, it shows us that the nerve fibre is developed as an outgrowth of the protoplasm of the cell body; that the process of the nerve cell with which the nerve fibre is continuous is always the axis-cylinder process. This process is physiologically centrifugal in character; that is, it carries impulses only *from* the cell.

(*b*) That, in addition to the axis-cylinder process, the nerve cell possesses numerous other processes of a different nature, both as regards structure and function. These are known as protoplasmic processes, and are centripetal in character; that is, they transmit impulses *to* the cell body. They are what might be called the "sense organs" of the cell, and represent its receptive apparatus, bringing it in touch with the terminal arborizations of the processes of other cells (Fig. 3).

(*c*) That the nerve cell with all its processes—this "neuron," as it is called—is a distinct and separate nervous entity, a complete unit in itself, and unconnected by continuity with any other nervous element. It follows directly from this that the passage of a nervous impulse from one nerve cell to another must take place either through contact or, more likely, through mere contiguity of the nervous elements concerned.

(*d*) That the nervous system as an organ is made up upon the same general plan of architecture as are the other organs of the body. The neuron represents the parenchyma cell of the different parts of the nervous system considered as organs, and from both anatomical and functional standpoints. The neuron of the brain, for example, holds exactly the same relation to the brain as an organ, as does the parenchyma cell of the liver to the liver as an organ. In each case it is the anatomical, the functional unit—that by virtue of which brain is brain and liver is liver; and in each case the parenchyma cells are supported by a connective-tissue framework, modified, it is true, in the case of the nervous system, differentiated both morphologically and embryologically from that found in the other organs of the body, and yet a real supporting connective tissue.

(3) The value of such a method of technique, to which we owe such fundamental facts as those enumerated, cannot be overestimated. But valuable as were the methods of Weigert and Golgi, and far-reaching as were their effects upon our knowledge of the structure of the central nervous stysem, they gave us no insight into the minute structure of the ganglion cell. It was not until Nissl announced a method of differential staining of the contents of the cell body that any advance was made in our knowledge of neurological cytology. When we consider in what a rudimentary state our knowledge of the ultimate structure of the nervous system really is, and especially how little we know of the physiological significance of our anatomical data, how little more we actually comprehend when we speak of the origin and the transmission of a nervous "impulse" than did Rene Descartes three centuries ago, when he spoke of "animal spirits"—we appreciate the attractiveness of a method which reveals the ultimate structure of the cell body and offers some hope of solution of the vexed questions which constitute the "metaphysics," as it were, of neurology.

Briefly stated, the technique of the method of Nissl is as follows: (*a*) Tissue, fresh as possible, is placed in a quick fixative, such as absolute alcohol or such mixtures as those of Lang and Van Gehuchten; (*b*) hardened in absolute alcohol; (*c*) embedded and cut in the usual way; (*d*) sections stained in a solution of methylene blue; (*e*) sections decolorized in alcohol containing aniline oil; (*f*) cleared and mounted as usual.

Subjected to this method of technique, we observe that the cells of the central nervous system present two widely different types of reaction: First, certain cells stain only as to their nuclei, the cell body remaining perfectly clear. Such cells are those found in the olfactory lobe, the cerebellum, the retina, forming the so-called granule layers. To these cells Nissl has given the name caryochromes. As only the nucleus stains, it is evident that nothing will be learned by the application of the method of Nissl to these cells, except as to their nuclei. Second, the vast majority of nerve cells, however, react both as to their nuclei and as to their cell bodies to the methylene-blue stain. To these cells Nissl has given the name somatochromes. As the somatochromes alone react as to their cell bodies to the method of Nissl, it is these somatochrome cells which acquire an interest when studied by this method of technique.

If we take as an example of a cell of this type one of the large ganglion cells of the ventral horn of the spinal cord, and pass it through the technique of Nissl, we can diagram its structure as in Fig. 4:

(1) A nucleolus which stains an intense blue.

(2) An intranuclear network or nucleo-reticulum—usually retains a faint blue color, but is easily decolorized, and then restains readily with a basic dye like eosin.

(3) A clear ground substance or nucleoplasm—unstained.

(4) A nuclear membrane which stains like the reticulum.

(5) A cell network or cyto-reticulum, faintly colored and in specimens not specially prepared, obscured by the more deeply stained elements of the cell body. This reticulum is present throughout the cell, and extends as fine striations into the cell processes.

(6) Deep-blue-staining bodies of various shapes and sizes, scattered through the cyto-reticulum and known as chromophilic bodies.

(7) A basement substance which is achromatic.

It is this stainable substance, these so-called chromophilic bodies, which are of special interest when studied by the method of Nissl. They present various forms; are deposited in larger or smaller masses; are regular or irregular in shape; may be triangular or elongated rods; may be arranged in rows or without any apparent order; may be close together or somewhat separated. Sometimes we find a large mass of chromophilic substance, as the "capuchon nucléaire" or nuclear cap; or, again, as the "cone de bifurcation," or triangle of division, as is called the triangular-shaped body which often marks the early bifurcation of the protoplasmic process. One part of the cell is always free from chromatic substance. It is the area adjacent to the axis-cylinder process, and called the "axon hill."

The manner of disposition of the chromophilic bodies furnished to Nissl a basis of classification. Having separated off the cells staining only as to their nuclei as caryochromes, he subdivided his somatochromes as follows:

(1) Arkyochromes, or cells in which the chromatic substance arranges itself in rows or chains.

(2) Stichochromes, or cells in which there is a more or less regular distribution of the chromophilic bodies throughout the cell.

(3) Gryochromes, or cells in which the coloring matter appears as fine granules.

(4) Arkyo-stichochromes, or cells in which a combination of the preceding is present.

At the time this classification was announced by Nissl, it was with the expectation that each morphological type of cell would correspond to a physiological type. Subsequent observations, however, have failed to confirm this theory.

Such being the appearance of certain cells of the nervous system when treated by the method of Nissl, what significance are we warranted in attaching to the picture?

Cajal, Held, and Van Lenhossek, working upon the nature of the chromatin, came to the same conclusion—namely, that all chromophilic bodies, however homogeneous in appearance, were really granular in character. Held and Dogiel, following up the idea suggested, examined fresh specimens in a passive medium and discovered that chromophilic bodies as such do not exist in these fresh specimens, and therefore not in the living cell. The living cell possesses a slightly alkaline reaction. This reaction changes to acid within a very few minutes after death. This change in reaction undoubtedly has a very decided effect upon the albuminoid elements of the cell. That the discovery of the non-existence of chromophilic bodies in the living cell vitiates the discoveries of Nissl, however, is far from the truth. Undoubtedly there exist in the living cell no distinct bodies which when dead and stained give rise to the Nissl picture; but it is nevertheless a fact that there does exist in the living cell some substance, a part of the cell protoplasm, which when treated by certain fixatives and stained by certain dyes, gives rise to the appearance seen in the Nissl preparations. That this is of the nature of a precipitation is probably true. That cells from different parts of the nervous system, of different sizes, shapes, and functions, should react in different manners to the same method, far from being a strange phenomenon, is what chemistry would lead us to expect. What we see in a nerve cell treated by the method of Nissl is an artifact, and yet it is an artifact which is always the same for a given cell and which is a real measure of the condition of the living cell. My own investigations by the use of the method of Nissl upon the cells of the central nervous system in the rabbit and in the guinea-pig have only confirmed an opinion I had previously formed, that in the present state of our knowledge on the subject we can safely say this and no more:

That, given a definite and satisfactory technique, a given nerve cell will always present the same reaction when subjected to that technique; that in comparing one cell with another, and especially in comparing cells presumed to be pathological with cells presumed

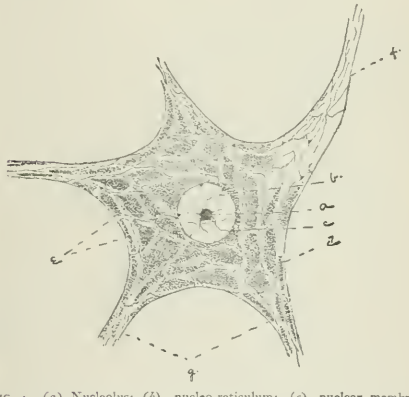

FIG. 4.—(*a*), Nucleolus; (*b*), nucleo-reticulum; (*c*), nuclear membrane; (*d*), cyto-reticulum; (*e*), chromophilic bodies; (*f*), axis-cylinder process; (*g*), protoplasmic processes.

to be normal, the two sets of cells must have passed through exactly the same technique.

Such being the appearance presented by a ganglion cell when subjected to the technique of Nissl, and such being the conditions of its application, what is the probable physiological interpretation of the picture?

(1) That the nucleus of a nerve cell differs in no essential from the nucleus of any other cell, either as to structure or as to function. It seems to preside over the constructive metabolism of the cell, to be the chief controlling agent in the transformation of the food products brought to the cell by the lymph into the food elements of the cell itself, and their further elaboration from food elements of the cell to form the nervous elements; in other words, the conversion of potential into kinetic energy.

(2) That the cyto-reticulum or cell network represents the working mechanism of the cell. It alone is concerned in the reception, transformation, and emission of nervous impulses, and its condition determines the capability of the neuron in its nervous capacity. Thus, let us imagine a nerve cell stained by the method of Golgi, and then the same cell stained by the method of Nissl and superimposed. The resulting picture may be diagrammed as in Fig. 5.

In this diagram it will be seen that the cyto-reticulum extends far out into the protoplasmic processes,

even into the gemmules themselves. It is believed to possess in this connection both conductive and contractile powers. Thus, while serving to place every remote part of the neuron in direct touch with every other part, and allowing the transmission to the centre of the neuron of any message received at any point in its periphery, it also serves as the retractive element for those same parts. Thus, for example, can a cell determine the extent of its contact with other cells; if in a condition of fatigue, it can retract its gemmules, thus throwing itself out of circuit, as it were, and allow itself time for recuperation. Just how far, upon this theory as a basis, we can explain such phenomena as sleep, as hypnotism, as coma; or, on the side of excitation, the phenomena of hysteria, of delirium, etc.—is as yet undetermined. If the passage of an impulse from one cell to another depends upon the contact or close approximation of its peripheral endings, we can very easily see how the separation of these endings can impede or even prohibit the passage of such impulse.

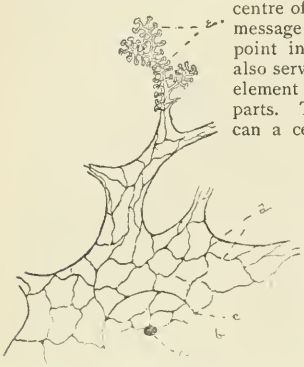

Fig. 5.

(3) That the cyto-lymph is the food element of the cell, bathing the cyto-reticulum on all sides, and acting as a reservoir of potential energy for its replenishing; the cytoplasm itself being constantly reinforced by an elaboration of the food elements brought to it by the blood through the lymph channels. That this cyto-lymph can be subdivided into two constituent elements—a coarser food product, which, when precipitated after death, is stainable as the chromophilic bodies; and a more refined food product, the direct food of the cyto-reticulum—is a theory that has recently been advanced. As lending support to this theory is the absence of the chromatic substance in the probable region of the most delicate functional activity, *i.e.*, that surrounding the exit of the axis cylinder. Such may be the case. In the light of our present knowledge, however, it would appear that such refinement in description is rather in advance of our knowledge of facts.

But if the new methods of technique have caused a revolution in our ideas of the structure of the normal nervous system, they have caused no less sweeping modifications in our views of the changes produced in that system as a result of disease processes. The method of Golgi, on acount of its unreliability and lack of uniformity of reaction, combined with the fact that this method shows only the neuron as a whole, and that lesions the most important are often evidenced only by changes within the cell, has had a very limited usefulness in neuro-pathology. The method of Nissl, on the other hand, giving as it does deep insight into the structure and condition of the cell protoplasm, is eminently fitted for the study of changes, even the most delicate, which are brought about as the result of disease.

At the time of the introduction of the method of Nissl, the nervous system had a distinct and fairly well-investigated normal and pathological histology of its own. It appeared to be, as it were, a region apart by itself, different from the rest of the body in structure and in reactions to disease processes. The differences in terms used sufficiently evidence this fact. The early results of research by means of the Nissl technique only added new terms and increased the confusion. Further research, however, by the use of the same method, has brought about a simplification not only of the results of previous work with the new technique, but also of the results of all the earlier work by means of older methods. A complete revision, marked by increased simplicity and unity, has taken place in the classic ideas as to the normal and pathological histology of the nervous system. That this is true as regards the normal histology of the nervous system has been shown in the description already given in this paper of the analogy of architecture of the brain and spinal cord to that of the other organs of the body.

Turning now to pathology, let us see in how far we can make the terms with which we are accustomed to describe lesions in other parts of the body serve the same purpose in describing lesions of the nervous system.

I. Parenchymatous Degeneration, or Acute Degeneration of the Nerve Cell.—If we examine the nerve cells of the cerebral cortex in a case of acute alcoholism—say in a case of death from delirium tremens—we notice certain changes in the appearance of the ganglion cells.

Fig. 6 represents cells from (*a*) a normal cortex; (*b*) a cortex from a case of acute alcoholism. It is immediately observed that some change has taken place in the cell, which has affected the nature of the precipitation of the cyto-lymph. It no longer comes down as well-defined granular masses, leaving the remainder of the cell perfectly clear, nor are the masses of staining substance as numerous as in the normal cell. The chromophilic bodies are seen to be broken up, to be smaller and less clearly defined, and to be fewer in number. The background against which these lie is not clear, as in the normal cell, but retains sufficient chromatin to enable it to take more or less of the blue stain.

Fig. 7 represents some Purkinje cells: (*c*) from a normal cerebellum; (*d*) from a cerebellum from a case of insolation.

Fig. 8 represents (*e*) a cell from the ventral horn of a normal cord, and (*f*) a cell from the same region of the cord in a case of rabies.

It will be observed that, in the three cases presented in Figs. 6, 7, 8, allowing for the inherent differences in cells from different localities, essentially the same condition is present in all the pathological cells. Not all the cells are in the same stage of degeneration. A careful study of the specimens from which the drawings are taken shows cells in all stages of chromatolysis, as the destructive change in the chromatic element of the cyto-lymph is called. Here and there are found cells to all appearances perfectly normal. From this all

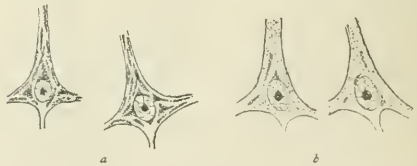

Fig. 6

grades of modification of the cytoplasm are observed up to complete destruction of the cell.

These degenerative changes in the nerve cell have been found, not only in the diseases mentioned in connection with Figs. 6, 7, 8, but in a large number of other diseases. These diseases fall into three general classes:

(1) Auto-intoxications; such, for example, as (*a*)

the various uræmic conditions, including eclampsia; (*b*) diabetes; (*c*) sunstroke.

(2) External poisons; such, for example, as (*a*) acute alcoholism.

(3) Infectious diseases; such, for example, as (*a*) typhoid; (*b*) pneumonia—in fact, the entire list of infectious diseases.

This lesion we have already characterized as parenchymatous degeneration. It is seen to occur in those

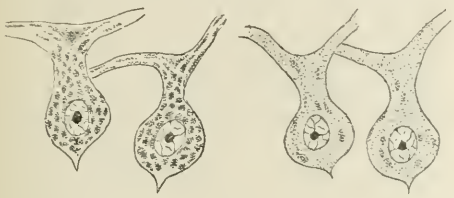

Fig. 7.

diseases in which we expect to find degenerative changes in the other organs of the body. It is, in all probability, in no way different from those degenerations. The essential nature is the same in all, its appearance modified only by the kind of cell in which it occurs.

Remembering now our physiological explanation of the normal appearance of the ganglion cell when treated by the method of Nissl, what insight can we get into the nature of this degeneration?

The nerve cell, like the other cells of the body, receives its nourishment from the blood through the lymph. Each nerve cell is surrounded by a lymph space. From this lymph the food elements which the cell requires are taken directly into the body of the cell. A further elaboration to fit them for use as food for the nervous mechanism of the cell results, as has already been said, in the so-called cyto-lymph, from the constituent elements of which the chromophilic bodies are precipitated. Any change, therefore, in the quantity or quality of the lymph would be evidenced by changes in the quantity or quality of the cyto-lymph, and such changes in the cyto-lymph would naturally be expected to show themselves in the resulting precipitate—namely, in the chromophilic bodies. The diseases in which we find these already described modifications in the precipitation of the cyto-lymph are such as would be expected to produce changes in the character of the blood and lymph. They are diseases in which we find degenerative changes in nearly all the other organs of the body. This, then, is the at

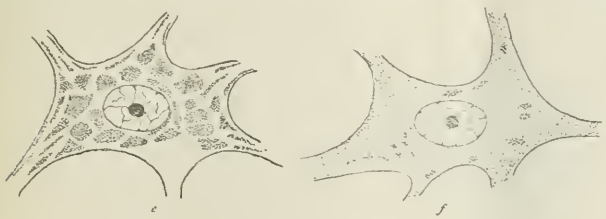

Fig. 8.

present accepted explanation of the changes in acute degeneration of the nerve cell, or, speaking of the different parts of the central nervous system as organs, in acute parenchymatous degeneration of those organs; a change in the character of the food elements of the cell, brought about by a change in the character of the cyto-lymph, caused by the action of the disease. That these changes in the food elements of the cell soon produce changes in the cyto-reticulum or true nervous elements of the cell is undoubtedly a fact. The nerve cell is the most highly differentiated cell in the body, and the higher in organization the cell the more immediately dependent is that cell upon its source of nourishment. Thus, the nerve cell depends, not hour by hour, but almost minute by minute, upon the surrounding lymph for its food supply. The cell has work to do; there is a dissipation of energy. There is, then, a very delicate equilibrium existing between food supply, on the one hand, and expenditure of energy, on the other; and any factor which tends to disturb this equilibrium immediately affects the functionating powers of the cell. The method of Nissl enables us to examine the condition of the cyto-lymph, but there is as yet no satisfactory method for minute examination of changes in the cyto-reticulum. There is undoubtedly some point in this degenerative process which, when reached, completely inhibits the activity of the cell. There is likewise a point beyond which, if a cell degenerates, the ability of the cell to return to normal is lost. The present state of our knowledge does not enable us to say just what appearance of the cell indicates that such point has been reached, almost complete chromatolysis seemingly being sometimes compatible with a very considerable degree of functional activity. Until some new method of examining the cyto-reticulum is discovered, these and similar questions appear destined to remain unsolved.

There is a form of parenchymatous degeneration which has been described as peculiar to lesions especially affecting the axis cylinder. This is well shown in Fig. 9, which represents a cell from the anterior horn of the spinal cord in a case of peripheral neuritis.

Fig. 9.

Its peculiar characteristics are as follows:

(*a*) A diffuse blue stain throughout the cell, with an absence of chromophilic bodies in its central area—central chromatolysis, as it is called.

(*b*) A peripheral arrangement of the remaining chromophilic bodies.

(*c*) Eccentricity of the nucleus; the nucleus, which in a normal cell lies, almost without exception, in the centre of the cell, having migrated so as to assume a position near or at the periphery. That migration of the nucleus is a phenomenon associated with starvation of the cell has been shown for the lower forms of animal and vegetable cells. Just what change in food supply determines this eccentricity of the nucleus has not yet been ascertained. That it is a special modification, and does not occur in all changes in cell nutrition, is proved by its occurrence in this form of degeneration of the nerve cell, while not occurring in the more common type previously described.

Viewed in this light, peripheral neuritis is primarily a disease affecting the food supply of the ganglion cell of the anterior horn of the spinal cord: and, this being the case, the parts of the neuron first affected are those parts most remote from the source of supply, *i.e.*, the peripheral nerves. Experimental section of the peripheral ends of neurons produces similar changes in the ganglion cell. This would mean that this type of degeneration follows loss of function of the axis cylinder—"axon degeneration," as it is called. The converse—that every cell presenting this type of degeneration is a cell the axis cylinder of which has ceased to functionate—is as yet not established.

II. Acute Exudative Inflammation.—If we examine the pons, the medulla oblongata, or the spinal cord, from a case of hydrophobia or from a case of rabies produced experimentally in one of the lower animals, we find certain lesions present. These lesions differ

Fig. 10.

in extent in different cases, and also in the type of lesion which predominates in a particular case. This depends, among other factors, upon the severity of the infection and upon the length of time the parts have been exposed to the poison before death ensues.

Fig. 10 represents the anterior horn of the spinal cord of a rabbit dead from experimental rabies.

The walls of the blood-vessels and the perivascular lymph spaces are seen to be crowded with escaped leucocytes. Accumulations of leucocytes are also seen, apparently at a distance from any blood-vessels, in among the ganglion cells, forming areas of exudation. Besides this emigration of white blood cells, there are also often present small collections of red blood cells in the tissues, constituting small hemorrhages. Apparently independent of the exudation and yet due to the same general cause, *i.e.*, the poison of rabies, is a more or less complete degeneration of the ganglion cells, an acute parenchymatous degeneration. This exudative inflammation follows the same laws as exudative inflammations in other parts of the body, modified only by the character of the tissues involved.

III. Acute Productive Inflammation.—In the case of rabies already referred to, there may be, besides the accumulation of leucocytes in the tissues, and especially in the walls of the blood-vessels and in the lymph spaces surrounding them, some new connective-tissue cells present in the vessel walls, resulting from the proliferation of the connective-tissue cells normally

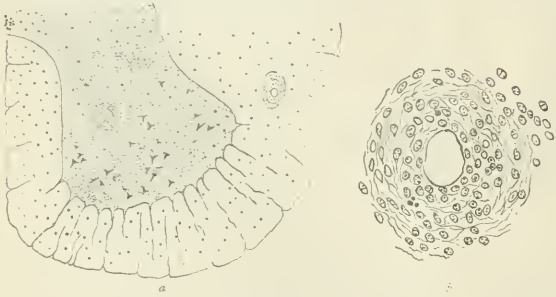

Fig. 11.—(*a*), General view; (*b*), blood-vessel enlarged.

found there. This lesion is, however, usually not well marked.

Fig. 11 represents a transverse section of the spinal cord in a case of Landry's paralysis. Only the anterior horn is drawn. In this case, besides the degeneration of the ganglion cells and the presence of some leucocytes in the vessel walls, there is a considerable production of new connective-tissue elements, this part of the lesion sufficiently predominating to warrant giving the picture the name of acute productive inflammation. Depending upon the stage of progress of the disease at the particular point from which the section is taken at the time of death, the associated exudative features may be more or less prominent, giving to the lesion the character of a simple productive inflammation or of a productive inflammation with exudation.

This lesion, again, differs in no way from the lesion of acute productive inflammation as found in the other tissues and organs of the body.

IV. Chronic Productive Inflammation.—Either following the long continuation of an acute productive inflammation or as a disease *sui generis*, there is found a chronic production of new connective tissue, as a result of proliferation of the connective-tissue elements of the nervous system. This type of inflammation in the nervous system is usually associated with the same general conditions and diseases as are similar lesions in other parts of the body; thus, chronic alcoholism, gout, rheumatism, syphilis, often act as predisposing causes.

Fig. 12 represents a section of the spinal cord in a case of multiple sclerosis. The stain is by the Weigert method, which, it will be remembered, stains only the medullary sheaths of nerve fibres. The areas of new connective tissue are, therefore, seen as light

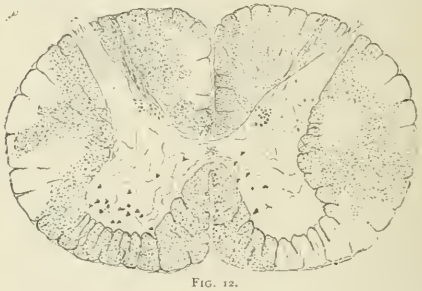

Fig. 12.

spots of about the same color as normal gray matter under the same stain. A point of considerable interest fails to show in this picture, owing to the stain. A specimen from the same case, stained by the picro-acid-fuchsin method of Van Gieson, shows it very distinctly. It is that in this form of inflammation the new tissue consists of not only the connective tissue formed as a result of the proliferation of cells in the walls of the blood-vessels and in the connective-tissue septa sent into the cord from the pia mater, but also of a proliferation of the neuroglia cells and fibres, *i.e.*, the connective tissue peculiar to the nervous system. This makes still more perfect the analogy to the chronic productive inflammations found in the other organs. The two kinds of connective tissue retain their identities, unless the process has gone on to such a stage that nothing but dense scar tissue is demonstrable.

It thus becomes evident that the same nomenclature with which we have been accustomed to describe pathological changes in other organs of the body is equally applicable to the description of lesions of the central nervous system. From the standpoint of the pathologist the exudative inflammations of the nervous system differ in no essential from the exudative inflammations occurring in other organs. The productive inflamma-

tions differ only in so much as they involve the type of connective tissue peculiar to the nervous system. The parenchymatous degenerations, while undoubtedly identical as regards their significance with the parenchymatous degenerations in other organs, are necessarily modified by the peculiar structure of the parenchyma cell itself.

To review, then, the conclusions to which the application of the more recent methods of technique to the nervous system has brought us:

In normal histology—

(1) The method of Golgi has given us a clear and definite conception of the general architecture of the central nervous system, and has demonstrated its analogy to that of the other organs of the body.

(2) The method of Nissl has allowed us to make great progress in our knowledge of the ultimate structure of the nerve cell.

In pathological histology—

(1) The method of Golgi has proved of comparatively little value.

(2) The method of Nissl has aided us in penetrating the mysteries of the pathological cytology of the central nervous system, and, in the light of the already described analogy in structure of the nervous system to that of the other organs, to bring the hitherto isolated pathology of the nervous system into harmony with the pathology of other organs of the human economy.

MONTAUK POINT AND THE GOVERNMENT HOSPITALS.[1]

By WICKES WASHBURN, M.D.,

NEW YORK.

GENTLEMEN: Montauk Point, Long Island, in the summer that is just passed (1898) became the subject of great interest to the general public, because so many of our soldiers were landed there on their return from Cuba and Tampa. Previous to this time Montauk Point had interested very few people besides the geologists. From a geological point of view Montauk Point, and indeed the whole of Long Island, is known to be in the line of a moraine which for many years marked the southern boundary of an immense glacier. This glacial boundary not only traversed the whole of Long Island, but Staten Island and that portion of northern New Jersey in the vicinity of Trenton, as is shown by the present geological formation, which is composed of its terminal moraine.

Now, if you will but remember that at the time these glacial deposits were made this whole portion of the continent was on a much higher level than it is at present, and that it has been submerged to such a degree that the Hudson River Valley has been shortened to the extent of from eighty to one hundred miles—that is, the present site of the city of New York was something more than eighty miles inland—then you will see that the submerging of this portion of the continent left the piled up glacial débris in the line of what is now Long Island unsubmerged, and Long Island Sound was formed by a portion of the lowland which lay back of it being submerged, but to a depth not sufficient to cover the old moraine, which thus became, and still remains, Long Island.

Remembering all these facts, one can easily believe that the water supply of Montauk Point comes across under the Sound (which is about twenty miles wide and one hundred feet deep on an average). Thus we have accounted for the numerous lakes on this narrow strip of land poking out into the ocean, and shown why the water supply should be the best possible. In one instance at least the dividing line between the Sound and the fresh water lake is something like two hundred feet only.

Montauk Point itself is ten miles long, varying from one-half to three miles in width. The soil is in its primeval condition over a very large portion of its extent. The ground is very uneven.

In no direction can one walk for any considerable distance without going up hill or down. Some of these elevations are as much as eighty-five feet in height, while the others are only forty feet. Indeed, the whole surface is very characteristic of glacial deposits and the intermediate kettle holes. After each rain of any amount the water will be found standing in these various kettle holes. A little attention to the condition of the soil will show why the water is so slow in disappearing, and also why it may not reappear for a long distance. The soil for some forty-five feet down is in alternate layers of sand and impervious clay; thus the water in the kettle holes is taken up only as fast as it can be absorbed by a few inches of the top layer of gravel, and cannot disappear below the level of this first layer of impervious clay until by some action of nature or of man an opening has been made through this layer of clay, which will allow water to percolate into the sand below; through this it will reach another layer of clay and may be carried to any distance. These alternate layers are for the most part only three or four inches of clay and from four to ten inches of sand.

It may be as well to recall that Montauk Point is the southerly of the two horns which form the extreme end of Long Island, and that it was reached previous to last spring only after some distance of staging, as the railroad, even with its one leg, didn't get out that far. The surgeon-general having selected this for the reception of returning soldiers, and as a point for their distribution, preparation began in the early part of August for the reception of the soldiers, both sick and well. On this whole territory, from Napeaque Bay to the lighthouse, there was not the semblance of a road, a tree, or a house, with the following exceptions: three old farmhouses that for several years have been known as hotels and designated respectively as "First," "Second," and "Third" house, each being from two and one-half to three miles distant from any other—the first two very near the south or ocean shore of Montauk, the third near the extreme easterly point of this southern horn of Long Island; the two life-saving stations, which are five miles apart and on the southerly or ocean shore. Besides these the Montauk Club on its reservation had built a clubhouse and a few cottages, not available for the general purposes of the army. Soldiers began to arrive by the transports and by train about the 12th of August. I myself arrived on the 16th of August. The depot was located near Fort Pond Bay, at which the troops landed. This depot is a crude affair, and all about was a surging crowd, ankle deep in sand. By great good luck I was able to report for duty at once to General Young, he being there at the station, as I afterward learned for that very purpose, *i.e.*, receiving and assigning new officials. I was given a pass through the lines to the general hospital. (I had learned previous to this time that my bicycle was to be of little use to me; fifty men were put to bed as the result of its use.) I started with it over the hills, passing near what afterward became General Shafter's headquarters, and finally reached the general hospital, the dimensions of which were but faintly outlined, and again was fortunate in finding the medical purveyor, Col. W. H. Forwood; he was not in charge of the general hospital as has been so many times stated, but was simply medical purveyor, as I have designated him, and who went from camp to camp, from hospital to hospital,

[1] Read before the New York County Medical Association, November 21, 1898.

once or oftener each day to see that their needs were supplied. Colonel Forwood's duties did not extend to the management or attention to any of the details regarding what was done at any of the camps or hospitals at Montauk. I dwell upon this because his position has been very much misunderstood and because he has been blamed for those things with which he had absolutely nothing to do. Personally, I believe that both Surgeon-General Sternberg, who selected the site of Montauk Point, and Colonel Forwood, who executed the former's plans, have built for themselves an enduring monument, which shall be an increasing credit to them as time goes on. I wish as much could be said for the general system which, of necessity, worked out those plans and administered the hospitals so excellently located and so admirably planned. The general hospital was located on one of the highest and one of the largest of those elevations which I have described. Each ward was composed of six tents, fourteen by fifteen feet, and two flies stretched over a framework in such a way that a flooring, one hundred and thirteen feet long by fifteen feet in width, was covered, the flies being placed after each second tent, thus securing proper ventilation. These flies were equal in size to the roof of a tent, and made, besides spaces for ventilation, a place for a ward kitchen under one and for a lavatory, arranged, in my wards at least, with commodes and bathtubs, protected by large drygoods boxes and screens. The spaces between the tents which constituted the wards was just a little more than equal to the tents themselves. There were nine of these wards situated on each side of a plank walk, which was fifteen feet wide and covered by the usual flies and separated from the entrance to the ward by about five feet more on each side. Beyond the end of this covered walk in one direction was the kitchen, standing immediately across the line of the walk itself. Extending eastward beyond the covered walk was a street of the same width as the space between the tents, situated on each side of which street were three tents similar to those used for wards: first, the dispensary and storeroom for drugs; second, the surgeon-in-chief's office and bureau of information; third, the storeroom for arms and ammunition and a place for guards. We also ate here from the table which the guards slept upon.

On the opposite side of this street was the surgical ward, over which Professor Senn so ably presided. This was the first tent from the end of the board walk on the north side of the hospital street; the second was a storehouse for government supplies; the third, the Red Cross headquarters, office, and storeroom. This formed the corner building, so to say, of the hospital street, and crossing this street at right angles, running nearly north and south, was what might be called the officers' street, for on it faced the tents of the officers, four rows deep, back of which, and in a direct line eastward from the covered walk on a still higher elevation, stood the tent and office for the surgeon in charge medically of the whole camp, who did not arrive until about September 10th. Very little of this had been arranged when I arrived on August 16th. Only a few of the eighteen wards were covered with canvas; still fewer were supplied with beds and bedding. The detention hospital was perhaps a little farther advanced as to construction at that particular time. Its location near the wharf at which the transports landed is only another evidence of the proper disposition of camps and hospitals by the medical purveyor. A few camps were situated here and there. The picture presented to the eye was indeed beautiful. A more salubrious climate could not be imagined. Gradually the general hospital grew, and all about us the white tents of the camps increased, until we had a city of twenty-five thousand people where only a short time before had been absolute desert waste. My first work after being assigned to the general hospital by Colonel Forwood was to get acquainted with the doctors, of whom there were only three, besides the surgeon in charge. I noted at once what it seemed strange should not have been thought of before: that there seemed to be no order at the hospital or in the camps, and no executive head anywhere. We should not wonder greatly that any set of men brought new to a business should fail in a large percentage of cases to achieve brilliant results, especially if those men have arrived at the age of forty-five or over. Now all of us must know when we come to think of the matter that none of the regular army surgeons could have had any experience in conducting a hospital. The executive work of a hospital is just as much a separate business from prescribing for the sick as is the management of a department store. What wonder, then, that since the ranking officers who, by virtue of their rank, must assume command at any army hospitals, whether they have shown any fitness or not, who certainly have had no experience, should make such dismal failures in the executive work of the hospitals as we read of wherever there have been army hospitals, and as I witnessed at the general hospital at Montauk. The hospital grew in numbers and importance. Surgeons came and went who never knew that there was such a man as surgeon-in-chief of the general hospital. Supplies came more or less intermittently, but certainly with no more delay than seems reasonably excusable, the distribution of these being left absolutely to chance. Many patients suffered for the lack of sheets in their ward, while sheets in plenty were piled away in a near-by ward. Patients were crowded into one ward and sleeping on the floor while there were vacant beds in the next. Physicians were transferred from one ward to another and from one duty to another, with absolute disregard of the idea of experience counting for anything. For a few days after my arrival there were no nurses except the hospital corps men, who in the first place were in large part wholly devoid of experience as nurses, and besides that were totally unfit in other respects to care for the sick. Besides these fatal disqualifications, it was impossible to keep one man in a ward long enough for him to learn the duties of that ward; indeed they were transferred, many of them, from day to day. All this made confusion worse confounded. It was no wonder that typhoid patients beginning to recover should wander about and go to the kitchen, dipping their typhoid hands into the general receptacles for milk. It was small wonder under these conditions that dysentery and diarrhœa patients should break open crates of peaches, tomatoes, and other vegetables, soiling those they did not eat, and eating greatly to their own detriment sometimes of decayed and unripe fruit. There being no provision for the typhoid-soiled sheets, shirts, and blankets, the spaces between the wards became littered with them and piled higher and higher, until a two weeks' accumulation was sufficient to load twenty-five wagons, drawn by four mules each. These loads were piled up like loads of hay. It is small wonder, too, that these hospital corps men, unused to disposing of typhoid dejecta, often, especially at night, threw the contents of the commodes between the tents. There was no possibility of disciplining these men, for generally each day there was a new set of men to perform those very necessary duties. The lavatories were poorly cared for and the odor from them was most offensive. Many of these things were corrected upon the arrival of the trained female nurses and the very efficient superintendent of nurses who came with them. The regular routine—that is, the constant change among the helpers in the ward—went on more or less as long as I remained at the general hospital, and I am informed

continued as long as the general hospital itself remained. I went to the surgeon in charge, as I believed it my duty to do, and reported to him these specific things that I have mentioned, and was assured by him that he would attend to them. Practically nothing, however, was done, and I went to the general in charge and spoke to him of these matters, some of which were afterward corrected. The extent to which this lack of system and lack of administrative experience went in some directions was serious and in other cases laughable. The wards were intended to hold thirty patients each originally, but were afterward crowded to hold fifty, by placing between the beds mattresses upon the floor. One night that I have specially in mind, my two wards, one of them admittedly having the sickest patients in the hospital, contained one hundred and three patients, while the two adjoining wards, I learned the following morning, contained but seventeen each. One of the laughable incidents caused by this lack of management was the placing of a very sick man in the tent and bed of the surgeon in charge, and one of the sad incidents was that of a man who died and whose body remained for several hours within a ward before it was removed. And still another which affected immediately the comfort of the patients was the allowing of two men to remain on the board walk for several hours, without any attention. More than once it happened that a physician was transferred from his ward and no one assigned to his place for several hours; patients admitted meanwhile to that ward received no medical attention; and this, too, when there was plenty of physicians assigned to the hospital. There was no system for leave of absence and substitution during such absence of one physician for another. The reader of this paper, however, always arranged for a substitute during his short absences, which were to go occasionally to the hotel for meals, and obtained permission from his immediately superior officer.

As the supply of the trained female nurses increased, things took on a more cheerful and better form. The physician or a substitute was hunted, as need required. About this time an addition to the general hospital, known as the annex, was constructed. The dimensions and general plans of the latter were not unlike those of the main hospital itself. In the one the trained female nurses heretofore referred to did their very efficient work, while in the annext he sisters of charity, many of them excellent trained nurses and all of them admirable women, also did good and faithful work; but for these women and their tireless energy, with long hours and laborious duties, the general hospital at Camp Wikoff would have been in a sad condition indeed. Few can realize the desperate condition of the men as they were received from the transports, and the arduous duties that devolved upon physicans and nurses in the early days of the hospital.

I recall one incident, which I believe occurred on the 18th or 20th of August, when only a few of the nurses had arrived and our staff of doctors was very small, probably not more than five or six. In the afternoon of that day there arrived at the general hospital a group of ambulances containing about seventy-five men, only a few of whom probably had a pulse at the wrist; many were unconscious. They had endured on the transport, for three days without food, to the limit of their physical strength, and with the long hard ride up from the dock, seated facing each other as in a stage, had simply, as they became exhausted one by one, fallen over and were tangled in among each other in a most woeful condition. By great good fortune we were apprised of their approach by an army surgeon, who happened to be coming in that direction and urged the ambulances forward himself, coming on at a gallop to let us know the desperate condition of the men. We abandoned all else, the doctors and nurses administering small doses of whiskey to each man before he was taken out of the ambulance, unloading them as rapidly as possible, and placing them in the shade of the tents upon mattresses on the floor. Before this was quite complete I went to the kitchen and brought ten or twelve quarts of hot milk, and the nurses under my supervision and that of another doctor fed these men, many of them too weak to raise their heads, a few ounces of milk every fifteen or twenty minutes for two hours or more. I am glad to be able to state that only one of these seventy-five men died.

It is not my intention, within the scope of this paper, to say very much of medical treatment and results; at a later time I may perhaps do so, but this proportion of deaths, small as it was, was quite as large as the general average. Although this was a period of much excitement with the country at large and with all those connected with the hurry and work at Montauk Point, there seems hardly excuse for such extravagant statements as have been published regarding the deaths at the general hospital. I believe, however, by this time the public has come to know that there was only in reality about one per cent. of the sick soldiers who died. My own experience of three weeks at the general hospital, I having had under my charge five hundred and seventy-three patients with only five deaths, if we leave out two that came *in extremis* and died within two hours, seems to have been about the general average. One of the incidents of Secretary Alger's visit will illustrate how differently army officials think of army hospitals and patients therein than is thought of the needs of patients in private practice, for Secretary Alger said to me when in one of my wards: "Now, doctor, what do you need? Everything looks very nice and clean and comfortable." To this I replied, "Why, general, I want many things; but most of all, more nurses." And he replied: "Why you have nurses here." And I said: "Yes, I have two for a ward of fifty patients in the daytime and one for two such wards at night, whereas in private practice I am accustomed to have two for each delirious patient; and here about you see fourteen delirious patients—here, and here, and here." To the credit of the secretary of war be it said that he then and there gave orders for as many nurses as the ward physicians might require, asking at the same time how many I desired; and I told him six for the day and two for the night for each such ward as we were then in. While we never quite reached this figure on the official roll, I did for this ward, through the kindness and liberality of some friends in New York, who became responsible for the pay of a special nurse to be assigned by me to any case that might require constant attention. The first patient to whom this nurse was assigned was the clerk of the regiment of Rough Riders, who elected to pay her themselves for the short time the poor fellow lived. The second was a patient like the seventy-five to which I have referred, who because of his starved condition required feeding every few moments for two days, after which he had sufficiently recovered to be attended by the regular nurses in the ward. The third case was similar to the last mentioned, but these cases were now comparatively rare since the experience of the 20th of August. Agents of the Red Cross and other societies had met the soldiers as they disembarked from the transports and had given them milk and stimulants as each man landed; consequently such cases of collapse had not been duplicated. The third patient who was under the care of this special nurse was, however, a long time in making anything like a complete recovery. There were now plenty of nurses. She accompanied him to his home and there remained for two weeks, his friends paying her the regular salary of a trained

nurse and making her a handsome present besides. I mentioned the incident of this special nurse to show how much good may be done with a little money properly applied, and how appreciative the friends of soldiers were. My sixth nurse in that particular ward was acquired by obtaining permission to have the wife of one of my typhoid patients, whom I had sent for, remain with him and nurse him. This she did faithfully and well, besides helping us with other patients in the ward. Another way in which I helped myself and some of the other ward physicians was through my position as dispensary physician. This work made it necessary for me to be up and at work at six o'clock every morning. From these dispensary patients who came from the regiments I was often able to select men who needed to be in the hospital for the treatment of local troubles that could not be treated in the regiment, but who were not too sick to take the places of helpers in the wards, thus enabling me to have more permanent men for helpers in the wards in place of the worse than useless hospital-corps men. My duties were growing thick and fast. In the third week of my residence at the general hospital, the executive officer having been appointed to look after the general sanitary conditions of Camp Wikoff, he assigned to me the duty of looking after the sanitary conditions of the general hospital. It was just at this time that the twenty-five loads of fæcal-soiled clothing and bedding were removed from between the wards. It fell to me to secure proper receptacles in which to place these articles as they came from the wards thereafter, and I was fortunate enough to be able to obtain with reasonable promptness a sufficient number of large galvanized-iron ash cans; but as these were without covers I secured through a carpenter sufficient board covering for them, and through efficient management of the engineers' corps after a very short time they were removed with reasonable regularity and returned promptly to the ward whose letter they bore. I also provided large drygoods boxes for the laundry linen, and barrels or ash cans for the garbage, where required. Besides all this work, I was from time to time assigned to the duty of receiving the patients for two or three hours a day. This latter duty I was never able to perform to my satisfaction, since the service was not continuous and the much-needed census of the wards was often incomplete, unreliable, or not at hand. I was able to do these outside duties and only because of the very efficient nurses in my wards, because of the system which I was enabled with their assistance there to establish. I had early classified my patients, putting the sickest ones in one ward, and the typhoid-fever patients in one end of that ward, and having one of my wards as a receiving ward and the other as a convalescent ward. Those recommended for furloughs were always instructed to be at one end of the convalescent ward at a given hour, and there the recommendations for furlough and the needed orders for clothing were ready for signature. I cannot pass from this subject without referring more specifically to the faithfulness and untiring energy of the nurses in my wards. I have never seen such devotion to duty and such intelligent interest in the work at hand. The nurses in my sickest ward, although not expected to go on duty until seven in the morning, often went on at six, and, their hours being over at seven, they frequently remained until half past ten. The accommodations for feeding and the food itself for these faithful servants of the government was often very inadequate. For myself, I often went until eight o'clock at night with nothing to eat except a cup of coffee and some boiled milk; for, from what I have said about the vegetables and the typhoid-fever patients going to the milk cans, you can readily guess I did not feel safe to eat from either of those, and as the meat was for a long time brought up loose in ambulances in which the sick patients had ridden, I did not care to eat that; and this brings me to the question of other departments than the medical. It seems to have been true in the quartermaster and commissary departments that men of rank rather than experience were intrusted with the transportation and care of all things needed at the hospitals and camps. Our own hospital quartermaster was a very obliging and energetic man, and I am sure that nothing within the scope of his power and experience was left undone, and it was not his fault that he had not had previous experience. Patients discharged from the hospital in a weak condition, but able to travel under favorable circumstances, were often kept a whole day in the hot sun about the station, waiting for transportation and commutation of rations, whereas it would seem an easy thing to have had the quartermasters' and commissaries' representatives call at the hospital each day and arrange these matters for the furloughed men, so that they could have gone to the depot and taken the train like any other passenger. Here, again, the Red Cross and the National Relief Association came to the aid of the soldiers by supplying them food and shelter near the station until these matters could be arranged, which sometimes took twenty-four hours. I myself through a friend in this city arranged with the Grand Army to have representatives of that body at the Long Island station in Long Island City, to meet the soldiers going on furlough and see such as required their aid aboard the trains, which were to take them in some instances to their far-away homes. Later a hospital car was put upon the Long Island Railroad, in which to care for any sick soldiers who might be aboard the train.

In the early part of September my official duties were performed at another hospital, the cavalry division hospital. At this time the various division hospitals were being established to look after the sick soldiers of those divisions, to relieve the general hospital of its overcrowded condition and as many of the soldiers as possible of the unsanitary condition which then obtained at the general hospital. Of these there were three, and the one to which I was transferred was under the supervision of a regular army surgeon, ranking as major. He was man enough to know that his being in charge of the hospital was because of his rank and not because of his previous experience in managing hospitals; and having been informed that I had had large experience in hospital management, while he could not give the charge to me, he gave me the direction of such matters as he could under army regulations, and advised with me freely about the manner of transacting the business of the hospital. At his request I selected the nurses, who through the kindness of the superintendent of nurses at the general hospital were sent to us. I selected the superintendent of nurses at this hospital from among that number. Regular requisitions were made from the wards through this superintendent of nurses to me at the storeroom, where I was in charge. Nurses were notified that when a given number of sheets were sent to the laundry from a certain ward an equal number of sheets would be returned, and a like custom would obtain with all the articles in use in the wards. There was, therefore, no suffering because of extra articles piled away, as in the general hospital. The lavatories were also under my immediate care. I had obtained through the major a concession from the brigade general to have a suitable detail of permanent men to look after each set of duties assigned to them. Two men were ordered to look after the lavatories, and were instructed to put a given quantity of chloride of calcium and of quicklime into the pits three times a day—at half past eight, half past twelve, and five o'clock. Each time after

these substances had been placed in the pits the entire surface of the pits was covered with two inches of soil, and when a pit was filled to within eighteen inches of the top it was covered over and the building removed to a fresh pit. This same plan was used with the kitchen sinks, into which all vegetable matter and slops were thrown and covered daily, new ones being prepared as required. In this way we avoided all camp odors. Matters went on systematically in these respects. One officer was detailed to receive the patients and to supervise the records of those admitted and discharged, thus avoiding all confusion in that direction. What was done at the cavalry division hospital could as easily have obtained at the general hospital, for the conditions were not materially different, and a part of the time the cavalry hospital was nearly as large in numbers as the general hospital. One of the physicians who had been on duty at both places told me that, with the system that obtained at the cavalry division hospital, a physician could with greater ease and more satisfaction take care of double the number of patients. It is not to be expected that the average man will so freely admit or so readily see that his inexperience needs the aid of another, and, lest I be considered as claiming for myself too much, let me say that I believe there were others besides myself who could have done at the general hospital what I did at the cavalry division hospital. It cannot be expected either that a man in the line of advancement will make requests of his superior officers that may be considered a criticism of what they are doing, and a little incident which took place at the general hospital well illustrates this fact. The road, or what was considered the road, passed to the windward of the general hospital. The road was often from two to four inches deep with dust. Six or eight times each day a group of one thousand horses would pass and repass, covering the unfortunate patients and others at the general hospital with a cloud of dust. None of the regular army officials seemed to notice this fact. Certainly the matter was not corrected till I myself called it to the attention of the general in charge of Camp Wikoff, who immediately had it rectified. While I do not believe he considered it a criticism of what had been done, still the regular army surgeon could not be expected to request him to make that change, thereby giving the patients that much additional comfort. One word more and I shall close. It is this very independence of rank and of favors yet to come that makes the contract surgeon the more likely to be an efficient hospital official. It is the lack of experience and the impossibility of anybody but the ranking official assuming general charge which make it certain that, unless by special act of congress the surgeon-general shall be empowered to employ physicians with experience in managing hospitals, we are sure to have a repetition of all our unsanitary camps and poorly managed hospitals and generally unsatisfactory conditions. I know it will be charged that the contract physicians have done many and various unwise and improper things. My own experience with them has been that they are a faithful set of workers, temperate in their habits, proper in their conduct, and very much more efficient in their work than the average run of men. I did not see any drinking at all among the contract surgeons. I wish I could say the same regarding the regular physicians in the army. One of the agents of the Red Cross said to me: "If these army officials would only do business in a business way, as you and I do, things would go better; but their first impulse seems to be, when anything is not quite understood, to go and take a drink." Had it not been for the patriotic citizens, as represented in the Red Cross, the National Relief Association, and other bodies, matters would have been far worse than they were, and the death rate would have been in all probability not seven to one shot in battle but fifteen, or even twenty to one.

In closing, let me say that I have attempted to deal with this question on general principles and wholly without personalities, save and except so far as was necessary in recounting my own personal experiences to indicate what was and what might have been done. My relations with all the officials were most cordial, and whatever was done was accepted by me as an official act done under the customs and regulations of the army, and if at times duties were unpleasant and results not satisfactory I believed them in the main to be the results of these customs rather than to be due to individuals.

SOME THOUGHTS ON RETARDING THE CHANGES OF OLD AGE.

By ALBERT SEITZ, M.D.,
M'MINNVILLE, TENN.

In the study of living forms, from the protozoa to the mammals, and from the protophytes to the seed plants, we find certain changes and conditions characteristic of old age. In the human subject the principal changes which we note are atrophic and degenerative in their nature. The muscles and glands are the parts more especially involved in senile atrophy, although other soft parts are affected to some extent. There is a diminution in size of the cellular elements, though without involving any essential change in their structure. The muscular fibres become small and are said to take on more uniformity of size, while the spleen and lymphatic glands undergo a remarkable diminution in weight and size, which increases as age advances. There is also some shrinking in volume of the glandular structures of the digestive tract. Wherever fat has accumulated it gradually wastes away. It is said that atrophy begins to take place before degeneration commences. Pigmentary and fatty infiltrations of the elements are common, as are also calcareous incrustations. As an instance of the location of this fatty degeneration, muscular fibres, both voluntary and involuntary, might be mentioned. It is also found in blood-vessels, especially the terminal arteries of the brain, and to some extent in the nerve cells and in the parenchyma of glandular organs. Pigmentary infiltration, it is claimed, is not so frequently met with as is fatty infiltration. In the pineal gland, in ligaments, cartilages, tendons, and the walls of arteries, calcareous deposits are common. In the brain and spinal cord the neuroglia increases until it frequently predominates over the nervous element, and there is a tendency to the deposition of amylaceous bodies in these parts. The fatty elements of the brain are diminished, while the water and phosphorus are increased in quantity. The height and weight of the body on account of these changes are diminished, the body as a whole being shorter and lighter, while its individual parts are also lessened in size, with the exception of the heart and kidneys. The heart as a rule is hypertrophied, while the kidneys are at least the size they were in middle life. Changes take place in the skin, rendering it dry and wrinkled, the hair becomes thin and white, the teeth drop out, the body bends. These changes induce a general decrease in vigor; the power of the muscles is lessened; the combustion going on in the body is diminished, as is shown by a decrease in the amount of carbonic-acid gas exhaled. The vital capacity of the lungs is decreased, although there is a quickening of the respiratory rhythm. The pulse rate rises, the secretions are diminished, and the quantity of urine is less. Such, briefly stated, are some of the characteristics of old age. This period of life is more

liable to certain diseases, as those due to arterio-sclerosis, to certain forms of rheumatism and gout, and so on.

What produces these changes in the body which drag us down to the grave? Is there no way to retard or prevent them? If we could obviate them even in a measure, how great would be the benefit, and with what rejoicing would the earth's inhabitants hail the discovery, especially those among them who have begun to enter the shadows which gather about life's evening. In the cycle through which a portion of the material world revolves, from the organic to the inorganic, from the living to the dead and back again to the living, it would appear that, as old age approaches, the material of the animal body takes on more and more the nature of the inorganic and becomes more and more akin to the mineral world. When an individual starts in life, he appears to be endowed with a certain power or ability to maintain his status in the highly organized animal world, and to resist largely the tendency of his tissues to become in their chemical nature more nearly akin to the mineral kingdom. What this power consists in I do not know; but it seems to be greatly impaired by age. Now, if by introducing into the body certain agents which might render the excess of accumulating mineral matter more soluble, so that it could be more easily eliminated from the body, we might get rid of one element that contributes largely to the deterioration and degeneration that come with old age. Again, all animal and vegetable tissues when young possess in a large measure this resistance toward the changes that take place in senility. Then, why would it not be a feasible and rational idea for those who are approaching the period of life when senile changes begin to make their appearance to take as nourishment only the tissues of young animals and vegetables, and thereby supplement their waning power of resistance with that of those organisms which contain it in abundance? And, also, as we now have a process of treating certain diseased conditions of different organs of the body with the products of the corresponding organs of animal bodies (and I believe with some success), why could benefit not be derived by administering the quintessence of the organs of young and healthy animals to those whose bodies are beginning to show the effects of age, and in that way furnish them artificially with the power to resist the encroachments of time? Two or three times a year, for instance, we might administer this treatment for a week or two at a time; and who can say that we might not retard in this way the capture of life's citadel by the king of the glass and scythe?

Asthma in Infants.—In an article on "L'Asma Infantile" (*Gazz. Med. di Torino*, No. 23, 1897), Dr. A. Muggia distinguishes what he terms "asthma ganglionare"—which depends upon congestion, inflammation, or tuberculosis of the bronchial glands—from reflex asthma and essential asthma resulting from disease of the bronchial mucous membrane. All three forms are of frequent occurrence in childhood. The first is associated with peculiar pertussis-like attacks of coughing, with laryngeal phenomena, dysphagia, vomiting, and engorged cervical and thoracic veins. The second and third forms always begin, even in the absence of any nasal affection, with pruritus or with a mucous or muco-purulent secretion of the nasal mucous membrane. Typical asthmatic attacks are rare in children; febrile symptoms are common, especially in delicate infants under four years of age, in whom Brissaud has directed especial attention to a so-called torpid form, with mucous nasal catarrh, considerable dyspnœa, infrequent cough, and slight bronchitis.

Progress of Medical Science.

Bile.—One of the most remarkable facts concerning the bile is its apparently small importance in the digestion of food. It is doubtless to a large extent excretory, but it is probable that it may in the future be found that bile is a more valuable digestant than is at present supposed.—Halliburton.

Bile is mainly a digestive fluid; *i.e.*, it is a secretion to be further utilized in the body, not merely an excretion to be forthwith expelled.—Waller.

The bile is to be looked upon as a comparatively insignificant byproduct, resulting from the extremely complex and diverse chemical operations which have their seat in the liver, the largest and perhaps most important of all the glands of the body.—Gamgee.

Bile is almost entirely the residual matter that is passed out of the liver—is really an excretion of the liver.—Lauder Brunton.

Bile will be considered in this article as an excretion, in accordance with the opinions of the majority of surgeons who have paid particular attention to this department of surgery. Physicians as a rule consider it a secretion.—Dr. Murphy in "Twentieth Century Practice."

A New Method of Disinfection of Dwellings.—Before the Berliner medicinische Gesellschaft, meeting of March 9, 1898, Dr. Schlossmann described in detail his method of house disinfection. He uses formaldehyde in his apparatus, formaldehyde being the antiseptic most frequently employed during the last decade in the new experiments on this subject. In the apparatus is placed a mixture of water, glycerin, and formaldehyde, which mixture is then boiled; in this wise not only the vapor of formaldehyde but also water gas are generated in the room, and there is reason to believe that the glycerin enters into chemical combination with the formaldehyde, thus enhancing the effect of the latter. By this method and with this apparatus, it has been possible to sterilize in three hours six or eight layers of gauze thoroughly soaked in pus; similar experiments with other infected material have been made, always with good results. It is not necessary to seal either windows or doors. The atomization causes a heavy, dense smell. Guinea-pigs left in the vapor die of pneumonia; this effect can be prevented by leaving some liquid ammonia in the room.

The Intestinal Bacteria of Nurslings.—As is well known, the intestinal canal of the newborn is free from bacteria. Very soon after birth—generally after ten or twenty hours, the earliest after four hours—Dr. K. Szegö has found bacteria in the meconium (*Archiv für Kinderheilkunde*, xxii., S. 25). The bacillus most frequently found was the bacillus coli, which, because of difference of growth of two forms, the writer designated as bacillus coli A and B. The next most frequent was the streptococcus pyogenes; the next, micrococcus liquefaciens albus. Further, the writer found the intestinal microbes described by Escherich. The source of the bacterium is as yet uncertain. It has been ascribed to the bath of the newborn children; also to the first nourishment received. Against these views are the observations of Szegö, who has several times found bacteria even before the bathing or the giving of nourishment. The first bacterium to make its appearance in the meconium was always the bacillus coli A. Neither the bacterium coli nor the other above-mentioned bacteria, nor their spores, were found in the bath water, milk, dust, or air of the room. Hence the manner of infection is not as yet clear. The normal intestinal bacteria found in

the older nurslings show no noteworthy difference from those found in the meconium; in the dyspeptic conditions of children the result of bacterial investigations is the same.

On Fibro-Myomata of the Uterus. — Dr. Oskar Kattmann has investigated four hundred cases of fibromyomata (*Archiv für Gynäkologie*, Bd. 54, Heft 2), and arrives at the following conclusions: Fibromyomata are most frequent among married women; then in unmarried women and those who have not given birth to children. This is contrary to the old idea that sexual life lessens the predisposition to this disease. Pregnancy and childbirth affect but little the frequency of fibroma uteri; on the other hand, in women who have this tumor, conception is less frequent than in the healthy. The following observations are particularly noteworthy, as contrary to generally accepted ideas. In almost one-fourth of the cases, neither the menopause nor the climacteric had any hindering effect upon the growth of the tumor. At these times the growth was in many cases more rapid, and the symptoms were more pronounced; this rapid growth and the more marked symptoms did not depend upon malignant degeneration of the tumor. Fibromyomatous growth may even begin at the menopause or climacteric.

Lumbar Puncture.—In a paper giving especial attention to the dangers which lumbar puncture may present in organic affections of the nervous centres, Dr. Etienne Martin gives, in the *Lyon Médicale*, October 9th, the following as the conclusions at which he has arrived: (1) Lumbar puncture may be contraindicated as dangerous in organic affections of the spinal marrow and of the brain. (2) It remains none the less demonstrated that in the majority of instances (meningitis, grave chlorosis, etc.) it may be practised without inconvenience as a method of diagnosis. (3) As a therapeutic measure, even if its efficacy is still much contested, it may be said that in permitting subarachnoid injections it opens up to therapeusis a still unexplored territory.

Observations in Diphtheria.—Dr. H. D. Jerowitz (*Journal of the American Medical Association*, October 29th) gives his conclusions resulting from an extensive experience in a town of one hundred and fifty thousand inhabitants, having no children's hospital or any other opportunity for studying these cases, except as they occur in private practice. They are as follows: (1) The majority of cases are mild, and affect only the tonsils and pharynx. (2) The exudation lasts from one to two weeks. There are exceptions to this. (3) Removal of the membrane is useless, as by denudation of the surface septic infection is promoted, and, besides, the membrane soon reappears and remains longer than if it had not been meddled with. (4) The involvement of the larynx is always sudden, and comes as a new attack, and not by extension of the diphtheritic process. (5) The larynx becomes involved in about four per cent. of the cases. (6) Every case complicated with uræmia had post-diphtheritic paralysis. (7) Laryngeal involvement is to be most dreaded between the ages of three and five. (8) Intubation and tracheotomy will become less and less necessary as the value of antitoxin is recognized. As regards treatment he states: "(1) The first thing noticed after using antitoxin is a reaction, an immediate effect, showing that antitoxin is a powerful agent. (2) In every case in which I administered antitoxin in the proper dose, the membrane disappeared inside of three days. Without its use, while I have seen patients get well in the same length of time, yet the majority of cases lasted from ten to fourteen days. (3) In all cases in which I employed antitoxin in the beginning, the larynx did not become involved and uræmia did not occur, while in cases treated without antitoxin the larynx became involved frequently and uræmia also followed. (4) In cases in which the membrane involved the larynx, trachea, and even the bronchial tubes, recovery followed when treated with antitoxin, while the same class of cases before the use of antitoxin always resulted fatally. (5) Neglected cases, complicated with septicæmia and laryngeal involvement, do not recover with any treatment. (6) In severe cases of dyspnœa, with occasional cyanosis, the use of antitoxin and emetics has obviated the necessity for tracheotomy. (7) Measles as a complication is no bar to the use of antitoxin. (8) In laryngeal cases complicated with uræmia or nephritis, antitoxin was followed by favorable results, thus proving that uræmia and nephritis are not necessarily contraindications to the use of antitoxin. (9) As paralysis was seen to follow only the cases of long duration, those in which antitoxin was administered early were not followed by paralysis. Of those in which it was given on the second or third day, it occurred in about eight per cent. From this it follows that antitoxin does not prevent paralysis, except indirectly by cutting short the disease. (10) Place of injection, behind the scapula. No abscess or other bad result followed."

Schenck's Theory: The Determination of Sex.— First of all, some would say that in certain regions and among certain peoples, where meat forms the principal diet, only male or principally male offspring would be anticipated. The nutrition of the mother certainly plays a very important part in the condition of the ovum within her body. The different experiments which breeders have made, and the observations which have repeatedly shown in the case of the invertebrata (V. Berlepsch, "Die Biene und ihre Zucht," second edition; Landois, "Physiologie") a connection between food and the development of sex, leave no doubt that, in the case of the human subject also, a certain diet of the mother would not be without influence on the ovum developing within her. Here, however, in the case of the ripening of the ovum, according to my opinion, the result does not depend on the diet alone, but rather on the process of metabolism in the mother. How the physiological combustion goes on in the organism, and what changes take place in it in consequence of the altered diet until the sugar entirely disappears, is, in the case of human beings, of the highest importance and furnishes an index of the consequences. In individual cases the diet is directed in accordance with the results that show how the food has been assimilated, and does not depend upon these alone. In other words, whether the mother eats much meat is a secondary consideration. Whether, and how, the food taken is completely made use of in the process of combustion, that is a matter of importance for the purpose we have in view. Any one, who keeps before him the fundamental principles of this theory, will see plainly that it is possible under certain circumstances to procure male progeny by means of the influence we have indicated. The wish to have female progeny is a desire for the gratification of which it is not at present possible to give any directions.—Dr. Leopold Schenck, "The Determination of Sex," page 16.

Another Theory of Sex Control.—Dr. S. R. Shepherd (*The Medical Brief*, page 881) writes: "My theory is based upon the postulates in general, that the universe is composed of electricity and matter; that life is electricity, or the product of the organic union of electricity with matter (it being a law of science and logic to attribute effects to the nearest adequate familiar force or cause, rather than to something remote and hypothetical); that each individual beginning is

a tiny spark emitted and separated from the infinite life-generating fountain of potential energy, static or etheric electricity. That electricity is male and female; that the male animal, being positive, is necessarily the sex to throw off or generate the spark of life; that everything in the universe, from atom to planet, obeys the law of electro-magnetism; that every motion, effect, or phenomenon in the universe is the result of electric causation; that sex is essentially electrical —life polarized; that there is no life without sex. That male and female germs are of opposite polarity; that the male germ, being positive and more energetic and hardy, is most likely (at least) to evolve out of negative conditions and to persist, develop, and attain vigor in those conditions—such conditions to be superinduced by subsistance for a time, possibly a month, more or less, upon a light, low, non-heat-producing, unstimulating diet, with habits tending to deplete. The struggle for existence begins the instant of the inception of a germ, and environment is everything. With medium conditions the sexes have equal chances. Let germs in large and equal numbers as to sex be deposited at one time in cold, negative, sterile, maternal soil, made so by this régime; the male germs will develop and persist, while the female germs will chill, droop, and perish in a few hours. Reverse the régime and produce vital repletion, *i.e.*, extreme warmth, high tone, luxuriant, tropical, positive conditions, for which the female germs, with opposite polarity, have an affinity, and they respond quickly, develop rapidly, get the start of, and crowd out the male germs (the conditions not calling out their latent forces), which perish, leaving the female germs to struggle among themselves, the fittest surviving."

A Case of Leukæmia following Trauma.—In the spring of 1896 the patient happened to be at a very large gathering, where he was severely crushed; the left side of the abdomen and chest walls were especially subjected to a great amount of pressure. The leukæmia dates back to this accident. As the patient, through the exertion of great strength, wrenched himself from this human vice and reached a free space, he sank senseless to the ground and remained in this condition for several hours. When he reached home he was obliged to go to bed, as he suffered from severe pain in the sides and chest. He had to remain in bed fourteen days, during which time the cervical glands became very much enlarged. The patient, now feeling fairly well, returned to work. The glands still increased in size, but without causing any discomfort. In May, 1897, the patient, whose former strength had not yet returned, began to suffer from asthma, palpitation, and pain in the left hypochondrium. For a short time he was able to do light work, but soon found himself unable to do any work at all, and was again confined to bed. Present condition: The pale, emaciated patient complains of debility and pain in the splenic and sigmoid regions; insufficient chest movement, since every deep inspiration causes pain in the left hypochondrium; dyspnœa on the slightest exertion. Cardiac dulness extends about one centimetre to the left of the mammillary line. Auscultation reveals a dull note all over. The apex beat is diffuse. Palpitation on even slight exertion. All palpable lymph glands are markedly enlarged, although painless. The blood examination reveals hæmoglobin, 45 per cent.; red cells, 1,800,000; white cells, 600,000; specific gravity, 1.040. Abdomen slightly distended, no ascites. The lower border of the liver extends slightly beyond the free border of the thorax. The spleen is markedly enlarged; its upper border reaches the seventh rib, the lower extends down to the level of the umbilicus. The upper surface of the spleen is smooth and very painful. Treatment consisted in the internal administration of Blaud's pills and the subcutaneous injection of arseniate of sodium. The patient remained in the hospital for forty days, and then left, much improved in the subjective symptoms. The objective symptoms, however, *i.e.*, the lymph glands, spleen, liver, and blood, remained unchanged.—Dr. Koschin, *Meditsinskoye Obosrenye*, Bd. 50, H. 3.

On the Complications of Pregnancy, Parturition, and the Puerperium in Chronic Heart Disease.—Most of the cases of chronic heart disease in which compensation is complete pass through the periods of gestation, labor, and puerperium without any manifest untoward symptoms, or with only slight symptoms, unless some complication, such as nephritis, bronchitis, or recent endocarditis, develops. On the other hand, in non-compensated heart lesions, the chances of passing through these three stages without incident are slight. The character of the lesion plays an important rôle, and, according to Dr. O. Feis (Volkmann's "Klinische Vorträge," 213), mitral stenosis is the most fatal. The frequent abortions and miscarriages in cases of heart disease should be looked upon as fortunate terminations. The greatest danger threatens during the period of labor, in consequence of the marked fluctuation in blood pressure, the psychical excitement, etc. The rupture of the membranes with escape of the water may be sufficient to call forth fatal collapse. Many of the deaths occur during the puerperium, and are usually the result of pulmonary emboli. As regards treatment, urgent symptoms are to be treated upon general principles; upon the appearance of threatening manifestations, abortion is indicated; it is not safe to postpone interference until the time of viability, since artificial miscarriage is attended with much greater danger than is abortion in these cases. Delivery should be performed as rapidly and carefully as possible (dilatation of the os uteri by colpeurysis). Chloroform may be cautiously administered. The mother is to be carefully watched after the birth of the child, for collapse frequently occurs just at this time. In beginning œdema of the lungs venesection is indicated. Milk diet and small doses of strophanthus may be given in the after-treament, the patient to be kept in bed three or four weeks.

The Menopause and the Kidney.—Dr. Le Gendre (*Gazette des Hôpitaux*, No. 146, 1897), as a result of many observations, concludes that the kidney is often affected by the menopause. In some women the menopause, or the diminution or retardation of the menstrual flow, is capable of producing a renal congestion of varying intensity, which manifests itself in different ways—sometimes by a diminished secretion of urine; at other times by slight albuminuria, or hæmaturia, lumbar pain, nausea, vomiting, and severe headache. Such symptoms can be relieved by diuretic treatment. If a chronic nephritis pre-exists, the menopause may cause the appearance of severe symptoms.

Uterine Hemorrhages as Affected by the Climate of Altitudes.—Dr. Septimus Sunderland (*Lancet*, October 15th) draws the following conclusions: (1) That a high, dry climate is beneficial in certain cases of chronic uterine hemorrhage that do not respond to ordinary treatment. If practicable, a residence at a high altitude should be tried for as long a period as possible in cases in which operation is not absolutely necessary, or is inadvisable from various reasons, or would prove unusually dangerous. (2) That a high altitude will probably be found useful in certain hemorrhages and congestions other than pulmonary or uterine. (3) That, in addition to other causes that diminish uterine bleeding at a high altitude, the lessened air pressure is an important aid.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, December 3, 1898.

THE WORK OF THE MEDICAL DEPARTMENT DURING THE SPANISH WAR.

THE report of the surgeon-general of the United States army to the secretary of war is published quite opportunely, while the war-investigation committee is in the midst of its labors and when much public interest is being directed toward alleged matters of neglect in the care of the sick and wounded soldiers, in which his department is most intimately and painfully concerned. In view of the facts stated in this document, much light is thrown in an explanatory way upon many points of responsibility for wrongdoing, which heretofore have not been very clearly presented—or at least have not been so directly admitted.

While the shortcomings charged against the medical department of the army are still fresh in the minds of the nation, it is becoming and proper to view the statements set forth in that spirit of justice and impartiality which seeks only the truth and the lessons which it may be capable of teaching. Although the general impression created by the calm analysis of the situation is one scarcely favorable to the present organization of the medical corps as to its capacity or resources, there is a general conviction that the best was done for the sick and wounded that was possible under the circumstances of conflicting authority, inadequate preparation, and the culpable want of forethought of the line officers.

The report opens with the significant statement that the number of medical officers allowed the army (one hundred and ninety-two) is inadequate even in times of peace, and in consequence of this it was necessary during the last war to employ a staff of six hundred and fifty contract surgeons, mostly, as it is implied, by the forced selection of a hurried call for their services. These were raw medical recruits, who were assigned to responsible positions and were afterward charged with incapacity. This may have been inevitable in the fate of sequences, but was none the less deplorable that it should be so.

The question of competent male nurses was also a very difficult one to settle, as not only the demand far exceeded the supply from the trained hospital-corps men, but it was almost impossible to get suitable assignments from regiments or obtain properly trained assistants from outside sources.

It would appear by the facts presented that there was an abundance of medical supplies for the field and home camps, but it was often impossible to obtain adequate or timely transportation. It is directly and explicitly charged that the lack of sufficient medical supplies at San Juan and El Caney was due to the fact that when the command embarked, the ambulance trains of all the divisions, with a large part of the outfit of each, was left behind. Of the property and supplies carried to Cuba, a portion was not available for service when most needed, as no opportunity was afforded for landing them. This certainly shifts the responsibility of results from the medical department to that of some other authority, presumably the commanding general; but further than this army etiquette, in official documents, saith not.

The prevalence of so much sickness in the various camps is frankly charged to imperfect sanitation and want of experience of medical officers in charge, rather than to badly chosen sites. It is certainly a shameful condition of affairs when, as claimed by the surgeon-general, its prevention was, by him at least, an impossibility. It is quite humiliating also to be compelled to state that the majority of the officers one is forced to assign to duty are incapable of intelligent service.

Another point in this connection which was a leading factor of diseased conditions was the reduction of the age limit from twenty-one to eighteen years. The penalty for such misjudgment of the actual physical strength of the would-be soldier was the inevitable breakdown from ordinary fatigue and that consequent lowering of vital resistance, which in their turn were ready invitations to general diseased conditions. Then, again, the bad policy of establishing camps in proximity to large cities was manifested in the prevalence of drunkenness and other forms of dissipation, from the influences of which we would fain believe some of the medical officers themselves were becomingly exempt.

It seems somewhat strange, when the deplorable conditions should have been known, even if not reasonably anticipated, that no determined effort to right matters on the part of the medical department was made, until typhoid fever became so rife in all the camps that it was only then necessary to have formal inspections of the sites with the view of applying the requisite but too long delayed remedy. Every true citizen must regret the necessity of such measures, and must blush for any army organization that makes such a course possible.

Our experience in the late war, dearly bought as it has been in much preventable sickness, suffering, and death, has offered us many striking object lessons in army organization which will doubtless be of great service to us in the future. There has been demonstrated a pressing need of centralized power in the consistent distribution of those responsibilities which may make the army and all its different departments a grand and perfect machine. In every branch of the service there are too much antagonism of interest and too much shifting of blame from one to the other to make any break or starting-point in the convenient and bewildering

round-robin system of common protection. So long as the present plan exists, no change for the better need be expected. In regard to the transportation of food and medical supplies, the quartermaster's department, in its supreme and wide-reaching executive capacity, decides absolutely all questions of emergency as to precedence and detail. Unfortunately the medical department is generally least of all considered, and is made to wait its turn at the foot of the list. Ancient experiences in this line repeated themselves in the war with Spain with such disastrous results that an official investigation was made imperative. What the real outcome of the inquiry may be cannot be conjectured, but it is hoped that the great mass of testimony taken may ultimately eventuate in some formal recommendation for the reorganization of our army supply system, whereby the dreadful mistakes so familiar to all may be effectually prevented in the future.

ASPHYXIA NEONATORUM.

New methods of sustaining life in those about to perish have always appealed strongly to medical men, and the more youthful the subject and the greater his life expectancy, the more gratifying oftentimes appear the results, to say nothing of the reproach cast upon the officiating obstetrician when the expected heir will not inspire. It is therefore with hopeful anticipation that one turns to an article by Dr. Stringer, in a recent issue of the *Virginia Medical Semi-Monthly*, "A Rational Method of Relieving Asphyxia in the Newly Born Infant." We can do full justice to the writer and his method in no better way than to quote his own words.

"A few years ago I was called to a multipara in labor, and was told she was only in her fourth or fifth month of pregnancy. In a few hours she was delivered of a fœtus, which I took to be about the age indicated. The fœtus, membranes, and placenta were all delivered by the same effort. Nothing unusual having occurred, the fœtus and envelopes were laid aside until my departure, when I had it placed in some cloths and rolled up to carry with me for the purpose of saving it as a specimen; but, it being late in the night, I deposited it until morning, when I proceeded to examine it, and, to my astonishment, found the fœtal circulation still going on, with the pulse at the wrist very perceptible. This was several hours after birth. Here was a case of fœtal circulation, to my mind, carried on by the aeration of the blood through the medium of the placenta exposed to the atmospheric air."

Fortunately an opportunity soon presented itself for a practical application of the discovery, and here again the writer speaks for himself:

"The child could not be induced, by the usual method of cold application and rolling, to make any effort at respiration. The circulation was still going on in the funis with some vigor, but the deepening of the dark hue of the surface plainly indicated that, unless oxygenation of the blood could take place, death would soon follow. Already the pulsation in the cord had become feeble, and was becoming more so rapidly, when I delivered the placenta, rapidly cleansed it of clots, and exposed the maternal surface to the atmospheric air. In a very short time the pulsation was perceptibly increasing in force; the livid and death-like hue was being displaced by one of life and health, and it required but a few moments for the restoration of sensibility, when the process of respiration commenced."

The above and several subsequent cases lead the originator of the method to look upon it as the only simple and rational one available. Unfortunately, however, it not infrequently happens, when the placenta is expelled with or shortly after the child in premature birth or precipitate labor, that death of the newborn ensues as a direct result of hemorrhage from the placenta. We are not prepared, therefore, to give that hearty indorsement to the plan of procedure which we otherwise might, and the query arises whether cutting the cord and thus insuring a slight amount of direct hemorrhage would not answer every purpose. Though having no direct bearing upon the efficacy of the treatment advanced, the unique feature of "perceptible pulse at the wrist" in a five-months' fœtus several hours after delivery is sufficiently interesting to excite comment.

HAWKING PHYSICIANS.

There may have been a time when the physician to some royal court found time and was permitted to engage in the sport of hunting with a hawk upon the wrist. Our present remarks do not apply to this kind of gaming, but to a less ennobling pursuit of crying one's wares upon the street or peddling them out for the highest price obtainable. Several of our contemporaries have had much to say of late upon the subject of commissions paid by specialists to general practitioners for cases referred to them. That there exists any very considerable amount of such reprehensible practice we are not inclined to believe, but that reference cases are at times paid for on the one side and the dividend freely accepted on the other is undoubtedly true. More's the pity.

What has been called "bargain-counter" surgery, especially in the realms of abdominal and pelvic pathology, must have some existence in fact, or one would not hear of it from so many different sources. The blame has been placed almost exclusively at the door of the specialist, but one correspondent touches the keynote, it would seem, when he says that "country doctors frequently go about from surgeon to surgeon, seeking the highest bidder." It would not be surprising if equal blame were to be attached to him who has the case to sell and to the one who is willing to buy. It was some years ago that many reputable surgeons in this city were shocked in their finer susceptibilities by a down East doctor who landed in town with six laparotomy cases, which he proceeded to farm out on terms most advantageous to himself. Many of the surgeons approached had not before heard of such shrewd businesslike methods being applied

to human existence, and very properly showed the visitor the door. Undoubtedly these surgeons would pursue the same course to-day. It is at least to be hoped they would. Whether or not this hawkster succeeded in finding an operator sufficiently devoid of ethical honesty to offer the proper "divy" is not divulged. He may have taken the subjects to one of our neighboring cities, where so great a cry has gone up against the giving and accepting of commissions as to lead one to infer that the practice is much more prevalent than with us. Or he may have gone with his half-dozen protruding females back to his quiet New England village, and by operating upon them himself secured the whole of a smaller fee. Whatever may have been the outcome of the pilgrimage, the lesson must have been learned that because one man "sells" another does not always feel inclined to "be sold."

Among the worst medical sins are to be reckoned those of commission. Physicians who indulge in such practices must sooner or later come to grief, and it would be better that both sides take warning before the patients discover for themselves that their welfare is being bartered and that they are likely to fall into the hands of incompetents willing to overcharge in order to pay exorbitant dividends.

News of the Week.

Professor Nothnagel, of Vienna, was recently reported to be dead, and several French and Portuguese journals have treated their readers to full and eulogistic obituary notices of the celebrated clinician.

A Pathological Diagnosis Society.—An association with this title was founded a few years ago in Liverpool under the auspices of University College in that city. The object of the society is to examine morbid specimens and report upon their nature. After the examination has been made a report of the findings is furnished to the physician or surgeon sending the specimen. A special room in the new Thompson-Yates laboratory building has been set aside for the sole use of the society.

Medical Temperance Work among Students.—A few weeks ago a meeting of the British Medical Temperance Association for the benefit of students was held in London. About seventy medical students from the various hospitals were present. Dr. Sims Woodhead, the president of the association, delivered an address in which he spoke of the important influence his hearers would be able to exert in their future practice if they were total abstainers. Many years ago it was the fashion to bleed and salivate, and when this was found to be injurious some of the older men said it was due to a change in the type of disease. He had no doubt that hereafter the same excuse would be made to account for the disuse of alcohol.

Dr. Theodor Gsell-Fels, of Munich, who died recently at the age of eighty, was a doctor in three faculties—medicine, philosophy, and theology. He was the author of numerous works on climatology and health resorts, including those of Switzerland, the Riviera, the South of France, Corsica, Algiers, and Tunis.

Filthy Streets.—The recent snowstorm has served to open the eyes of the people of New York to the fact, patent long ago to bicyclers and others who have occasion to note the conditions of the thoroughfares, that the brief era of real street-cleaning, inaugurated by the late Colonel Waring, is of the past. Anything more dirty than the present state of the New York city streets is difficult to imagine.

A Medical Legislator.—Dr. Nelson J. Henry, of this city, has been elected an assemblyman in the next State legislature.

A Journal Consolidation.—The *Canadian Medical Review* and the *Canadian Practitioner* have been consolidated, the resultant periodical retaining both names and calling itself the *Canadian Practitioner and Medical Review.*

The Spitting Nuisance in a Medical College.—A rule has been made that there shall be no smoking by the students of the College of Physicians and Surgeons within the college building, and spitting in the corridors or classrooms is also forbidden.

To Report on Antistreptococcus Serum.—At the last meeting of the American Gynecological Society a committee, composed of Drs. Williams, Baltimore; Norris, Philadelphia; Fry, Washington; Reynolds, Boston; and Pryor, New York, was appointed to report next May upon antistreptococcus serum. The use of the serum prepared by the New York Board of Health is recommended. Sterile culture tubes can be secured from Dr. Torrens, 435 Pleasant Avenue, and from Dr. Jeffries, 212 East Thirty-fourth Street. Samples of discharges should be sent to Dr. Jeffries, who will at the earliest moment notify by telephone or telegram the physician attending the case under observation, whether or not streptococci are found. In return for this physicians are requested to furnish notes of their cases showing when and in what amounts the serum was used, what general treatment was employed, what local treatment was applied, and the results. It is desired by the commission to make the report as exhaustive and thorough as possible, and to accomplish the object sought the co-operation of the profession of the city is necessary. Notes of cases in which the serum has not been used are also desired. While it is manifestly desirable that one kind of serum be employed in all cases, the committee will be gratified to receive the results obtained with any which may please the fancy of any particular observer.

Experiments with Sanarelli's Yellow-Fever Serum.—In the current number of the "Public Health Reports," issued by the Marine Hospital service, is a report by Dr. Wasdin upon the employment of Sanarelli's antiamaryllic serum in New Orleans during the past summer. Opportunity to use the serum presented itself in but three cases, two mild ones and a third in which the patient was apparently moribund when brought under observation. This patient died twelve

hours after the serum was injected without having shown any favorable symptoms. In the other two cases there was a marked reaction—fever and great vasomotor disturbance; but Dr. Wasdin says that the patients would have done just as well without the serum, and indeed its only effect, to judge from the report, was to increase the sufferers' distress. In the same number, Dr. Havelburg, inspector of the Marine Hospital service at Rio de Janeiro, reports a number of experiments made with the same serum, in which the results were far from satisfactory, and indeed would indicate that the serum is worthless. They also throw suspicion on the bacillus itself, and it would appear doubtful whether the micro-organism discovered by Sanarelli has any pathogenic relation to yellow fever. Dr. Havelburg also speaks in far from uncertain tones of the unscientific and unsatisfactory evidence offered in favor of Freire's bacillus xanthogenicus and his prophylactic serum.

The Guild of St. Luke.—Dr. Angus Campbell writes to *The Lancet* in protest against the state service annually organized by the Guild of St. Luke in St. Paul's Cathedral, London. He says that this service possesses many highly objectionable features and tends decidedly to lower the profession in the eyes of the intelligent. "To prove this latter contention the general tone of the notices of the function in the lay journals is sufficient, and if the members of the guild were not so very thick-skinned these notices would themselves be sufficient to deter them from repeating their annual display. Unlike some other professions," he continues, "that of medicine has never been given to show. A public muster of members in gorgeous attire is in itself an innovation requiring some justification, but the matter becomes much more serious when we remember that this display is preceded by preliminary puffs in nearly all the lay papers, evidently inspired, wherein certain names are given, and that notices of the function are inserted in most lay and religious papers, names being again introduced. What is this but advertisement? Yes—advertisement of a most insidious and reprehensible character, for not only do those whose names appear advertise their persons and occupations, but they also contrive to establish in the minds of the weaker sort a reputation for piety."

The Etiology of Malaria.—The Rome correspondent of *The Lancet* writes that the Italians have long been working steadily and silently on the subject of the etiology of malaria and have obtained results only now becoming known. Profiting by the experience of Laveran, if not by that of Manson and Ross, Dr. Amico Bignami, *privat-docent* in pathological anatomy at the university, had in 1896 by observation and experiment convinced himself that malaria was a "disease of inoculation." The same year, working in concert with Dr. Dionisi, also of the Roman school, he experimented on the possibility of engendering malarial fever by means of the punctures of mosquitoes. Their experiments yielded no positive result, but were repeated in August and the first half of September (still in 1896), once more with a negative response. Dr. Bignami and Dr. Dionisi had failed to satisfy themselves, among the numerous tribes of mosquitoes, as to that one which had relations, mediate or immediate, with malaria. However, Dr. G. B. Grassi succeeded last summer in completing a series of observations by which he ascertained and determined the mosquito tribes which had power to convey the disease. Italian medicine, already distinguished in the malarial field by the studies of Tommasi-Crudeli, Baccelli, Golgi, Celli, Marchiafava, and others, chiefly of the Roman school, expects to establish a claim to having made out the special tribes of malaria-conducting mosquitoes—tribes three in number and found exclusively in the fever-infected localities. Dr. Dionisi has discovered in bats a malaria-infection due to parasites closely resembling those found in the blood of malarious man.

A Dublin Disinfecting-House.—A mortuary for the bodies of persons dead of infectious diseases has been built in Dublin in connection with a disinfecting-house. If for any reason the body of one dead of an infectious disease cannot be buried immediately, permission will be given to keep it in this mortuary for a period not to exceed twenty-four hours.

The Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about $180, will be made on July 14, 1899, provided that an essay deemed by the committee of award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published, and must be received by the secretary of the college on or before May 1, 1899. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the college; other essays will be returned upon application within three months after the award. The prize for 1898 has been awarded to Dr. S. A. Knopf, of New York City, for his essay entitled: "Modern Prophylaxis of Pulmonary Tuberculosis and its Treatment in Special Institutions and at Home."

A Long Wait.—They tell of a Chicago physician who, opening the door of his consultation room, asked: "Who has been waiting the longest?" A tailor who had called to present his bill rose and said: "I have, doctor; I delivered your clothes to you three years ago."—*Chicago Clinic.*

Sir William MacCormac on the Prince of Wales' Injury.—Sir W. MacCormac, speaking a short time ago at Swansea and referring to the progress of surgery, said he remembered the time when operations were looked upon as very different matters from what they are now—when they were thought to some extent rightly a confession of failure on the surgeon's part.

Surgeons then did not receive the consideration they now received at the hands of all, and he believed the reason for thinking their operations the unmitigated evils they used to be thought was because their means of dealing with wounds were not what they were now. Through the advance which surgery had made, operations were now practised which formerly were not thought possible or justifiable. The progress of surgery, indeed, had been so remarkable and had obtained such a hold on the public mind that the surgeons of the country were considered a sort of high-priest to whom nothing was impossible. As an instance, he mentioned the case of a very exalted personage who not long ago received a serious injury. This exalted personage was the subject of advice not only from his own country men and women, but from people in all parts of the world. But one thing that particularly impressed itself upon him was a suggestion made publicly that at all events his broken kneecap could be sutured. In such an operation, as some said, there were no difficulty and absolutely no risks; but though he did not go so far as that, nevertheless he was happy to be able to say that, in spite of what some of their foreign critics had been pleased to say in regard to the treatment, the recovery of that exalted personage had been everything his best friends desired.—*London Times.*

The New Vaccination Law in England.—It becomes increasingly clear that the vaccination act was devised by some ironic imp, whose joy is to make dignitaries ridiculous. Having achieved instant success in the house of commons with Mr. Chaplin and Mr. Balfour, it has now passed to the magistrates' bench, where it gives promise of having a long and delightful run. In London, so far, Mr. Curtis Bennett, Mr. Mead, and Mr. Plowden have been the chief exponents of its mirth, in a rôle which combines omniscience with extensive lecturing. They have not yet, it is true, devised a sure method of dividing the sheep from the goats—the mere objector from the conscientious objector; but that is simply because they have not applied the Roentgen rays with sufficient persistency and discretion. Meanwhile, the public is anxious to know when, where, and how Mr. Curtis Bennett was vaccinated four times, and also if he is prepared publicly to bare his arms to the shoulder, like De Rougemont. If he will undertake this latter test, we promise him a large and amused audience any morning at Marylebone. Further, if it is shown that he has had the courage to be vaccinated four times, we can assure Mr. Bennett that he will have scored the highest honors in this farcical comedy.—*Saturday Review.*

London School of Medicine for Women.—This school has received a grant of 100 guineas (about $500) from the Skinners' Company, and 50 guineas (about $250) from the Mercers' Company toward the building-fund.

Vaccination.—The New York City board of health has issued the following circular in reference to vaccine and the method of vaccination: "The part of the body to be preferred for the vaccination is at the insertion of the deltoid of either arm. When the leg is vaccinated (possibly on account of the greater difficulty of keeping it quiet and clean), inflammatory complications are more frequently present and are apt to be more severe. The skin at the place chosen should be made clean. It is doubtful if attempts at more than simple cleanliness are of value; reports of series of cases in which one arm has been vaccinated with only ordinary attention to cleanliness and the other arm vaccinated after most rigid antiseptic measures had been carried out, indicate that no greater freedom from inflammatory complications resulted in the antiseptic arm than in the other. The scarification should be made with a sterile instrument. The department of health recommends the use of an ordinary cambric needle, because a new one may be used for each case and there is thus no possibility of the transference of an infection from one person to another. When, however, the necessary precautions can be taken to render the instrument aseptic, any other sharp instrument serves as well. It is of great importance that the scarified area should be not more than one-eighth of an inch square, because the larger the area the greater the tendency to subsequent infection and to inflammatory complications. Moreover, with the more concentrated virus at present issued by the department of health, a small scarification is ample for invariable success. It should be noted that a vaccine vesicle enlarges peripherally, and the resulting crust always covers a considerably greater area than that originally scarified. The virus should be rubbed in thoroughly and allowed to dry for at least ten minutes. It is a convenience to blow the virus from the capillary tube in which it is contained on to the accompanying piece of wood and then rub the wood on the scarified area, instead of blowing the virus directly upon that area."

Restricting the Doctors.—An English journal says: "The British Medical Association and the General Medical Council are preparing still further to tie the hands of medical men. A few months ago the unqualified assistant was tabooed. Now medical men who cover unregistered dentists are to be punished wherever possible. The dental acts forbid unqualified and unregistered dentists to administer anæsthetics, but the acts have been evaded by procuring a qualified doctor to undertake this forbidden work, while the so-called dentists perform the rest of the work. Medical men are now to be prohibited from assisting this device, and those who disobey will be liable to be relieved themselves of the right to practise."

Effects of the Lee-Metford Rifle.—"A recent number of the *African Review* contains," says the *British Medical Journal*, "a report—which from 'information received' (as the police say) we have reason to believe accurate—of an extraordinary occurrence that not long ago caused considerable excitement at Maritzburg. While a number of colored worshippers were gathered together in the church of that town, their devotions were interrupted by the smashing of a window, followed by the fall of a man on the opposite side of the church.

It was found that he had been shot, the bullet having penetrated the left side of the chest and lodged in the heart. Dr. Charles Ward, the district surgeon, made a post-mortem examination, and found the bullet—a Lee-Metford one—impacted in the aorta at its point of passage through the diaphragm. The bullet had travelled from some hills outside the city, a distance of between three and four miles, as estimated by an officer of the garrison, and was so nearly spent that, after passing through the window of the church, a waistcoat, shirt, rib, and pericardium, it penetrated the descending arch of the aorta. It had not momentum, however, to go right through the vessel, but dropped down inside it. The case strikingly illustrates the long range at which the Lee-Metford rifle is effective."

The Neglect of Sanitary Precautions in the Nile Campaign.—It is generally thought that the last Soudan campaign was so well managed in every particular that it would be difficult to find a fault with any of the arrangements. It, however, appears from the following article in the *Sanitary Record* that there were mistakes made. The *Sanitary Record* says: "It is a grave reflection on the administration of the Nile campaign, in almost every respect perfect, that men who, by the systematic observance of everything that could conduce to physical and moral health and strength, had attained a pitch of training and hardening such that, though undergoing the greatest exertion in the hottest season in one of the most torrid regions of the globe, they were rendered almost insusceptible to fatigue and enjoyed a greater freedom from illness than is usual under the most favorable circumstances, should, at the very moment of triumph and the attainment of the end of the war, be attacked with typhoid to an extent apparently as great as in the former Soudan expedition, when the methods and precautions that have on this occasion marked their progress up the Nile valley were unknown. The etiology of enteric fever in Egypt presents a problem of considerable interest, and in some respects a difficult one. Whatever may have been the case in ancient days, there is no doubt as to the fact that the use of the unfiltered Nile water is almost constantly followed by typhoid among Europeans and probably among the natives to an unsuspected extent. In Lower Egypt this need not cause any surprise, considering the grossly polluted state of the river and canals; but in Upper Egypt the sewage contamination cannot be great, and while the well-known turbidity is caused by mud brought down from the mountains around the Victoria Nyanza, from which the river itself is fed and which from its enormous volume cannot be appreciably fouled by the excreta of the sparse population of the highlands and forests of Uganda. We are thus driven to the conclusion that in these regions, under special climatic conditions, the bacillus of typhoid is indigenous, thriving in the soil and water independently of human intervention; while the turbidity and temperature of the water enable it to maintain its vitality longer than it does in European rivers, in which it usually perishes after having run a course of many miles, except where the water is turbid to a degree sufficient to intercept the light. Be that as it may, we have a right to ask what measures were taken for the filtration of the water served out to the troops. The old regulation army filters were notoriously ineffective, and Megnin's "filtres rapides," used in Lord Wolseley's expedition, were found scarcely better; but Pasteur's are perfectly impervious to germs of any kind, and M. Defries has produced combinations of Pasteur's tubes, capable of filtering and, in fact, of sterilizing water in any quantities, whether as portable filters like water carts for army purposes or installations for the supply of towns of almost any size. Was the army provided with a sufficient number of these, and, if not, why was so obvious a means of preventing a fatal disease neglected? But for this one omission, the campaign under the sirdar would have been distinguished as the first in the history of war in which the sanitary administration was absolutely perfect."

Tight Waists.—We look upon it as a barbarous custom for Chinese women to constrict their feet. Li Hung Chang thinks it more barbarous for Americans to constrict their necks and waists; and the old man is right, for there are no vital organs in the feet.—*Annals of Hygiene.*

An Error in Diagnosis.—Dr. Blondel (*Ann. de Gyn.*, August, 1898), during the curettage of a uterus for menorrhagia and purulent discharge, thought the instrument had penetrated the uterine wall. Five months later the same thing occurred. Upon dilation of the organ it was found to be bipartite, and that the curette had only passed from one cavity into the other. Both cavities were then curetted and complete cure was established.

A Small Entrance.—Dr. Albespy (*La Gynécologie*, August 15, 1898) was called by a midwife to see a case in which the uterus was supposed to be prolapsed and the cervix presenting at the vulva. The supposed cervix uteri was found to be the dilated orifice of the urethra and the vulva was entirely closed by a persistent hymen. Careful examination revealed a small aperture in the upper half of the hymen, through which opening liquor amnii was escaping. The patient stated that she had had only one imperfect form of coitus with her lover on but one occasion.

Massage Treatment in China.—The *Scientific American* says that an article appeared recently in the *Deutsche medicinische Wochenschrift*, in which reference was made to a book lately published by T'an Wei, governor of Hufeh. The author, a great authority on massage, was consulted by the late empress of China. The Chinese legends contain many references to various systems of physical exercises, and these are associated in a curious way with metaphysical thought. Life, according to the Chinese traditions, is entirely dependent on "air current"—it is proof against disease. The object of physical exercise is to circulate the "air current." The Chinese system is divided into three periods, each period occupying one hundred days. The first period should commence at the time of the new moon. The patient must rise at 4 A.M., and walk outside his house, and take seven deep in-

spirations. Immediately after this two youths, who have been specially trained, commence a gentle friction all over the body, starting from the cardiac area. At the time of full moon a further set of inspiratory exercises must be taken. Later on and in the second period the various parts of the body are rubbed with wooden planks until the muscles are hardened. It is not until the hardening of the muscles takes place that the real physical exercises commence. Between the fifth and sixth month is the period of greatest activity; the European dumbbell is replaced by large sacks filled with stones. In the third period back muscles are chiefly exercised. Great benefit is said to result from this system of treatment.

Dangerous Trades in Great Britain.—The third interim report of the departmental committee appointed to inquire into and report upon certain miscellaneous dangerous trades has just been issued. Directions were given by the home secretary that the committee should inquire as to the conditions of work as they affect the health of the operatives in twenty-two different industries and processes; eight of these were dealt with in the first and second interim reports, and the committee now give particulars relating to file cutting, galvanized iron works, sole stitching by American machinery, glass polishing, the use of converters in metal works, the manufacture and use of grindstones, testing of bottles by compressed air, and "ending and mending" in velvet works.—*London Times.*

Operation Not Responsible.—A gentleman recently sued a well-known Lyons surgeon for damages laid at $2,000, for the death of his wife, who had been operated on. The decision was to the following effect: "The patient appears to have died from septic troubles connected with metritis determining pulmonary congestion following the operation. But the operation cannot be held responsible for complications which cannot be foreseen and which rarely occur. If such responsibilities were admitted, the practice of medicine in many cases would be rendered impossible."—*British Medical Journal.*

A New Decoration.—"The Red Cross medal" has been founded by the German Emperor, at the suggestion of the Empress Victoria Augusta, lady patroness of the German Red Cross societies. The medal, of which there are to be three classes—bronze, silver, and gold—is to be bestowed on persons of both sexes, without distinction in rank or position in life, for special services rendered to the Red Cross cause.—*British Medical Journal.*

Lead Poisoning in the Pottery District of Great Britain.—Some startling statements have, says an English weekly journal, been recently published in North Staffordshire, on the authority of a nurse whom the Women's Trades Union League sent into the district, to make inquiries respecting the number and nature of existing cases of lead poisoning. She told an interviewer that she was astounded at the extent of the suffering of people of both sexes employed in the pottery industry. She had seen within two months as many as one hundred and fifty patients whose symptoms were those of lead poisoning. Locally, the matter is regarded as most serious.

"Weylerism": a New Disease.—The Havana correspondent of *The Sun* says that there is in that city an infectious fever of a new type, unknown until to-day to the medical profession, which is called "weylerism," because it was first noticed among the reconcentrados, victims of Weyler. It does not yield to quinine or to any other treatment. Healthy people who come in contact with the reconcentrados catch the fever and die of it in a few hours.

A Red Cross Hospital Ship on the Nile.—The Red Cross Society's steamer *Mayflower*, which was chartered by the National Society for Aid to Sick and Wounded in War (the British Red Cross Society) to convey sick and wounded soldiers from the Soudan between Assouan and Cairo, is a stern-paddle steamer, one hundred and forty feet long. She carried two medical officers and eight men of the royal army medical corps, lent by the government, and two nurses sent out by the society. Reconstructed from a pleasure vessel into a hospital ship to hold fifty-two sick and wounded, and on an emergency seventy-two patients, she was fitted out with the most modern medical and surgical appliances and medical stores of every description. The sick and wounded thus enjoyed the luxury of being conveyed by river, and were saved the heat, choking dust, and severe discomforts of the railway journey of about six hundred miles between Assouan and Cairo, which a high authority has described as the worst part of the transit from Khartoum.—*The Hospital.*

The Crusade against Consumption.—There are said to be in existence at the present time about one hundred sanatoria for consumptives, forty-three of which are in Germany and twenty in America. The German sickness insurance companies have appropriated nearly four million marks for the erection or subvention of sanatoria.

"The Chicago Medical Recorder" is an interesting journal which publishes the papers read before the Chicago Medical Society. The MEDICAL RECORD is the source whence many and certainly the most interesting of the news items of the *Recorder* are derived. The members of the Chicago Medical Society should suggest to their editor the propriety of giving credit for matter taken verbatim from other journals.

A German Gynæcological Clinic.—Dr. Ernest B. Sangree thus describes, in the *Times and Register*, what he saw in Winckel's clinic at Munich: "Four large sofas and soon three half-dressed women shuffling in, each of whom was conducted to a sofa, on which she reclined. The fourth sofa was pushed aside to make way for a bed wheeled in, on which was a sallow, thin, very sick-looking woman, too ill to walk. To each of these women a student was assigned, with instructions to make a diagnosis. Along with the patients the "exhibits" were brought in. In plain view and near the women was a small table with several pans, two

of which held underdone babies, one much macerated and the other apparently born dead and before its time. A tumorous uterus with its appendages, the results of an autopsy, and a large multiple fibroid from one of the women, completed the side lights. All these were quite uncovered, and I saw each woman take a nervous glance and try to look another way, while the very sick one trembled like a leaf as her eyes fell on them, and ever and anon returned as if fascinated by the ghastly objects."

The Anatomico-Biological Institute of Berlin.—The second Anatomical Institute of the Berlin University, of which Prof. O. Hertwig is the chief, has been reorganized, and is in future to be called "Anatomico-Biological Institute." The institute will be devoted to work on the borderland of anatomy and physiology. It has three departments—one for histological research, one for embryological work, and one for comparative anatomy.

Dr. Carl Beck has resigned his professorship at the New York School of Clinical Medicine.

Craig Colony Prize for Original Research in Epilepsy.—The president of the board of managers of Craig Colony offers a prize of $100 for the best contribution to the pathology and treatment of epilepsy, originality being the main condition. The prize is open to universal competition, but all manuscripts must be submitted in English. All papers will be passed upon by a committee, to consist of three members of the New York Neurological Society, and the award will be made at the annual meeting of the board of managers of Craig Colony, October 10, 1899. Each essay must be accompanied by a sealed envelope containing the name and address of the author, and bearing on the outside the motto or device which is inscribed upon the essay. The successful essay becomes the property of the Craig Colony, for publication in its annual medical report. Manuscripts should be sent to Dr. Frederick Peterson, 4 West Fiftieth Street, New York City, on or before September 1, 1899.

Bequests to Hospitals.—Mrs. Lucretia A. Wilder, whose will was recently filed in the Suffolk probate office, left about $16,000 to the Winchester Home for Aged Women in Charlestown, the Massachusetts General Hospital, and the Boston Homœopathic Hospital, in equal shares.

An Anti after Revenge and Cash.—The editor of the *Verulam Review*, a rabid antivivisectionist, having been sharply taken to task by the *British Medical Journal* for intemperate statements as to the acts of certain investigators, has lost his temper and announces his intention to sue the editor of the latter journal for libel.

Contract Surgeons in England.—The surgeons of the collieries and the lodge doctors in Durham have inaugurated a movement to obtain better pay for their services. The present fee of the colliery surgeon is a shilling a month from each collier, and for this sum he is expected to treat the entire family and to furnish all needed medicine.

Medical Mayors.—Among the mayors elected in the principal cities and towns of England and Wales, the second Wednesday of November there were no less than nineteen medical men.

A Bullet Embedded in the Heart for Thirty-Seven Years.—A correspondent of the *Baltimore Sun*, writing from Morgantown, W. Va., asserts that a man named William B. Smallridge, who died a few days ago at Glenville, in Gilmer County, carried a bullet in his heart for thirty-seven years. He was a member of company E, first West Virginia infantry, in the civil war, and in September, 1861, while marching through Gilmer County, was shot by some one in ambush, the bullet entering Smallridge's chest at the lower point of the scapula, on the left side, passing thence directly through the left lung into the left ventricle of the heart. The force of the bullet was so broken that it did not penetrate the inner wall, but the regimental surgeon pronounced the wound fatal and left Smallridge to die. He did not die, however, but was sent back up the Little Kanawha River in a skiff to his home, in Glenville, where he recovered and has since lived. A few weeks ago, while on his death bed, he asked Dr. G. O. Brown to make an examination of the wound after his death. This Dr. Brown and Dr. O. B. Beer did and found the bullet embedded in the heart. The man had never suffered from any disturbance of the heart. His death was due to cancer. This report is confirmed by Dr. Beer in a letter in the Cincinnati *Lancet-Clinic* of November 19, 1898.

A Monument to a Plague Victim.—It is proposed to erect a monument to the memory of Dr. Franz Hermann Müller, who died a short time ago of the plague in Vienna. A committee has been formed for the purpose, under the chairmanship of the dean of the medical faculty, Professor Puschmann.

A Dog Quarantine.—The Pennsylvania State board of health has established a three months' quarantine against all the dogs in a village in the northern part of the State, in which there had been almost an epidemic of hydrophobia among the cattle, hogs, and dogs.

The Indian Territory Medical Association will hold its semiannual meeting at Wagoner on December 6 and 7, 1898, under the presidency of Dr. G. R. Rucker, of Eufaula. Dr. LeRoy Long, of Caddo, is the secretary of the association. The programme contains twenty-one titles of papers promised by the members in the sections of medicine, obstetrics and gynæcology, and surgery.

Another Medical College Burned.—The building of the Indiana Medical College, the medical department of the University of Indiana, at Indianapolis, was burned early on the morning of November 25th. Dr. Norman Shobe, who was in the building and attemped to escape by means of the stairway, was caught between the second and third floors and was very severely burned. He was rescued later.

Typhoid Fever is prevailing to an unusual extent in London this autumn.

Reviews and Notices.

Atlas of Syphilis and the Venereal Diseases: Including a Brief Treatise on the Pathology and Treatment. By Prof. Dr. Franz Mracek, of Vienna. Edited by L. Bolton Bangs, M.D. Philadelphia: W. B. Saunders. 1898.

It is especially the colored plates which make this work attractive and useful. The descriptions are certainly much more readily grasped by the student and practitioner of limited clinical experience in syphilis and allied affections by the presentation of cases in this way. It is not a complete treatise, but one to be studied in conjunction with more extensive works. The illustrations are for the most part quite good. The chapter on gonorrhœa is short, but the treatment outlined for this as well as for its sequelæ and complications is sufficient to meet the average needs.

Manual of Chemistry. A Guide to Lectures and Laboratory Work for Beginners in Chemistry. A Text-Book Specially Adapted for Students of Pharmacy and Medicine. By W. Simon, Ph.D., M.D., Professor of Chemistry and Toxicology, College of Physicians and Surgeons, Baltimore; Professor of Chemistry in the Maryland College of Pharmacy. New (Sixth) Edition. In one 8vo volume of 532 pages, with 46 engravings and 8 colored plates, illustrating 64 of the most important chemical tests. Philadelphia and New York: Lea Brothers & Co.

In putting forth a new edition of this carefully prepared work there have been additions and subtractions, both resulting in a betterment of the whole. There are seven subdivisions of the subject, appropriately led off with the fundamental properties of matter and the results of attractions between masses, surfaces, and molecules. In the second chapter are given the theoretical views on the atomic constitution of matter. This subject, surrounded as it is with difficulties, has been elaborated in such a way as to appear clear to one whose knowledge of chemistry is limited. A feature of the work which will interest the pharmacist and student of pharmacy is the fact that all chemicals mentioned in our "Pharmacopœia" are included. Laboratory work will be facilitated by the chapter (v.) devoted chiefly to analytical chemistry. After treating of organic chemistry the author finishes the work with a chapter prepared especially in the interest of students of physiological chemistry. Throughout the newer methods have been incorporated, and attention has been paid to those relating to clinical examinations in the detection of disease.

Preliminary Report of an Investigation of Rivers and Deep Ground Waters of Ohio as Sources of Public Water Supplies. By the State Board of Health. 1898.

The splendid work of the Massachusetts State board of health on the water supplies of that State has stimulated other commonwealths to examine their own potable waters, and reports have been issued from various State boards with more or less regularity ever since. Many of these reports have more enthusiasm in them than intrinsic merit, and still others show the cloven hoof of the political job printer, while still others have accurate and worthy information to convey. It is somewhat difficult to say to which class this present report belongs. On the whole it gives some very useful local information, of interest to the health of the property owners of Ohio, but of no scientific value to the outside hygienist. The elaborate plottings of the chemical constituents seem to indicate that the chemist was doing his work; but what do they tell us? So with the numbers of bacteria to the cubic centimetre, contributed by the bacteriologist; what bacteria were they? From some points of view the publication is to be commended; from others, and those which we consider the more lasting, it is worthless.

Clinical Lectures on Mental Diseases. By Thomas S. Clouston, M.D., Lecturer on Mental Diseases in the University of Edinburgh. New (Fifth) edition. Crown 8vo, 750 pages, with 19 full-page colored plates. Philadelphia and New York: Lea Brothers & Co.

The rapid succession of editions of Dr. Clouston's book disarms the reviewer at the outset; and, indeed, the "Clinical Lectures" have been so recently mentioned in these columns that brief notice only is necessary now. The present edition is mostly a reprint from the last, although several new plates illustrating degenerative processes in the neurons have been added. It is essentially as a clinical treatise that the book has gained its great popularity. Its delineations of clinical types are of the first rank. But there is too little consideration, even for a clinical treatise, of the lights now being thrown on psychiatry by the bordering sciences of biology, of chemistry, and of normal psychology, to entitle this work to the foremost place in its class.

Student's Histology. A Course of Normal Histology for Students and Practitioners. By Maurice N. Miller, M.D., etc. Revised by H. U. Williams, M.D., etc. Third Edition. Illustrated. New York: William Wood and Company. 1898.

This work, a third edition of which is now offered, is, according to its title, a manual for the use of the student. As such it serves its purpose well and we are glad to recommend it. The illustrations have the diagrammatic quality which is of value in a drawing intended to teach something, especially to the mind considering a subject for the first time. Clearness of presentation and accuracy are of more value in a work of this kind than is originality, and in this respect the book is a success. The previous editions of the book have settled its high place, and this later one has increased its value. A student's manual upon histology is essentially a laboratory guide.

Notes on Disinfectants and Disinfection. By A. G. Young, M.D., Secretary of the State Board of Health of Maine. From the Tenth Annual Report. 1898.

This is more than an ordinary compilation from text-books concerning what is known of the subject of disinfection. It is a timely contribution to the subject and is well done.

The Book of Leviticus. A New English Translation, Printed in Colors Exhibiting the Composite Structure of the Book, with Explanatory Notes and Pictorial Illustrations. By the Rev. S. R. Driver, D.D., Regius Professor of Hebrew, and Canon of Christ Church, Oxford; Assisted by the Rev. H. A. White, M.A., Fellow of New College, Oxford. New York: Dodd, Mead and Company. London: James Clarke and Company. Stuttgart: Deutsche Verlags-Anstalt. 1898.

The Bible, or any part of it, is not the kind of literature that is in an ordinary way sent to a medical journal for review. When, however, it is understood that the portion under discussion is the book of Leviticus, and furthermore that the aim in this latest revision has been to render the sense as faithfully as possible rather than to sacrifice that sense in order to give a literal translation, and that the translation is made directly from the original Hebrew, there will not be so much cause for surprise. Leviticus, as is well known, is that book of Moses containing the regulations as to the mode of killing animals for sacrificial purposes and the hygienic ordinances of the Jewish people; thus there occur many points appertaining to medical matters. The laws of the Jews in regard to what they should eat were sufficiently clear and comprehensive, and were calculated to promote good health. The knowledge of leprosy in its different features possessed by the Jews was, for the times in which they lived, curiously accurate, although of course the fact that the disease was and is still very prevalent in and about Palestine must be taken into consideration. They seem to have recognized three varieties: the common white leprosy, tubercular elephantiasis, and anæsthetic elephantiasis. When the priest delivered judgment that a person was suffering from either of the latter forms, strict segregation was ordered. It should be observed, however, that contagion due to human leprosy is nowhere suggested, and also that there would appear to have been a belief that the disease was curable. The chapter dealing with the laws of purification is very interesting, and tends to show that the Jews in those far-off days were not unacquainted with venereal disease. The book of Leviticus in its new form proves more clearly than ever that the Jews, or rather the Israelites, had an intelligent conception of the laws relating to personal hygiene. In the present translation of Leviticus the main sources have been separated from one another and the laws distinguished by means of colors arranged according to their date of origin. The volume is beautifully printed and gotten up, and is embellished by some good illustrations. There can be no doubt that the series of which Leviticus is one will be received with great interest by students of the Bible.

Therapeutic Hints.

Scarlatinal Nephritis.—The chief aim should be to prevent the retention of these products by the organism, in two ways: (1) By combating the nephritis itself; (2) by heightening the excretory functions of the skin and the intestines, or supplementing them by suitable means. To fulfil the first indication—*i.e.*, to lessen the formation and spread of the toxins—the most efficacious means are: more or less absolute milk diet, according to the gravity of the case, combined with hydrocarbons; proscribing absolutely meat and eggs; rest in bed for three weeks at least; alkaline waters, Vichy particularly; pure air, constantly changed. The second indication is met by giving diaphoretics and purgatives and using other means to heighten the activity of skin and bowels for the elimination of the toxins, thus relieving the kidneys. As soon as albuminuria disappears, cutaneous perspiration also increases; to aid in this increase have recourse to warm baths and hot compresses—the air of the room should be uniformly warm; 95° F. for fifteen or twenty minutes at a time; purgatives, enemata of warm water, and infusion of senna. Calomel is to be avoided.—KONTREBINSKY.

Treatment of the Various Forms of Albuminuria in Diabetes Mellitus.—Dr. Carl Grube, of Neuenahr, Germany (*British Medical Journal*, July 23d), says: "As regards the treatment of the functional albuminuria, the chief object we have to attain is the reduction of the irritation of the kidneys. This we accomplish by diminishing the glycosuria, which, as every one who has had any experience of the disease knows, can be done satisfactorily only by dieting. In cases of real chronic nephritis it is often difficult to treat both affections satisfactorily, and one has to try not to do harm in one way by doing good in the other. If, as sometimes occurs, the glycosuria ceases altogether, or at least becomes quite inconsiderable, as the nephritis develops, the treatment is somewhat easier, as the dieting gives less trouble. On the whole, the prognosis in these cases is very grave. The cessation of the glycosuria seems to show that the tissue of the kidneys is more changed than in those cases in which there is still some excretion of sugar. If milk is well tolerated I prescribe it freely. Mineral waters can be beneficial, especially those of Neuenahr, after the use of which I have sometimes seen decided improvement. If the patient has sufficient strength warm baths may be made use of with advantage. They relieve the kidneys by increasing the action of the skin. That it is essential to keep these patients quiet, or even in bed for some time, and to avoid everything that could increase the irritation of the kidneys, need scarcely be pointed out."

Recurrent Epistaxis.—

℞ Antipyrin 0.5
Tannin 1
Powdered sugar 10
M. S. Use locally.

—RENDU.

Influenza with Nervous Symptoms.—

℞ Quininæ salicyl 20
Phenacetini 15
Camphoræ 0.2
M. div. in dos. æq. No. x. S. Two to six powders daily.

—BACCELLI.

Pertussis.—

℞ Antipyrin ..... gr. ss.–ij.
Ammonium bromide ..... gr. i.–ij.
Ammonium muriate ..... gr. v.
Syrup ..... q.s. ad ʒ i.
M.

Iron Diuretic.—

℞ Tinct. ferri chloridi ..... ʒ iv.
Potass. acetatis ..... ʒ iv.
Syrupi simp. ..... ʒ ij.
Aquæ ..... ʒ ij.
M. Two or three teaspoonfuls four times a day.

This is pleasant to take and effective. It forms the acetate of iron, the same as in Basham's mixture.—J. D. ALBRIGHT.

Diuretic in Chronic Interstitial Nephritis.—

℞ Ferri citratis ..... ʒ ij. ℈ij.
Potassii citratis ..... ʒ v. ℈i.
Syrupi limonis ..... ʒ ij.
Aquæ ..... q.s. ad ʒ viij.
S. Take a dessertspoonful before each meal, well diluted.

—DR. I. N. DANFORTH.

Acute Colic.—

℞ Chloroformi ..... ʒ iss.
Tinct. opii deodorat ..... ʒ i.
Camphoræ ..... gr. iv.
Ol. cajuputi ..... ʒ i.
Aquæ ..... ʒ ij.
M. S. One teaspoonful every hour or two.

Post-Partum Hemorrhage.—

℞ Ergotin ..... ʒ ij.
Chloral ..... ʒ ss.
Distilled water ..... q.s. ad ʒ i.
M. S. Ten or twenty minims injected deeply into the muscles of the buttock.

—SIR JAMES YOUNG SIMPSON.

Diuretic Pill.—

℞ Scillæ pulv.,
Digitalis pulv.,
Caffeinæ citratis ..... āā ʒ ss.
Hydrarg. chlor. mitis ..... gr. v.
M. ft. pil. No. xxx. S. One pill three times daily after meals.

—*Practitioner.*

Vomiting.—In obstinate cases of vomiting after surgical operations, try the popular prescription:

℞ Spiritus chloroformi ..... ♏ viij.
Aceti opii ..... ♏ iij.
Mucilag. acaciæ,
Aquæ ..... q.s. ad ʒ i.
Repeat every hour.

Or:

℞ Hydrarg. chlor. mit. ..... gr. $\frac{1}{10}$
Cerii oxalatis ..... gr. ij.
Codeinæ sulphatis ..... gr. $\frac{1}{8}$
Ft. chart. Give at intervals of half an hour until four or five powders have been administered.

—DR. THOMAS L. RHOADS.

Acute Diarrhœa.—

℞ Sodium bicarbonate ..... ʒ i.
Aromatic spirit of ammonia ..... ʒ iij.
Comp. tinct. of cardamom ..... ʒ vi.
Cinnamon water ..... ʒ vi.
Dose, two tablespoonfuls every two or three hours.

—DR. BURNEY YEO.

Coccygodynia.—

℞ Ext. belladonnæ ..... gr. $\frac{1}{4}$
Ext. hyoscyami ..... gr. $\frac{1}{4}$
Iodoformi ..... gr. $\frac{1}{4}$
Ol. theobromæ ..... gr. xx.
M. et fiat suppos. No. i. S. Use at bedtime.

—WHITLA.

Fissure of the Tongue.—

℞ Acidi carbolici ..... 1.5 parts.
Tinct. iodi ..... 5 "
Glycerini ..... 15 "
M. S. For local application with a camel's-hair brush.

—*Monatssch. f. Dermatol.*

Irritable Bladder.—

℞ Salol ..... ʒ ij.
Tincture of hyoscyamus ..... ʒ ij.
Infusion of buchu ..... q.s. ad ʒ vi.
M. One tablespoonful three times daily.

Ulcers of the Leg.—

℞ Carbolic acid ..... gr. xxx.
Boric acid ..... ʒ iiss.
Powdered camphor ..... ʒ ij.
Ichthyol ..... ʒ v.
Oil of sweet almonds ..... ʒ iiss.
Zinc ointment ..... ʒ iij.
M. S. Apply topically.

—Elden.

Treatment of Lupus Erythematosus.—Dr. P. G. Unna, in a discussion on the nature and treatment of lupus erythematosus in the *British Medical Journal*, September 10th, draws up a short scheme of treatment for the practical physician. A cautious treatment may begin with bandages of lead water at night or the application of a powder bag, and during the day with a dusting powder or a zinc-sulphur paste, with ichthyol or resorcin eventually to be rubbed in, or a gelanthum with ichthyol or soft soap, or with both, may be prescribed for the night. Under this treatment the inflammation subsides, and it will be possible to distinguish the indolent from the irritable patches. If the latter show signs of fixed œdema, collodion with soap or ichthyol may be applied, while in cases of darker redness it may be advisable to use the micro-cautery. In addition to these dressings an external application may be used at night, consisting of lead water, ichthyol, or very weak caustic potash (1 in 10,000) solution. On the other hand, the indolent patches require more vigorous management, as by the soap treatment, which may be easily modified in strength and quality by use of the lather of soft soap, salve soap, or mercurial soft soap. These patches are best covered immediately after such a treatment by a wet bandage, and zinc-oxide mull or mercury-plaster mull. Strongly hyperkeratotic patches require before the soap treatment a peeling off process by means of salicylic soap-plaster mull. The patches on the scalp should be treated thoroughly with soft soap and then covered with ointment. In cases of anæmia, flushings of the face, or when digestion is disturbed, an appropriate plan is to give ichthyol internally during the whole course of treatment. Such a treatment, it is true, does not always work *cito*, but it does work *tuto*, and also comparatively *jucunde*.

Pultaceous Sore Throat in Children.—

℞ Calcium permanganate ..... 0.10–0.20 cgm.
Distilled water ..... 20 gm.
M. For external use

The throat is washed out with a very warm boric lotion every three hours during the day, and once or twice during the night. After each washing, the affected parts are painted with the above solution, care being taken to detach the false membranes, but without undue force.—Monmarson.

Hoarseness in Singers.—Singers' nodules are the result of faulty methods of singing, especially of that part which has to do with the tone placing. What is especially interesting to us is that on correction of this fault, and systematic exercise which has for its purpose the placing of the tone well forward, will cause the disappearance of the nodules without the necessity of removal by caustics or crushing forceps, as recommended in most works on laryngology.—F. A. Bottome.

In Acute Gouty Cystitis.—Rest in bed, with a slop diet and diluent drinks, is most necessary for an amelioration of the condition. It is surprising how rapidly patients improve under full doses of colchicum without any local treatment. By local treatment I mean hot baths, for unless the urine should become foul and necessitate attention it is the worst thing for the patient to attempt to wash out his bladder—first, because it is unnecessary, and, secondly, because the irritation of the catheter and lotions intensify the inflammation. Among other drugs to be taken internally besides hyoscyamus, colchicum, potash, uva ursi, and buchu, are the more modern preparations, such as piperazin or urecidin. My experience with lithia is that while it undoubtedly does good in chronic cases its administration in acute cases is apt to intensify the condition. —Mr. Campbell Williams, *The Clinical Journal*, September 28th.

Malaria.—In a clinical lecture, published in the *Tri-State Medical Journal and Practitioner*, Dr. Francis Delafield, of New York, says: "An arrangement which works here in New York is a combination with the quinine of acetanilid and arsenious acid:

℞ Quininæ sulphatis ..... gr. iij.
Acidi arseniosi ..... gr. $\frac{1}{60}$
Acetanilid ..... gr. ij.
M. et ft. capsula No. i. S. Take four in the twenty-four hours.

Now, why this combination is better than quinine alone, or when arsenic is added, or why adding two grains of acetanilid makes it more efficacious than one-thirtieth of a grain of arsenious acid and three grains of quinine, is a question I cannot answer. I have found that it is so by personal experience; I found that the adding of the acetanilid gave me such results that I could not get along without it. I do not give large doses of quinine alone. I have been treating malarial fever in New York for twenty years, and I find that just such a combination of drugs answers very well in my hands; it is even better than Warburg's tincture."

Snake Bites.—

℞ Hydrarg. chlor. mitis,
Pulv. rhei ..... āā 2 gm.
M. S. Take at once.

Follow this with six decigrams of calomel, to be taken every six hours until five doses are taken. The infected spot should first be disinfected.—*Tribune Medica*, Rio de Janeiro.

Dentition.—

℞ Cocainæ hydrochlorat ..... gr. iiss.
Chloroformi ..... ♏ xvi.
Glycerini ..... ʒ vss.
Ess. rosæ ..... gtt. vi.
M. S. Apply, with friction, to the tender gums.

—Champret.

Rhus Poisoning.—

℞ Ammonii muriat ..... ʒ i.
Aquæ ..... ♁ ij.
M. S. Keep the parts wet with absorbent cotton soaked in this solution.

—A. V. Hudson.

Croup.—

℞ Eucalypti ..... 50 gm.
S. Use as a vapor, obtained by means of pulverizers placed near the bed of the child.

—Bonamy, of Nantes.

Diabetes.—My experience leads me to dissent entirely from the proposition implying that danger of producing diabetic coma is in a general way to be apprehended in severe cases by the sudden adoption of the diabetic dietary. I believe the notion is founded upon pure conjecture, and consider that the cases in which it would be inadvisable to commence at once with the fully altered diet are so rare that they may practically be regarded as constituting a negligible quantity.—F. W. Pavy.

Delirium Tremens has been successfully treated by means of hypodermic injections of sulphate of atropine. In almost all cases a dose of one-sixtieth of a grain produced deep sleep.—Tonvime.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

One Hundred and Forty-Second Regular Meeting, Friday, November 4, 1898.

DR. W. GILMAN THOMPSON, PRESIDENT, IN THE CHAIR.

A Case of Pneumo-Hydrothorax was presented by DR. ALEXANDER A. SMITH. The patient was a man, forty years old, who, in January, 1898, after exposure, had an attack of illness which his physician pronounced grippe; his symptoms were those of a severe cold, and it took him about three months to recover his usual health. In July, after again exposing himself, he was seized with a chill, and soon developed a severe pain in the side. A pleurisy on the left side was made out, and during the course of his illness he was tapped three times, from fifteen to eighteen ounces of fluid being withdrawn from the pleural cavity at each tapping. The patient claimed that from the onset of this attack he could hear a peculiar sound in his chest. In October, 1898, he came under Dr. Smith's care in Bellevue Hospital, with the evidences of a pneumo-hydrothorax well marked. The speaker said that at the present time the heart was displaced to the right, and there was complete dulness over the left lower chest. When the man shook himself, a splashing sound was produced, which could be heard for a considerable distance. He complained of some cough, and tubercle bacilli had recently been found, for the first time, in his sputum. The patient had stated that he had never experienced any severe pain, as was usual in these cases. He had a slight evening rise in temperature, and his weight fell from one hundred and ninety to one hundred and thirty-three pounds, this latter in August. Since then he had regained some of the lost weight. He now weighed one hundred and forty-eight pounds, having gained three pounds since he came to the hospital two weeks ago. It seemed remarkable that the man could remain so comparatively comfortable, and even improve so much, with the evidence present of a pulmonary tuberculosis and pneumo-hydrothorax.

DR. E. G. JANEWAY said he had observed only two cases of this kind which had ended in recovery. He thought it well to allow the fluid to remain in the pleural cavity, as it was really a conservative process, compressing the lung and retarding the progress of the tuberculosis. As an illustration of how well a person can get along with the use of only one lung, Dr. Janeway mentioned the case of a man, now under his observation, whose left lung, as the result of some growth or condition — probably congenital—was practically solid. At various periods in this patient's life he had been told by physicians in this country and abroad—among the latter, Erb—that he had pleurisy with effusion. Dr. Janeway said he also had held that opinion until he had introduced a needle into the man's pleural cavity in five different places, and had failed to withdraw any fluid. The heart was displaced three inches to the right. This patient's right lung was in fairly good condition, and he suffered no inconvenience; he enjoyed mountain climbing and had ascended Pike's Peak and a number of the higher mountains in Switzerland.

A Plea for Earlier Recognition and Prompter Action in Malignant Disease.—This paper was presented by DR. JOSEPH D. BRYANT (see page 793).

DR. ROBERT ABBE said that the proposition contained in Dr. Bryant's paper appealed to surgeons more strongly every day, they being brought to face neglected cases which might have been regarded with increasing hope if seen earlier. The earlier a malignant growth was attacked, the more thoroughly and easily could it be removed, with less likelihood of a recurrence. The speaker said he wished to refer to a point not strictly apropos of the purpose of the paper, but bearing on the subject. During the past two years he had seen a number of cases in which a cancer of the breast had recurred in the form of minute nodules in the lymphatics of the skin—not in the subcutaneous tissue—and he was inclined to attribute such recurrences to infection of the skin at the time of operating; previous to such an operation the assistant usually gave the skin a vigorous scrubbing with a coarse brush, rubbing away from the seat of the trouble. Recently, Dr. Abbe said, he had done away with this vigorous method of cleansing the field of operation, relying merely on simple sterilization by local applications. By so doing he hoped to avoid one possible source of spreading the infection.

DR. CHARLES MCBURNEY said that few surgeons would disagree with the conclusions of Dr. Bryant. Perhaps the most important point which had been raised was that in regard to the early recognition of malignant disease. The speaker said that, while he had no statistics to bear out his statement, he was of the opinion that just as many cases of cancer too far advanced for radical operative interference were presented to the surgeon to-day as was the case fifteen or twenty years ago. In spite of the wider dissemination of knowledge in regard to this disease among the laity and general practitioners, and the greater faith in surgeons, the proportion of suitable cases presented for operation remained apparently unchanged. Very few cases of cancer of the breast, for example, were brought to the surgeon during the best period for operation, namely, when only a small tumor had developed, without dissemination. Not uncommonly the general practitioner kept such a case under his observation for six months or a year, and then brought it to the surgeon with the statement that he "had kept it until it was ready for operation." In one instance coming under the speaker's observation, in which a tumor of the breast was as large as a man's closed fist and a number of glands in the axilla were as big as horse chestnuts, the physician who brought the patient had stated that he had kept her under his own care "until just the right time." The delay in asking for operation might be due to the ignorance of the patient or to her aversion to having anything done, or it might be due to the desire of the attending physician to treat the case himself by simple and pleasing methods. Some of these obstacles to early operation would continue in the future as they had in the past.

Dr. McBurney said that he had the highest faith and confidence in surgical measures as applied to malignant disease in many parts of the body, when undertaken early and applied with a free hand along intelligent lines. The speaker said it had never occurred to him that a recurrence of the disease in the lymphatics of the skin after amputation of the breast was attributable, as suggested by Dr. Abbe, to infection of the skin by too vigorous cleansing methods employed previous to the operation, nor did he regard that as a very likely cause of recurrence. Tendency toward the formation of secondary carcinomatous nodules in the skin usually showed itself at the first examination, and was as common among those who totally neglected cleanliness as among the better class of patients who gave daily attention to cleansing the skin.

DR. JANEWAY said that while the statement was self-evident that the sooner an accessible malignant growth was removed the better, the patient frequently objected to operative interference. The objection usually raised by such patients was that they had a friend or relative

or knew of a similar case in which such an operation was done without avail. The speaker said that he himself had been struck by the large percentage of recurrences after operation for malignant disease. The number of recurrences would no doubt decrease with improved technique and an earlier recognition of the nature of the disease. In regard to cancer of the breast, such a tumor was not infrequently overlooked by the patient until it had attained quite a large size. An objection that had been raised against early operation in this class of cases was that a number of instances were reported in which the breast was removed for conditions which proved to be non-malignant. So far as cancer of the stomach was concerned, it would probably be a long time before early operations would be resorted to for the relief of this condition, on account of the difficulties of early diagnosis. Besides, a gastro-enterostomy, with a permanent fistula and its accompanying discomforts, for the purpose of prolonging the patient's life for a brief period, was not very attractive.

Dr. Andrew H. Smith said he knew of a number of cases in which a tumor which was situated on the under side of a pendent breast had escaped attention for some time. When the tumor was located on the upper portion of the gland, it was more apt to be observed early. The speaker said that not all general practitioners were guilty of the sin of negligence of which they were so frequently accused by the surgeon. In a case which came under his observation last summer, the attending physician was apprehensive he had to deal with a case of cancer of the breast and inclined to advise its immediate removal. The case proved to be one of abscess of only ten days' standing, and rapid recovery took place when the pus was evacuated.

Dr. George F. Shrady said that too much stress could not be laid on the great importance of the early recognition and surgical treatment of malignant disease. The speaker said he could hardly accept the theory of Dr. Abbe, that after an operation for cancer of the breast a recurrence in the shape of nodules in the lymphatics of the skin was attributable to roughly handling or rubbing the skin previous to the operation. It was more probable that the skin had already become infected by that time, and Dr. Shrady said he was inclined to the opinion that such recurrences were more apt to occur in cases in which adhesions of the skin to the tumor existed. In such cases, in order to avoid a recurrence, he left an unusually wide area instead of trying to save the skin for flaps, as the surgeon was tempted to do. In operating in these cases, he made large curved sliding flaps at right angles to the long axis of the wound-incision, which permits one to cut away a large strip of skin and still close the gap. This method was described in the Medical Record, December 2, 1893. The speaker said that in those cases in which he had resorted to this incision, no recurrent nodules had appeared. We should strive to educate both the profession and the laity to appreciate the importance of the fact that a tumor of the breast in a woman past forty should not be neglected.

Dr. Beverley Robinson said he was inclined to agree with the statements made by Dr. Janeway. He could recall a number of cases of cancer which were operated on as early as one could reasonably expect, in which the operation did not prove very beneficial to the patient. In one case now under his observation, that of an old woman who was twice operated on for cancer of the breast, there was now an infiltrated condition of the arm and forearm, which was very painful and for which practically nothing could be done. Dr. Robinson said he did not agree with the statement made by one of the speakers, that a tumor of the breast was not infrequently overlooked by the patient until it had attained considerable size. Women were apt to detect any abnormal condition of the breast very soon, and any well-informed general practitioner who saw such a case was always ready and willing to call in the surgeon.

Dr. Bryant, in closing, said that his chief purpose in presenting the paper was again to call attention to the great importance of the early recognition of malignant disease, and its prompt and thorough surgical treatment. When the condition in which many of these patients were brought to the surgeon to-day was taken into consideration, the results of operative treatment were as good as could be expected. In a recent article in the *Annals of Surgery*, Dr. Halsted had reported that fifty-two per cent. of his cases of cancer of the breast had passed the three-year limit. The extensive excision practised by that surgeon was well known. In his article he stated that in his cases a recurrence was more common in a distant part than in the adjacent tissues; a recurrence in the latter locality, he argued, was due to incomplete removal or to infection at the time of operation, perhaps as suggested by Dr. Abbe. In any case in which a tumor of the breast existed and which was regarded as innocent, the latter fact should be proven by an exploratory incision, if necessary. No such growth should be left if there was any doubt as to its true nature. The fact that many of these operations gave only temporary relief, as suggested by Dr. Janeway, was well known; but this only emphasized the importance of earlier operative interference. By operating early we reduced the mortality and offered the patient greater chances for permanent relief. It was true that sometimes these tumors existed for some time without the knowledge of the patient; in other cases they had a knowledge of such a growth, but kept it to themselves; while there were still others who consulted a physician or surgeon regarding it, and begged that if it was anything serious the fact should be kept from them. It was unwise for the medical attendant to request a patient to call and see him if the tumor increased in size or if another followed operation. The patient should be examined by a physician as often at least as once a month or so, until the time limit of return was long passed.

A Hairpin Extracted from the Female Bladder.—Dr. Robert F. Weir showed a hairpin which he had extracted from the bladder of a young woman. The patient explained that about three months previous to the operation she had used the pin for the purpose of wiping away a bit of discharge from the meatus urinarius, when a sudden knock at the door so startled her that she let go of the pin and it slipped into the bladder. A searcher was introduced into the woman's bladder, but the foreign body could not be recognized by its touch; in a certain portion of the bladder, however, the beak of the instrument turned downward caught on something. The bladder was so irritable that the patient was etherized, and the urethra dilated until the finger could be introduced into the bladder, which recognized the pin; but repeated efforts with forceps and lithotrites failed to detect or catch the foreign body. Finally, with one finger in the bladder and a finger of the other hand introduced into the vagina, after considerable manipulation the rounded end of the hairpin was coaxed into the urethra and then withdrawn with a forceps. Although the hairpin had been in the bladder about three months, it was entirely free from phosphates, but was covered by a tenacious mucus.

Dr. Weir mentioned a similar case which had come under his observation some years ago. In that case the young woman said she had accidentally sat down on the hairpin, and it entered her bladder, where it remained eight months. It was thickly incrusted with phosphates, except at its free ends.

Dr. W. T. Bull said it was rather exceptional that

so resisting a foreign body as a hairpin should escape the ordinary methods of detecting its presence in the bladder. In a similar case which came under his observation some years ago, it was perfectly easy by bimanual palpation to make out the position of the pin and to extract it by means of a bent probe. In cases in which this was not feasible, an *x*-ray picture might prove of value, and would be preferable to such extreme dilatation of the urethra as that practised in Dr. Weir's case.

Dr. Weir said that there had been no incontinence of urine following the dilatation.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, November 21, 1898.

George Tucker Harrison, M.D., President.

Stricture of Œsophagus after Typhoid Fever; Gastrostomy.—Dr. Frederic S. Dennis presented a case of stenosis or stricture of the œsophagus following typhoid fever. The patient was a man who had enjoyed perfect health up to the attack of typhoid fever, about one year ago. Following this illness the œsophagus became obstructed and, after six months, entirely occluded. For months he was unable to swallow anything, and was nourished by rectal enemata and occasionally by a little milk which could be passed through the œsophagus. When first seen he was greatly emaciated and cyanotic in appearance, and his temperature was subnormal—in other words, he was starving. Gastrostomy was done last March in such a way as to leave a fistulous opening without any peritoneum in contact with it, and consequently it had remained patent. Although this man had not taken anything by mouth since the operation, he had gained seventy-eight pounds, his weight now being one hundred and sixty-eight instead of ninety pounds, as it was at the time of the operation. This was good proof of the excellent nutrition that had been maintained notwithstanding the gastric fistula. This case was one of the two to which Dr. Keen had referred in his paper last spring on "Surgery of the Stomach." The stricture of the œsophagus was produced during the healing of a typhoid ulcer.

Tuberculous Joint Disease.—Dr. Dennis also presented two cases illustrating tuberculous joint disease. In the first case, that of a young man, about six inches of the humerus had been taken away eleven years ago, and the patient was presented in order to show the extent of motion that could be preserved after such an extensive resection. The second case, also in a young man, was one of tuberculosis of the joint, in which the soft structures of the joint alone were affected. The disease developed after an injury to the joint. When he first came under observation, there was a sinus discharging pus. The sinus was laid open, and all of the soft structures were removed. As the bones were found to be denuded of periosteum but free from necrosis, they were left undisturbed—in other words, the operation consisted in a resection of the elbow-joint for tuberculous joint disease without removal of any of the bones. Since the operation the joint had been stuffed with iodoform gauze and injected thoroughly with an emulsion of iodoform and glycerin. The result was an exceedingly satisfactory one, and the motion in the joint was increasing daily.

Lupus Erythematosus with Probable Malignant Degeneration; Long Duration.—Dr. Robert Abrahams presented a woman, eighty-one years of age, who, forty-two years ago, noticed a small pimple on the middle of the left cheek. After a while several similar papules appeared on the same side of the face, and then she observed that at times some of these papules became depressed, and that there was a decided tendency to extend at the periphery. Although the patient had visited the most celebrated medical centres of the world, she had obtained no benefit from medical treatment. At the present time the whole left side of the face—cheeks, eyes, eyebrows, and ear—was the seat of a typical lupus erythematosus. There was a small elevated mass on the cheek, which seemed to him to merit special attention. For many months he had noticed a gelatinous mass in one of the atrophic areas on the cheek, and a few weeks ago this began to ulcerate. It now bled freely. His provisional diagnosis of this lesion was flat epithelioma. The case was presented not only on account of its very typical appearance and the great extent of the lesion, but because of the remarkable duration of the disease—forty-two years. Fifteen or twenty years usually constituted the limit. Another interesting feature was the possibility of malignant disease supervening upon lupus erythematosus.

Osteomyelitis of Tibia.—Dr. Thomas H. Manley presented a young man who had come under his observation about two years ago. About one year previously the right knee had been wrenched during a game of football, and subsequently synovitis had developed. Notwithstanding prolonged treatment in hospital he was not benefited. Examination showed osteomyelitis of the head of the tibia; consequently he had made an opening with a drill, and had evacuated the pus. Improvement had been very marked after this, and the man had recovered so perfectly that the government had accepted his services in the late war in Cuba.

Crushing Injuries.—Dr. Manley also presented a little girl, in order to call attention to what he considered to be the proper line of procedure in dealing with certain violent injuries which heretofore had called for primary amputation. The patient had sustained a severe crushing injury of the limb in the evening. He had first controlled the hemorrhage, and then, after thoroughly cleansing the parts, had "embalmed" the limb, as it was called, until reaction had set in and a line of demarcation had formed so that one could tell exactly where to separate the living from the dead tissues. For forty-eight hours this little girl's limb had been allowed to remain in the embalming dressing, and then it had seemed wise to complete the severance of the limb. The child was twelve years old at the time. She is now fourteen years old, and presents a somewhat tender and conical stump.

Homologous Ligation of Arteries.—Dr. Manley next presented a young man, who, five years ago, had had his left leg caught in a moving bridge. It had occurred to him some years ago that it would be desirable whenever possible to use the tissues themselves for the control of hemorrhage, instead of introducing foreign ligature material. Following out this idea in the case presented, he had performed homologous ligation of arteries, by turning them upon themselves, thus producing hæmostasis. When the patient entered the hospital the limb hung only by a few shreds. The limb was embalmed until a line of demarcation had formed, and then the tissues were dissected up sufficiently to get a flap which would properly cover over the stump. In his experience the utility of a stump could not be measured by the amount of skin over it. Some of the most useful stumps that he had seen were those which had simply a cicatricial investment.

Multilocular Dermoid Cyst of the Scrotum.—Dr. Manley next presented a photograph of an unusual tumor—one of multilocular dermoid cyst of the scrotum, complicated by a hernia on the right side. The patient was a man of sixty years, and the mass

weighed fourteen and three-quarters pounds. It had been necessary to support the mass by a sling from the shoulder. On hypodermic puncture and the removal of some of the contained fluid he had found cholesterin, fat, and other substances, such as one would expect to find in a dermoid cyst. The cyst was drained, and with good result.

Dr. Manley also exhibited two small tumors, one from the cervix uteri and the other from the scalp.

Resection of the Head of the Humerus after Severe Injury.—Dr. J. F. Erdmann presented the head of a humerus removed from a German, fifty-two years of age. The man was a sailor, and had been injured on board ship six weeks before coming under observation. The diagnosis was supraclavicular displacement of the head of the humerus, but it was found impossible to reduce the dislocation, and an incision was made between the deltoid and pectoralis major. This disclosed the fact that three inches of the humerus was absolutely bare of periosteum, and that the capsular and muscular attachments had been torn off. After removal of the head of the bone, it was ascertained that the capsule had united at the point at which it had been originally torn. At the end of the second week passive motions were being made, and at the end of the third week the man had 40° of motion from the body. From the condition found at the operation it was evident that an enormous force must have been exerted in order to rip the muscles and periosteum from the bone in this manner.

Dr. Manley said, with reference to the first case of tuberculous joint disease presented by Dr. Dennis, that the youth of the patient at the time of the operation should be borne in mind, as showing what could be done in these subjects. If the deltoid was divided, it was highly probable that the function of the shoulder would be impaired. To the fact that this muscle had been spared by Dr. Dennis in his operation, the speaker attributed much of the good functional result secured.

Wood-Fibre Splints; A Safe and Quick Method of Joint and Bone Fixation.—Dr. Edward A. Tracy, of Boston, read a paper on this subject. He said that the fixative material which he used was wood-fibre, reinforced by gauze. It was made in large sheets of wood pulp suitably pressed and shaped. The fixation was obtained by moulding a properly shaped piece of the splint material on the limb, and bandaging it snugly. When adjusted properly, this usually produced immediate fixation. A paper pattern should first be made. The wood-fibre splint was more easily manipulated than leather, and was porous. It was applied directly in contact with the skin, and without padding. The speaker then described how the material might be conveniently used in various locations, and exhibited a number of splints by way of illustration. One of the best examples was a splint made in two lateral pieces, which had been moulded to the lower limb and worn for eight months in a case of tuberculous joint disease. This demonstrated the durability of the splint material, and how easily the splint could be tightened as the swelling subsided. The speaker claimed that plaster of Paris as ordinarily applied over padding did not give such good fixation as the wood fibre, because of the application of the latter directly to the limb. Moreover, the wood-fibre splint, being removable, was less dangerous than those of plaster of Paris. He was of the opinion that it was very common to see deformity of the leg after fracture of the leg bones, because of the use of plaster of Paris and the consequent imperfect immobilization.

Dr. Manley thought this splint material would prove an ideal one in the management of rachitic deformities. The material was cheap and porous, and was easily made plastic. In fractures of the extremities, however, he believed better results were to be obtained without splints, simply by taking advantage of position and relaxation of the muscles. He did not believe plaster of Paris should ever be used in cases of fracture when the surgeon had a choice of materials. The principle of fixation seemed to be a wrong one, for union appeared to be favored by occasional removal of the dressings and movement of the fragments.

Montauk Point and the Government Hospitals.—Dr. Wickes Washburn presented a paper on this subject, and illustrated it by maps and drawings (see page 801).

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent).

CONGENITAL STENOSIS OF PYLORUS—PYLORIC OBSTRUCTION—ANEURISM OF CAROTID—POLYURIA—COLEY'S FLUID IN SARCOMA, REPORTED SUCCESS—SOME BOOKS—COLLEGE OF SURGEONS—HARBEN LECTURE—TYPHUS—TROPICAL DISEASE—DEATHS OF TWO OCTOGENARIANS.

London, November 18, 1898

Congenital hypertrophic stenosis of the pylorus has this year attracted attention on both sides of the Atlantic. Altogether some twenty cases have now been collected, besides a number of others which may be considered doubtful.

Two cases were reported in a paper by Dr. E. Cantley, at the last meeting of the Medico-Chirurgical Society. One patient was a boy who died in his fifteenth week from vomiting and marasmus. The other, also male, died in his eighth week "in a fit." In both, vomiting was the prominent symptom and the wasting was rapid. Such is, in fact, generally the course, and there is generally constipation without signs of intestinal obstruction or gastritis. Sometimes a tumor may be detected. The specimens exhibited at the meeting show the pathological changes. In both the pylorus was about an inch long, forming a thick elongated tumor, well defined at either end. The thickening was evidently due to hypertrophy of the unstriped circular fibres of the middle coat of the pylorus. Other changes secondary to this may be found in the pylorus, stomach, or œsophagus. Thus the mucous membrane in these specimens was thrown into longitudinal folds and appeared thickened, but microscopic examination showed that there was no actual thickening of this layer. But though due to the contraction, the folds increased the stenosis by blocking the lumen. The diagnosis must usually be made from the characteristic course, but sometimes a tumor has been felt during life, giving certainty, in which case it was thought surgery must intervene. Other treatment could only be palliative.

Dr. Norman Moore suggested, in connection with the sharp limitation of the hypertrophy to the pylorus, the same condition being found in specimens of epithelioma, that perhaps it arose from the junction of two processes of development.

Dr. Rolleston seemed inclined to admit the theory of Dr. John Thomson, of Edinburgh, that the condition was due to spasm, perhaps arising from absorption of amniotic fluid, which acted as an irritant. The change is certainly confined to the muscular coat, but Metzler maintains that there is no proof that spasm of the pylorus can set up hypertrophy.

The Medical Society had a "clinical evening" on Monday. Mr. Owen (president) showed a man on whom he had operated for pyloric obstruction, which proved to be from malignant growth. The stomach

was made to communicate with the jejunum, and the patient said he was in good health and had gained twenty pounds in weight since the operation.

Dr. Taylor showed a case of aneurism of the right carotid. The patient had previously been operated on for popliteal aneurism on both sides.

A woman with polyuria—passing more than two hundred and eighty ounces daily—was shown by Dr. Hadley. There was no sugar, but a trace of albumin was found. The urea was in excess. The appearance of the woman gave rise to a suggestion of myxœdema. Another view was that the affection might be granular disease commencing in an unusual manner.

Mr. Battle showed the man he exhibited last year, when there were several tumors over the scapula and enlarged axillary glands. Specimens of the growths had been declared by pathologists to be spindle-celled sarcoma. A three months' course of injections with Coley's fluid ended last May. There is now no trace of the tumors.

There was a marked difference of opinion expressed as to this case. Mr. Moullin congratulated the operator on the first successful case of undoubted sarcoma cured in England. In his own cases he had not been able to prove that they were sarcomatous, though they were assuredly neither inflammatory nor gummatous, and they disappeared under the treatment.

Mr. Owen (president) could not credit that this case had been sarcomatous, and it ought not to appear in the "Transactions" as a cure of sarcoma. He mentioned a case treated for malignant disease of the end of the femur, which on operation had been proved to be tuberculous joint disease.

Mr. Waterhouse was just as sceptical after trying the fluid in five cases. In three of these there were rigors and in the other two the patients died of hyperpyrexia. He related a case, pronounced by two eminent pathologists to be sarcoma, but the patient refused operation, and three months later there was suppuration and a piece of necrosed bone came away.

In reply, Mr. Battle said his own impression at first had been that his case might be syphilitic, and he therefore gave a full course of iodide in large doses, without the least effect. After two months of this sections were submitted to Dr. Jenner and Mr. Shattock, who both pronounced the disease to be spindle-celled sarcoma. He believed that it was so, and the members could now see for themselves that the man was healthy and without a trace of the tumors he had when they saw him a year ago.

The Society of Anæsthetists has issued its first volume of "Transactions"—a less ambitious work than many of similar name, but one of considerable interest. The price is only 5*s*.

Sir William Flower's "Essays on Museums and Other Subjects Connected with Natural History" will interest many medical men. Some of the "essays" are severely scientific; others are biographical sketches of some of the author's eminent friends, and remarks on their works.

The life of Dr. Southwood Smith, the eminent sanitarian, has appeared from the pen of his granddaughter, Mrs. C. L. Lewes, who is a sister of Miss Octavia Hill, and connected by marriage with Mr. G. H. Lewes.

"Lectures on Giddiness and on Hysteria in the Male," by Sir T. Grainger Stewart, is a notable little book, of which the second edition is ready. Price, 2*s* 6*d*.

Dr. Lionel Beale's "Vitality: An Appeal, an Apology, and a Challenge" is a reprint of the articles under that title which appeared in *The Lancet* a few months ago. The subject is intensely interesting, and Dr. Beale is a master whose challenge is not to be easily taken up. He insists on the microscopic view of the matter, and in this his researches and experience give him the highest place. The reprint is issued at 6*d*.

Morris' Hunterian lectures on "Renal Surgery" have appeared in book form.

Dr. Luff's new book on "Gout" embodies his Lumleian lectures on that disease.

Poland's "Traumatic Separation of the Epiphyses," with its numerous plates and engravings, is a fine illustration of the value of *x*-rays, which is also shown in the same author's "Skiagraphic Atlas" of the development of the bones of the wrist and hand.

"Windyhaugh," by Graham Travers, is a story embracing a psychological study of a girl's life from childhood to womanhood. It ought to be a picture, for Graham Travers is a woman and a doctor, her real name being Margaret Todd. A former novel by Miss Todd, issued some six years ago, was "Mona Maclean," in which Mona was rejected at the final examination, but came out with a medal on a second attempt. It is said the novelist did the same.

The annual meeting of fellows and members of the College of Surgeons was held yesterday. There was a dense fog, but nearly one hundred persons turned up. Several resolutions in favor of reforms were again passed *nem. con.*, for the members of the council present did not care to vote—knowing, I suppose, that nothing would be done. But it was announced that a proposal to adopt a gown for members as well as fellows had been referred to a committee. The college has no doubt the same right to authorize such decoration as have the ancient orders of Druids or Foresters, or even the Freemasons.

Sir R. Thorne delivered his concluding Harben lecture on phthisis on Wednesday. He does not support notification of the disease, and explained the provisions in this direction in New York, where, he said, the application of it was limited.

A nurse put one-half ounce instead of one-half drachm of laudanum into an enema. At the inquest the matron admitted that it was her own duty to measure the medicine. The question arises whether the matron ought to be trusted to measure poisons. Too much is left to nurses and the nursing department in many hospitals.

Some scattered cases of typhus have been notified in London. This disease is so seldom seen here that errors or difficulties of diagnosis are likely to occur.

The colonial office has sent a circular to the medical schools, respecting the provision recently made for instruction on tropical diseases.

Two octogenarians died last week. One was Surgeon-General Maclean, late professor in the Army Medical School, which he joined when it was founded. He had previously had a most distinguished career. His "Memories of a Long Life" is a most interesting book. His text-book of tropical diseases and other professional writings are well known. He was eighty-seven at his death on the 10th inst. Dr. McDermot, who was in his eighty-third year, died on the 9th inst. He had enjoyed an enviable position as senior practitioner in the pleasant city of Bath, where he settled some forty-four or forty-five years ago.

Le Grand Lac Salé.—According to the *Journal de Médecine de Bordeaux* of October 2d, a French traveller in his tour of the world discovered, at some twenty kilometres from Salt Lake City, a lake whose borders were marked by an abundant crystallization during the winter. The translucent irregular crystals were found to be composed almost exclusively of the sulphate with traces of chloride and carbonate of sodium. Here is a sufficient quantity of saturated Glauber-salt water, the *Journal* remarks, to purge the whole of Europe.

"HAWAII FROM A HEALTH POINT OF VIEW."

To the Editor of the Medical Record.

Sir: In the Medical Record of October 15, 1898, you have an editorial on "Hawaii from a Health Point of View," that can hardly be allowed to pass unchallenged, as it gives a very erroneous impression of the conditions as they exist in Hawaii to-day. You say:

"For many years the Sandwich Islands have been hotbeds of disease, and until drastic measures have been put into force are likely to remain so. In the Medical Record of April, 1889, Dr. Prince A. Morrow, who probably is better acquainted with the subject than any one else, contributed some notes of observation on matters medical in the Sandwich Islands, which although some few years have elapsed since they were written, will to all intents and purposes apply with equal force to the present situation there. . . . Dr. Morrow says: 'The demographic effects of introduced diseases in a virgin soil can nowhere better be studied, and they exhibit facts of the most remarkable interest. The natives have proven strangely susceptible to the diseases of civilized life, and trifling ailments—such as measles, whooping-cough, etc.—acquire by their transplantation into this soil all the virulence of a fatal pestilence. Measles and whooping-cough, introduced in 1849, almost decimated the population; the mortality was excessive, almost every case terminating fatally. The ravages of smallpox, introduced in 1853, were none the less frightful. In the island of Oahu over fifteen thousand died, and the marshal of the islands informed me that he superintended the burial of ten thousand victims of this disease in Honolulu alone — more than one-half of its entire population.'* With regard to leprosy Dr. Morrow says, in 1889: 'Nowhere else in the world can be found a parallel to the extraordinary development and rapid spread of this disease, which in the short space of little more than one generation has attained such alarming proportions and proved such a terrible menace to the public health.'

"That matters have not changed much for the better in this respect, an article by Dr. Burnside Foster, in the *North American Review* of September last, would seem to demonstrate. Dr. Foster says: 'Leprosy up to 1849 was unknown in the Sandwich Islands, at which date it was introduced by two Chinese sailors, and the disease has spread so rapidly that at the present time nearly ten per cent. of the Hawaiian natives are lepers.' These being the facts of the case," etc.

Now, Mr. Editor, these are emphatically not the facts, and if Dr. Prince A. Morrow is the best informed person on the subject, then I am sorry to say that he knows very little about the conditions as they exist here to-day. He describes them as they were during the first half of the present century, and we are led to infer that the same conditions prevail at the present time. Nothing could be more contrary to the actual facts. It is true that in the early part of this century contagious diseases wrought sad ravages among the native population. It is true that measles and whooping-cough had a terrible mortality in 1849, because the natives in their ignorance persisted in bathing in the sea and the cool mountain streams to allay the accompanying fever. It is true that smallpox slew thousands in 1853 for similar reasons and because they had not the protection of vaccination. But since those early days even the natives have learned how to care for their sick, not so well as one could wish perhaps, but sufficiently to avoid such mortalities. During a residence of twelve years in Honolulu I have seen epidemics of measles, whooping-cough, the grippe, dysentery, cholera, and enteric fever sweep over the place, and can truthfully say that the mortality has been no greater, if anything less, than it is from the same diseases elsewhere. During the past five months quite a general epidemic of measles has prevailed, brought here by United States troops. Only two persons have died of the disease, one in August and one in October—not a very high mortality; and yet Dr. Morrow says: "The mortality was excessive, almost every case terminating fatally."

There has been no general epidemic of small-pox in Honolulu since 1881, when there were 780 cases and 282 deaths. Yet scarcely a year has passed since then that one or more cases of the disease have not been brought to our doors from abroad; but, owing to the efficient system of quarantine that has been established, it has never been able to pass this barrier. Compulsory vaccination has been enforced many years, and the inhabitants now have the benefit of this protection, which they did not possess in earlier days. The board of health imports fresh vaccine lymph from New Zealand every month to meet any emergency that may arise from this disease, and we now have no more to fear from it than have the great cities of the United States. In 1895 cholera gained a foothold in Honolulu, but after a fierce struggle of a month's duration it was stamped out. In this epidemic eighty-eight cases and sixty-five deaths were reported, occurring in twenty-five different localities extending over a distance of three and one-half miles. A large fresh-water mountain stream emptying into Honolulu harbor, about forty acres of rice and taro land (covered with water) became infected. But in spite of this start the board of health organized the entire community into a corps of assistants and stamped the disease out.

We are now passing through a fatal epidemic of typhoid fever, but it is confined to the United States troops at Camps McKinley and Otis, and is due to the almost criminal negligence of the commanding officers in not adopting proper measures for disposing of the camp refuse and fæcal filth.

In regard to leprosy, your quotations are equally misleading. The idea that ten per cent. of the native population is afflicted with leprosy is simply preposterous. The last census, taken in 1896, gives the native and part-native population as 39,504. If your statement is true, then there must be 3,950 lepers among the Hawaiians. Such a statement would be ridiculed by every medical man on the islands. There were, on October 31, 1898, 1,076 lepers of all nationalities at the settlement on the island of Molokai, 1,015 being Hawaiians or part Hawaiians. Deduct this number from 3,950 and there would be left 2,935 Hawaiian lepers at large in the islands. I seriously doubt if there are much over one-tenth that number of lepers at large in the whole group. Segregation has been thoroughly enforced during the past six years (ever since the overthrow of the monarchy), with the result that the number of cases sent annually to Molokai is becoming less and less.

From the board-of-health statistics we find that there were sent to Molokai in 1893, 211 lepers; 1894, 138; 1895, 106; 1896, 143; 1897, 123; and during the first ten months of 1898, 75.

This decrease of over fifty per cent. in six years is very significant, for the law of segregation was never so rigidly enforced as during this period, and it leads us to hope that in a few years more no lepers will be at large. Another hopeful sign leading the health authorities to believe that they are getting toward the end of the arduous task of apprehending lepers is the mild character of the cases that now come before the board for examination. In 1893 and 1894 fully thirty per cent. of the cases examined were advanced, being of many years' duration, and the disease had al-

ready wrought sad ravages in the unfortunate patients. During the past two years not more than five per cent. can be put in this class, the remainder being composed of mild and recent cases.

Segregation was the means that rid Europe of the leprosy centuries ago. It is the method by which Norway is freeing herself of the disease to-day. Hawaii is following her example with gratifying results. Not only is this practical plan being pursued with a thoroughness which hardly needs any assistance from the United States, but other work is being prosecuted without interruption; namely, scientific investigations as to the nature of the bacillus of leprosy and experimental work in therapeutics.

One would infer from the tone of your editorial that nothing is being done here to check the spread of the disease, and yet upon investigation you will find that as much attention is being paid to it as anywhere in the world.

The entire population of the Hawaiian Islands is only 110,000, including about 50,000 Asiatic contract laborers, but this small community expends $125,000 annually for the segregation and care of the lepers. This is done as thoroughly and as humanely as possible. One might travel from one end of the group to the other and not meet a leper. Therefore Dr. Foster's fears in regard to the dangers of infection are not well founded.

It might be well for Dr. Foster to instruct the New York board of health in its duties to the public in this matter, for, by a singular coincidence, the very journal that announced the conclusions reached by the Congress of Leprologists in Berlin in October, 1897, namely, that leprosy was contagious, also gave as an item of news that the New York board of health had winked at the escape of the lepers from North Brother's Island.

F. R. Day, M.D.,
Member of the Hawaiian Board of Health.

Honolulu, November 9, 1898.

THE SURGICAL NURSES FROM THE ACADEMY OF MEDICINE.

To the Editor of the Medical Record.

Sir: On page 784 of your issue of November 26th, there is "A Word upon the 'Surgical Nurses' Sent out by the Academy of Medicine." For the information of your correspondent, who could have obtained it, however, without occupying one and one-half of your columns, I request you kindly to publish this brief reply to some of his statements.

"The red lines drawn through the names of all the medical men, members of the committee on nursing," mean that these medical men ceased to be members of the committee four years ago. The executive committee of the New York Academy of Medicine has been in charge of the nurses' bureau since, and has utilized the old blanks, which had been printed in large numbers. It reports to the council every month. Miss R. MacHaffie, "whose name does not appear upon the surgical register of this city" (I admit I do not know what the surgical register is), is the clerk of the bureau.

The "inference" that the charge of this department is now "relegated to other than medical hands" is not based on facts. The gentleman does not expect a member of the executive committee to do the clerical work?

"If this be so, perhaps a word of gentle advice may not be amiss." But it *is* not so. Still the gentleman's advice, as long as it is given "in no carping spirit," is always welcome. Some of it is, however, superfluous. The nurses *are* divided as he advises into groups—surgical, medical, gynæcological, obstetrical; also children, nervous, insanity, chronic, trained and untrained. But they are not asked about their religion, as the gentleman appears to suggest, nor does the bureau care for their "medical training." The bureau wants nurses, not medical men or women. Least of all, does the committee select them "as exponents of surgery—and of asepsis." That is what the most enlightened "surgical specialists" are for, guided by bacteriologists, not nurses.

"Some physician familiar with the names of prominent surgical specialists should be in charge of the bureau, as has been the case until of late. But as matters now stand, we have no real guarantee." The executive committee of the academy in charge of the bureau consists of physicians; they have been elected by the academy, and grew up in New York. They know the prominent surgical specialists and those not "prominent"; in fact, they are well acquainted with the profession at large. One of them, usually the chairman, examines every application of a nurse, and recommends or rejects. If mistakes are made, "it is obvious that some of the doctors who recommend the nurses registered there should be more careful in signing credentials." I fully agree with your correspondent. The committee of the nurses' bureau cannot go behind the returns. We have to accept a nurse that comes to us with the most excellent recommendations. When he or she turns out badly, the only thing we can do is to dismiss the nurse from our list, as we promptly did when your correspondent entered a complaint.

In connection with this case, Mr. Editor, I wish to remind your correspondent that it occurred in the good old times he eulogizes, before MacHaffie's clerkship, viz., four years ago. The complaint is dated March 30, 1894. As to the third case of your correspondent, on account of which he complained over the telephone, the same nurse was retained six weeks in preference to one we sent as a substitute. He will also remember that the nurse's application was sent him and that he was requested to enter his complaint on the same, which he did April 7, 1897. The service of the nurse began March 27, 1897. So it appears your correspondent has nurtured his grievance a long time before expressing it. Meanwhile, he seems never to have inquired into the working of the bureau.

The "home-rule policy" suggested by your correspondent may not please most men. But if any physician specifies the city or the school from which the nurse should come, he will be accommodated if it be possible. As a rule, and in justice to the nurses, they are sent—according to their specialties—in regular order.

Now, Mr. Editor, if your correspondent—himself a fellow of the academy, which he sometimes visits—had made inquiries in the office of the bureau, where the clerk is always present, or of the superintendent and librarian, or of the undersigned, he would not have been obliged to "infer" things that have no existence or to advise rules which have been in effect for years.

A. Jacobi,
Chairman of Executive Committee, New York Academy of Medicine.

Novel by Rider Haggard Treating of the Vaccination Question.—A new novel entitled "Doctor Theme," by Rider Haggard, will be published by Messrs. Longman & Co. in November. The story, which is told by the principal actor, Dr. Theme, after the final catastrophe, deals with the result of the conscientious-objector clause, under which the safety of many thousand children and through them of the community is practically left in the hands of the antivaccinationist party.—*British Medical Journal.*

New Instruments.

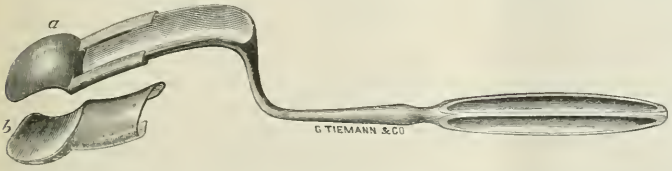
A CERVIX-ELEVATING ATTACHMENT TO THE VAGINAL SPECULUM, FOR EXPOSING THE POSTERIOR FORNIX.

By WALKER M. BRICKNER, M.D.,
HOUSE SURGEON, MT. SINAI HOSPITAL, NEW YORK.

MANIPULATION about the posterior fornix of the vagina, either in vaginal section or, more especially, in the introduction and removal of drainage tubes or gauze packings in cases of pelvic abscess, etc., is frequently rendered difficult by the overhanging of the cervix uteri—which obstructs the view and impedes the application of instruments. The cervix may be lifted with a volsellum, but this requires an additional hand and in itself is an obstruction in the vagina.

The accompanying cut illustrates a simple device for lifting the cervix completely from sight and freely exposing the full extent of the posterior portion of the vaginal roof. It consists of a slightly concave, metallic spatula, large enough to receive and support the cervix (*i.e.*, about three-fourths of an inch square), fitting by means of a cap over the end of the speculum, beyond which it projects.

The speculum is introduced with the spatula attached, and then turned so as to catch the cervix in



the upper, concave surface of the latter. The introduction is easy and painless, and the spatula, instead of occupying valuable space, creates more. A little additional upward pressure on the speculum will put the posterior fornix widely on the stretch. In vaginal section the landmarks are thus freely exposed and lighted by reflection from the spatula. Similarly, openings in the roof of the vagina, posteriorly or somewhat on the side, may be so stretched that gauze or tubes can be slipped in with minimum production of pain.

The attachment here presented was made to fit an anterior vaginal "spade," but I see no reason why it cannot be equally well fitted to a bivalve or other speculum.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 26, 1898:

	Cases.	Deaths.
Tuberculosis	145	136
Typhoid fever	44	28
Scarlet fever	113	5
Measles	146	4
Diphtheria	163	22
Laryngeal diphtheria (croup)	10	7
Cerebro-spinal meningitis	0	6
Chicken-pox	30	0
Small-pox	3	1

Beds of the Various Nations.—In England the old four-poster bedstead is still the pride of the nation, but the iron or brass bedstead is beating it out of the field. The English beds are the largest beds of the world. A peculiarity of the German is its shortness; besides that, it consists frequently, in part, of a large down pillow or upper mattress, which spreads over the person and usually answers the purpose of all the other ordinary bedclothing combined. In the tropics men sleep in hammocks or upon mats or grass. The East Indian unrolls his light, portable charpoy or mattress, which, in the morning, is again rolled together and carried away by him. The Japanese lie upon matting, with a stiff, uncomfortable wooden neck rest. The Chinese use low bedsteads, often elaborately carved, and supporting only mats or coverlids. The ancient Greeks and Romans had their beds supported on frames, but not flat like ours. The Egyptians had a couch of a peculiar shape, more like an old-fashioned easy chair, with hollow back and seat.—*Indian Lancet.*

Death within Twenty-Four Hours may be expected when the respiration and heart beats approximate.—*Medical Sentinel.*

The Mother Should be the Nurse.—The following ancedote, recorded of Blanche of Castile, shows strong maternal feelings, and has a tendency to recommend the duty enforced in this essay. Blanche of Castile performed for Lewis, her son, in his infancy, with peculiar attention, the duties of nurse. A lady of the court who, in imitation of her royal mistress, nursed her own child, took upon her, during a severe indisposition of the queen, to relieve the wants of the prince, who languished for his accustomed nourishment. Blanche on reviving, having called for her son, put him to the breast, when the child, already satisfied, refused the feverish milk. The queen, suspecting what had passed, affected a desire to see and thank the person who had performed for the young Lewis this maternal office. The lady, summoned to the chamber of her mistress, confessed the fact, alleging that she had been moved by the cries of the infant prince. Blanche, without speaking, darted a scornful glance toward the officious proxy, and compelled the child to throw back the milk he had swallowed, declaring "that no other woman should dare to dispute with her the title of mother to her son."—JOSEPH ADDISON, *The Spectator.*

Longevity.—Tesla thinks a man has just so many hours to be awake, and the fewer of these he uses up each day the more days will they last. "I believe that a man might live two hundred years if he would sleep most of the time. That is why negroes live to such an advanced age, because they sleep so much. The proper way to economize life is to sleep every moment that it is not necessary or desirable that you should be awake."—*Popular Science News.*

What is a Great Physician?—The late Hon. Thomas F. Bayard, in an address to a medical class, made the following remarks: "I never knew a really great physician who was not greater as a man—I mean whose greatness did not rest upon his personal and moral basis, which elevated and strengthened his professional life, infused itself into the community in which he lived, and was, in fact, the underlying and pervading cause of his influence and consequent success in his profession. It has been my personal fortune to know such a man. It has been my privilege and delight to accompany him in visits where his only medicines were the personal presence and conversation of the man himself. He had shared and lessened their anxieties; counselled the wayward; had led the

sick back to health; cheered the weak hearted; had rejoiced with them that did rejoice and wept with them that wept. And I have seen such a man so surrounded by an atmosphere of love and trust, holding as it were the heartstrings of a family in his hands, their guide, philosopher, and friend; and then I realized what a moral force in society the profession, properly comprehended and properly followed, was capable of exerting, and how relatively small a part of its usefulness was the administration of medicine."

The Adulteration of Coffee.—*The Lancet* says: "On reflection we should not think that the method of adulteration, about to be described, is 'new,' for it seems to us that it offers some explanations of the wooden character of the coffee infusions which are commonly offered to the public in this country. Coffee affords a most excellent beverage, but nobody seems to be able to get it good, and this is probably the reason why the consumption of coffee is rapidly declining. But the material must, of course, be good and fresh, with all the aromatic oils preserved intact. We have heard that by coating the roasted berries with a thin film of gelatin, the delicious aroma of freshly roasted coffee may be indefinitely preserved. But this step would be quite futile in view of the 'new' adulteration. This consists in washing, coloring, and drying the berries in centrifugal machines with sawdust, with the result that the crevices of the berries become filled with powdered wood, which is said to make them of a fine white color, and thus to enhance the market value of the product. This ingenious but immoral process is said to be carried on in Hamburg, Bremen, Antwerp, and Rotterdam, and we respectfully request our customs authorities to keep a sharp lookout on the consignments of coffee coming from these places, in spite of the market value, as it is said, being thus enhanced."

Incompatibles.—Dr. F. A. Ruddiman (*Journal of the American Medical Association*, October 15th) in an article on this topic says: "To become convinced that the subject of incompatibility is one that has not received the attention which its importance demands, we have but to glance over the appended prescriptions, which are a few of those to be found in standard works on medicine and therapeutics.

℞ Collodii,
Spt. ammoniæ,
Tinct. iodi.....ːāā part. æq.
S. Paint over part with a camel's-hair brush.

—Potter's "Materia Medica and Therapeutics," 6th ed., p. 716.

In this prescription the iodine is changed chiefly to ammonium iodide with a little ammonium iodate. Did the prescriber know this, and did he wish to get the action of these instead of the action of iodine?

℞ Hydrarg. iodidi viridis..... gr. ¾
Potass. chloratis..... gr. iij.
Potass. iodidi..... gr. ¾
Chocolate..... q.s.
M. ft. in tabellum No. 1.

—Hare's "System of Practice and Therapeutics," vol. ii., p. 160.

In the presence of moisture the potassium iodide reacts with the mercurous iodide, causing the formation of metallic mercury and the much more active mercuric iodide (the red iodide of mercury). The potassium chlorate in the presence of a mineral acid, as the hydrochloric acid of the gastric juice, causes the iodine to be set free.

℞ Hydrarg. chlor. corrosiv..... gr. ss.
Potassii iodidi..... ʒss.
Decocti cinchonæ..... ʒviij.
S. ℥ i. ter die post cibum.

—Farquharson's "Therapeutics and Materia Medica," p. 334.

The potassium iodide combines with the corrosive sublimate and forms first the red iodide of mercury, and then combines with this to form the soluble double compound—potassium mercuric iodide. This double compound combines with the alkaloids of cinchona in the decoction and forms a precipitate. The danger in this prescription lies in the mercury being thrown out of solution. Did the physician realize that it is possible for the patient thus to take most of the mercury at one dose?

℞ Sodii sulphitis..... ʒ ij.
Sp. ætheris. nit..... ʒss.
Liq. ammon. acet..... ʒiij.
Aq. dest..... ʒij.
M. S. Teaspoonful every two hours.

—Hare, vol. ii., p. 391.

The spirit of nitrous ether is decomposed, giving off the gas nitric oxide and part of the sodium sulphite is changed to sodium sulphate.

℞ Hydrargyri..... gr. ¼
Iodi..... gr. ¼
Ac. tannici..... gr. ¼
Glycerini..... ℥ xv.
M.

—Hare, vol. ii., p. 125.

The iodine will change the mercury to mercuric iodide. The tannic acid will change part of the iodine, with the formation of hydriodic acid, which will further combine with the red iodide of mercury.

℞ Tinct. ferri chloridi..... ʒ ij.
Acidi sulphurosi..... ʒ i.
Potass. chlorat..... ʒ i.
Glycerini..... ʒss.
Aq. calcis..... q.s. ad ʒiij.
M. Dose, one teaspoonful every hour to two hours for a child of three years.

—Smith's "Diseases of Children," 6th ed., p. 321.

On adding the sulphurous acid to the tincture of iron the mixture becomes of a much darker color at first and then nearly colorless. The glycerin may now be added and then the potassium chlorate dissolved in the water. There is barely a sufficient amount of water to dissolve the chlorate, and after mixing with the ingredients some of the salt is thrown out of solution by the alcohol in the tincture."

Health Reports.—The following statistics concerning yellow fever, small-pox, cholera, and plague have been received in the office of the supervising surgeon-general of the Marine Hospital service during the week ending November 26, 1898:

		Cases.	Deaths.
Yellow Fever—United States.			
District of Columbia, Washington.	November 18th	1	1
Yellow Fever—Foreign.			
Brazil, Rio de Janeiro	September 30th to October 14th.	19	3

THE PRETUBERCULOUS STAGE OF PHTHISIS, OR THE CONDITION WHICH ANTEDATES TUBERCULOUS DEVELOPMENT, AND SOME AIDS TO ITS DIAGNOSIS.[1]

BY HENRY P. LOOMIS, M.D.,

NEW YORK.

EVERY one who carefully analyzes the histories of cases of pulmonary tuberculosis must be impressed with the fact that, while the majority apparently start with local manifestations, a large number have exhibited for a longer or shorter time well-marked evidence of an antecedent morbid condition of the general system.

Naturally the first question which arises is, Does such antecedent condition exist with appreciable and unvarying symptoms? There are some who say that it does not exist with symptoms sufficiently constant to be of any positive diagnostic value, but for myself I feel so assured of its existence with these conditions, that I cannot overestimate the importance of determining and understanding as far as possible fixed signs and more or less reliable and constant manifestations, as of supreme importance to both the individual and the State, and it is therefore to the recognition of this pretuberculous stage as an important time of warning that I would specially call your attention.

For the sake of lucidity in the points which I would emphasize, I have assumed that there exists a stage or condition precedent to the initial development of tubercle and to the first appearance of appreciable signs of phthisis, this latter condition being known as "the incipient stage" of phthisis; the former condition may be called the "pretuberculous" stage, bearing somewhat the same relation to phthisis that transient albuminuria does to nephritis. It may be read as an important warning, or may be ignored as a morbid condition quite apart from danger of subsequent tuberculosis.

In examining recruits for the army, the examination is especially directed to detecting the least evidence of a liability to phthisis; yet statistics show that 7.2 per cent. of those in the French army, who have passed a most rigid examination on this point, subsequently developed phthisis; and in the German, Austrian, and United States armies the percentage is even higher.

The evidences of a vital condition which predisposes to the development of phthisis or actually marks the true pretuberculous stage may, for convenience, be grouped under the following heads:

I. Corpulence, or the relation of the weight of an individual, expressed in pounds, to his height, expressed in feet.

II. Chest condition.—1. Conformation of chest. 2. Chest measurement. 3. Vital capacity.

III. Constitutional condition.—1. Chloro-anæmia. 2. Digestive disturbances.

IV. Character of the pulse.

These heads should be considered in detail, as they are far from having the same absolute value, and their importance consists in the relation they bear to each other and to an abstract standard of normal health.

[1] Read before the American Climatological Association.

I. Corpulence.—The word corpulence has been introduced by French writers, with the definite meaning of the relation between the weight of an individual and his height, and in the same definite sense I use it now.

Progressive loss of weight, coming on without any apparent cause, such as loss of appetite or other indication of deranged nutrition, is in my opinion one of the most constant symptoms of the pretuberculous stage; in many cases it precedes for weeks or months the slight cough with no expectoration, which marks the actual beginning of a pulmonary change, suspected but often not recognized. Out of forty cases of phthisis which have come under my observation, and of which very complete records have been kept, fifty per cent. show this antecedent loss of flesh steadily increasing.

While the scales are used very generally in hospitals and sanitariums, it is seldom in private practice that use is made of them for this purpose, which I think is a grave mistake; for not only are they of great service in estimating how much below par is the nutritive condition of a patient, but they are of even greater value in determining how much a patient is improving under a given line of treatment. For it is so seldom as to be almost never that a tuberculous patient gains in weight without a corresponding improvement in his pulmonary condition. The actual weight of a person is of no help in estimating his nutritive condition, but the weight relative to the height, or his "corpulence," is of great importance. If this falls below a certain normal standard and remains so without any evident cause, the possibility of tuberculosis developing in those of suitable age is very great, if the disease has not already actually commenced.

The military standard of foreign armies recognizes this important sign, and no conscript is accepted whose corpulence falls below a normal standard. To weed out tuberculosis as far as possible is the object of this rule.

The corpulence of an individual is obtained by dividing his weight by his height; as, for example, take an average man of 5 feet 8 inches, whose weight is 150 pounds (military standard); his corpulence would be expressed thus:

$$\text{Corpulence} = \frac{\text{Weight, 150 lb.}}{\text{Height, 5' 8''}} = 26.47$$

or 26 as a standard. Any man whose corpulence falls below 23 should be considered abnormally thin. From investigations made by the writer he considers in this country 25 to be the normal standard, the foreign military standard of 26 being too high. While the normal corpulence of men has been settled by military standard, special investigations have been made by Bouchard to determine that of women. After a long series of studies he has found it to be 23; in any case where it goes below 21, a woman should be considered abnormally thin. In estimating the exact value of corpulence, it should be considered in connection with the "vital capacity" (or the thoracic perimeter divided by the height of the invididual). The following case will illustrate this:

Pretuberculous Condition with Chloro-anæmia.—Emma P——, housemaid, aged 18. One sister tuber-

culous at thirteen; patient has always been perfectly well, menstruated at fifteen.

First examination. Anæmic, suffers from dyspepsia; pulse, 99; weight, 104 pounds; height, 5 feet 2 inches; corpulence, 20; thoracic perimeter, 30 inches; pulmonary condition normal.

Second examination (one year later). Weight, 101 pounds; corpulence, 19; thoracic perimeter, 29 inches. Signs of beginning tuberculosis at right apex; arterial pressure, 5 inches of mercury.

II. Chest Conditions.—1. Conformation of the chest. There is no question that a large proportion of persons have chests which in their conformation differ widely from a normal standard, and this without in any way rendering them especially liable to tuberculosis. Many of these irregularities may be due to faulty positions assumed in childhood, or to the character of occupation in later life, as habitually leaning over a desk, etc. In a word, malformed and flat chests are not necessarily found in consumptives; still there is equally no question that there is a special chest conformation which is found in very many cases of phthisis, and which when present in the pretuberculous stage strongly predisposes to the development of the disease. This chest may be described as follows: Narrow in its anterior-posterior diameter, with wide intercostal spaces; the scapula prominent, with depressions of the supraspinous and infraspinous fossæ; also a subclavicular depression—in other words, a leanness and hollowness to the whole chest. Such a chest, when found in an individual presenting other symptoms suggestive of the pretuberculous stage, is an important link in the chain of evidence.

2. Chest measurement. More important than the shape of the chest are the data obtained by measuring the circumference of the chest; this can be done by use of a graduated tape, or, better, by a double tape (two ordinary tapes joined together), so that the commencement of each tape is in the centre of the double tape, which centre is placed over the spine. The tape should be carried around the chest on a level with the nipples; sometimes, especially in women, it should be carried around lower down opposite the ensiform cartilage. By having a double tape we can compare not only the mobility of the chest wall, but also the expansion of the two sides. It has been found that the two sides are unequal in their circumference in two-thirds of the persons examined. The right side is one-half inch or more larger than the left, but both lungs expand almost equally. The average circular measurement of the chest varies in man within normal limits, but it never should go below 35 inches.

The average of two measurements, taken at the same point—one at the moment of forced expiration (cough), the other at the end of a forced inspiration (deep sigh)—is the "thoracic perimeter." Investigations have shown that the most important point, in estimating the value of the chest measurements as a sign of the pretuberculous stage, is when the relation between the thoracic perimeter and the height is ascertained. This relation constitutes what the French call the "vigor of constitution" of an individual. French military surgeons first ascertained its importance, and its value does not seem to be appreciated in this country. The thoracic perimeter should never be lower than one-half the height of an individual.

I have examined a number of cases of early phthisis to ascertain the accuracy of this statement, and have found in a few cases this ratio kept; in most cases it fell below and in none rose above this standard. It seems, therefore, that the "vigor of constitution," ascertained by the means just indicated, may be an important help in diagnosing not only early phthisis, but the pretuberculous stage; this rule applies equally to women as to men.

3. Vital capacity. Hutchinson, the inventor of the spirometer, demonstrated by numerous experiments on respiration that in a healthy person there is a certain amount of so-called vital respiratory capacity, varying according to age, weight, and height. Normal persons should be able to exhale a certain cubic mass of air on a full inspiration succeeding a complete expiration. Vital capacity by itself is, in my opinion, only another very slight help in diagnosis, but when taken in connection with height it becomes an important aid.

The normal vital capacity for a man of 5 feet 8 inches is 230 cubic inches. In a number of patients of about 5 feet 8 inches in height, and in the early first stage of phthisis, I found the vital capacity averaged only 160 cubic inches. Personally I have found that the determination of vital capacity in its relation to height gives more accurate data in determining the pretuberculous stage and early phthisis than either corpulence, chest measurement, or chest conformation.

Any valuable use of the spirometer is largely a matter of education, patients having to be taught how to use it or the results obtained will not be reliable. The other disturbances of the respiratory organs beside tuberculosis which modify vital capacity—such as pleurisy, bronchitis, etc.—must not be forgotten, and the possibility of their presence in any given case must be thought of. Again, it is well to remember that if a slight increase in vital capacity appears during the treatment of early phthisis, it points toward a favorable prognosis. French investigators have established a boundary line between normal and subnormal vital capacity, which we may adopt with advantage.

The relation between height and vital capacity for the normal and healthy man is 1 to 3; for women, 1 to 2.6. That is, for each inch of height (man) there should be 3 cubic inches of vital capacity; when the proportion falls below this, we may infer a considerable disturbance in the respiratory capacity. For example, in a man of 5 feet 8 inches this vital capacity should not fall below 204 cubic inches. By way of illustrating the value of the inter-relation of corpulence, thoracic perimeter, and vital capacity in diagnosis, I quote three actual cases given by Dr. Papillon, of the Paris Hospital—three women of the same weight, 108 pounds, but whose corpulence and vital capacity differed to a marked degree.

Case I.—Woman, 5 feet 5 inches; weight, 108 pounds.

(*a*) Corpulence $= \frac{\text{Weight, 108 lb.}}{\text{Height, 5' 5''}} = 20$

(below normal).

(*b*) Thoracic perimeter = 31 inches (1½ inches less than half her height).

(*c*) Vital capacity = 122 cubic inches (47 cubic inches less than normal for a woman of this height; normal, 65 inches by 2.6).

Remarks.—In spite of this patient's apparently excellent appearance, she was in the early first stage of phthisis; her corpulence and thoracic perimeter were slightly below normal, but her vital capacity was much reduced.

Case II.—Woman, 5 feet 1 inch; weight, 108 pounds.

(*a*) Corpulence $= \frac{\text{Weight, 108 lb.}}{\text{Height, 5' 1''}} = 12 +$

(*b*) Thoracic perimeter = 31 inches (½ inch more than half her height).

(*c*) Vital capacity = 198 cubic inches (40 cubic inches above normal: normal, 158 +).

Remarks.—This woman in weight was apparently below normal, yet her vital capacity and thoracic perimeter were above normal, so we could consider that there was but slight danger from pulmonary complica-

tion. [Note: The case proved to be one of simple anæmia.]

Case III.—Woman, 4 feet 10 inches; weight, 108 pounds.

(*a*) Corpulence $= \frac{\text{Weight, 108 lb.}}{\text{Height, 4' 10''}} = 22$

(*b*) Thoracic perimeter = 31 inches (2 inches more than half her height).

(*c*) Vital capacity = 142 cubic inches (8 inches below normal; normal, 150 cubic inches).

Remarks.—This case was one of cured phthisis; the patient entered the hospital for rheumatism; while her corpulence and thoracic perimeter were up to normal or above, her vital capacity was, in proportion to her height, so slightly out of ratio as to be virtually normal.

These three cases are interesting as showing how little value mere weight has as a determining quality, unless taken in relation to height and to thoracic perimeter. The thoracic perimeter, almost identical in these cases, changes its significance completely when considered in relation to height, being less than one-half the height in the early tuberculous case, and above the half height in the other two.

The following cases of persons who have recovered from phthisis illustrate the return of corpulence and thoracic perimeter to a normal standard:

MALES.

Normal Corpulence Not Below 23; Thoracic Perimeter Not Less than Half the Height.

Case.	Weight	Height. Feet.	Inches.	Corpulence.	Thoracic Perimeter.	Normal Thoracic Perimeter for Individual.
1	148	5	11	25	35¼	35
2	152	5	8	26+	35½	34
3	137	5	7	24+	34½	33½
4	136	5	5	25	33¾	32½
5	144	5	8	25	35½	34
6	139	5	7	25	33	33

FEMALES.

Normal Corpulence Not Below 21; Thoracic Perimeter Above Half Height.

Case.	Weight.	Height. Feet.	Inches.	Corpulence.	Thoracic Perimeter.	Normal Thoracic Perimeter for Individual.
1	118	5	3	22	31	31
2	136	5	5½	25	31¾	32
3	135	5	6	24+	31¼	32
4	119	5	2	22+	31½	30
5	101	4	9	21+	29¼	28½
6	108	5	3	20½	31+	31

III. Constitutional Condition.—1. Chloro-anæmia. Many believe that there is an actual antagonism between the two conditions of chlorosis and tuberculosis. Haplin, who has investigated this subject, states that in forty cases of true chlorosis in tuberculous families which have come under his observation, only two subsequently became tuberculous. Many believe otherwise, and consider certain chloro-anæmics to be well on the road to tuberculosis, and when once tuberculosis has set in the chlorotic state darkens the prognosis. They point out that while the anti-anæmic treatment by iron benefits pure anæmics, it gives only negative results in cases having a tendency to phthisis.

The writer's personal experience has led him to believe that chloro-anæmia is often one of the most pronounced symptoms of the pretuberculous stage of phthisis, especially when taken in connection with loss of weight without cause and poor chest development. I believe that an unexplained chloro-anæmia in young men should always make us suspicious of tuberculosis. In young girls this symptom is not so important, for from their manner of life and physical condition they are specially subject to true anæmia; in fact, I feel one should view chlorotics who grow thin without a cause with grave suspicion. Their corpulence should be ascertained at regular intervals, while rest, fresh air, nutritious food, and appropriate tonics should be at once ordered. In chloro-anæmics, besides loss of weight, thinness of the chest is a bad sign and suggests liability to development of tuberculosis. True chlorotics, as we know, show slight, if any, loss of adipose tissue, and the chest development meets normal requirements. Clinical examinations of the blood have been made, especially in France, during the last few years, to ascertain if there be any characteristic change there which marks the pretuberculous stage, and also what is the condition of the blood found in the very early stages of incipient phthisis. There is a good deal of variation in the conclusions reached, but most authors agree that the hæmoglobin is diminished out of all proportion to the loss in the number of red corpuscles. Henocque concludes, after a long series of investigations, that tuberculous chloro-anæmia is characterized by one thing, viz., "the diminution of the oxyhæmoglobin in the blood." Laache says that in his cases he found the red cells diminished twelve per cent. on an average, while the hæmoglobin has reached a loss of twenty-nine per cent.

My observations so far. cannot lead me to indorse these statements, for while I have had but a limited experience in examining the blood of persons whom I considered in the pretuberculous stage of phthisis, yet of those in the earliest recognizable stages I have examined a number. These examinations tend to show that when the disease is established nothing characteristic is found in the blood, unless we consider as characteristic the absence of microscopical evidences of anæmia, such as the pallor of the patient would suggest. The following report of the blood examination of twelve persons undertaken under my direction at the very beginning of phthisis may be interesting in this connection. (See table on page 832.)

Conclusions.—(1) The numbers of red blood corpuscles and the percentage of hæmoglobin were well within normal limits, and there was no evidence of such anæmia as one would expect from the pallor of some of the patients.

(2) The red blood cells were well nourished and of normal development. This is opposed to the condition found in chlorosis, and could be considered as a point of differential diagnosis.

(3) Leucocytosis was present in only two cases. The increased percentage of young cells (large and small lymphocytes) was only such as may be found in any blood poor in nutritive qualities.

(4) Absence of basophiles in half the cases (Neusser claims that when found they indicate that the system is capable of resisting tuberculosis and so warrants a favorable prognosis).

(5) There was nothing characteristic in the blood. All variations noted were within accepted physiological limits.

2. Digestive disturbances. All must have noticed how often disorders of the digestive system usher in the earliest stage of phthisis, but have we noted how many of those cases affected with this disease have suffered for months or even years with dyspepsia in some form? What is this relationship between digestive disorders and phthisis? Are these disorders cause or result? Are they symptomatic of the invasion of the tissue by the bacilli, or are they symptomatic of the tissues undergoing changes lessening their power of resistance to the inroad of the microbe? I believe that digestive disorders precede the deposition of tubercles in the lungs in many cases. Numerous cases that have come under my observation ap-

pear to prove this statement; nine out of forty cases of phthisis, of which I have complete records of antecedent conditions, showed continued digestive disturbances extending over months or even years before the disease was recognized by physical signs. Digestive disorders which cannot be permanently corrected at the tuberculous period of life are often a symptom of the pretuberculous stage of phthisis. The lesson we should learn is not to overlook the possibility of tuberculosis in those cases which superficial inquiry would classify as cases of "indigestion" simply. This "indigestion" is sufficiently often the forerunner of phthisis to put us on our guard.

IV. Character of the Pulse.—The character of the pulse in establishing the early diagnosis of phthisis, and as one marked symptom of the pretuberculous and very early stage of the disease, is, in my opinion, important. Only in the last few years has any attention been paid to these indications of the pulse. Since my attention was called to the matter by a paper of Dr. Wells, of Chicago, written in 1895, I have been surprised to note how characteristic and constant is the pulse of this condition, and it has led me to suspect tuberculosis in several cases weeks before the physical signs appeared. It has been claimed that the reason this pulse has been overlooked by clinicians is that it is found only at the very beginning of phthisis and in the pretuberculous stage, and disappears early in the disease. This pulse has two characteristics:

1. Change in position of the patient has but little influence on its rhythm. To ascertain whether this is so in a given case, the patient must be examined several hours after eating and when free from excitement. Ordinarily the pulse varies about fifteen beats in a healthy man on change of position.

2. Relative feebleness of arterial pressure. This characteristic of the pulse, suggested by Dr. Wells and confirmed by the French investigators, is believed by them to be an important element in diagnosis. They found that, instead of the arterial pressure being 15 to 18 cm. of mercury, as in the healthy man, it was always less than 13 cm., sometimes even as low as 10 cm. In pulmonary tuberculosis they also found that in those few cases of normal or excessive arterial pressure there was some other condition associated with the tuberculosis, such as nephritis, to account for the increase. If this were true only in the advanced stages of tuberculosis, it would not be of any diagnostic value; but it was also found in the pretuberculous and very early stage—in one case where physical signs did not appear for nearly two years later. This lessening of arterial pressure must certainly put the organism in a state of microbic receptivity. We should be especially anxious in cases of anæmia with feeble arterial pressure. The pulse of this lowered arterial pressure yields a peculiar sensation, somewhat suggesting the "Corrigan" pulse, being tense, jerky, and hurried, seldom beating less than 100 per minute, often 110 to 120. In the early stage of phthisis we also note a non-concordance which often occurs between the acceleration of the pulse and the rise of temperature. I have personally confirmed these characteristics of the pulse as just described, and I bring them before you as well worthy of further study.

Dr. Andvord has just published a very interesting article on "Latent Tuberculosis and the Pulse of the Tuberculous," in which he claims that the pulse tracings of this condition are characteristic, viz., there is

Report of the Examination of the Blood of Twelve Cases in the Incipient Stage of Phthisis.[1]

a suddenness of the ascent and descent of the curve. He also noted that as a person recovered from phthisis the pulse curve came down more nearly to normal. He was unable to find any characteristic tracings in the pretuberculous stage.

Summary.—1. It is possible in many cases, especially in chloro-anæmics, to diagnose phthisis previous to the appearance of physical signs or of tubercle bacilli in the sputum.

2. Weight, respiratory capacity, and chest measurement have no value in establishing the possibilities of the development of phthisis in themselves, but must be considered in relation to the height of the person, when they furnish three important aids to diagnosis.

3. Corpulence is obtained by dividing the weight expressed in pounds by the height expressed in feet (in a normal man this should be 26; in a woman, 23).

4. Thoracic perimeter is found by taking two measurements of the circumference of the chest—one at the moment of forced expiration, the other at the end of a forced inspiration. The average of these two measurements should never be less than half the height.

5. Vital capacity is the amount of air expressed in cubic inches which can be exhaled after a full inspiration. Normally it should bear the relation to the height of 3 to 1 for a man and 2 to 1 for a woman (*i.e.*,

[1] The specimens of the blood from the cases were taken about three hours after a meal and as nearly as possible under the same conditions. Tubercle bacilli were found in the sputum of all the cases.

for every inch of height there should be 3 cubic inches of vital capacity).

6. Chloro-anæmia and persistent and unexplained disturbances of the digestive system are symptoms of the pretuberculous stage of phthisis.

7. There are two characteristics of the pulse found in the pretuberculous and early stage of phthisis: (*a*) Change of position has practically no influence on its rhythm; (*b*) relative feebleness of arterial pressure.

A PRELIMINARY REPORT FROM CLINICAL OBSERVATIONS OF THE SUCCESSFUL REDUCTION OF SUGAR IN THE URINE AND AN ABEYANCE OF THE PATHOLOGICAL SYMPTOMS IN DIABETES MELLITUS.[1]

By ABRAHAM MAYER, M.D.,
NEW YORK.

Mr. Chairman and Gentlemen: I offer for your consideration this evening a preliminary report of clinical observations I have made in the reduction of sugar in the urine of patients suffering from diabetes mellitus, and an abeyance of all of its concomitant symptoms by the administration of a drug well known to all of us.

The results are so marvellous that were they obtained in only a single case you would perhaps hesitate to believe in the efficacy of the remedy; but as they are the same in all of the eleven cases experimented upon, as I will show, there can be no denying that *post hoc propter hoc* in the application of this remedy is a positive fact.

I have not completed all the experimental work, and have not elaborated all the scientific facts as to the physiological action of the remedy in this disease, as such takes and entails a great deal of time and an enormous amount of experimental research, which up to the present I have not had. My observations date back over the past six months, and during this short time the clinical results have been so positive that I feel justified in reporting them to the profession. For this reason I ask an apology for the incomplete scientific researches brought out in this paper, and offer it to you, as my title reads, only as "a preliminary report of the successful reduction of sugar in the urine and the subsidence of the pathological symptoms in diabetes mellitus." These observations are all clinical. The time has been too limited for the assurance of a positive cure, and I can only add that if the results continue as they have been so far in all of my cases, we have a remedy in our hands that has exceeded all other therapeutic measures.

To go into the physiology and pathology of sugar excretion is beyond the scope of this paper. You know there are theories upon theories as to the production of glycosuria, and to give a description of each would entail volumes. There are a few points, however, to which I wish to call your attention. It is well known that the liver is not the only organ which stores up glycogen, but muscle cells and glands likewise possess this property. As the organism requires it, these glycogen reservoirs are called upon to replete the sugar which has been used up. In this way in health the blood contains a fairly constant quantity of sugar. In diabetes mellitus the glycogen from these reservoirs is converted more or less rapidly into grape sugar, which enters the blood, producing a hyperglycæmia, and hence a glycosuria.

Some observers, like von Noorden, believe that in diabetes mellitus the capacity for burning up grape sugar circulating in the blood is morbidly depressed. Hence comes its rapid excretion by the kidneys.

[1] Read before the Metropolitan Medical Society, on November 22, 1898.

Again, after complete extirpation of the pancreas true diabetes mellitus ensues. The experiments of von Mering and Minkowski on animals in which this was done led them to formulate the following theory: Either there accumulates in the organism after pancreas extirpation some substance which has an injurious effect on the conversion of carbohydrates; or there accumulates after this operation some substance, or some function is abolished, which in the normal condition serves to facilitate the conversion of carbohydrates.

Others again, like Lenné, believe in a derangement of a metabolic function of the organism, in consequence of which the power to convert and assimilate carbohydrates in a normal way is more or less lost. This derangement of a metabolic function depends on an alteration of certain nervous elements (trophic nerve centres).

Lepine, of Lyons, does not deny the influence of the nervous system in the causation of an increased sugar production. As regards experimental pancreatic diabetes, Lepine believes that the pancreas produces a glycolytic ferment, which enters the circulation and destroys the grape-sugar molecule within the blood or in the tissues.

As the most careful examinations of the brain, pancreas, liver, and other organs in a great many cases fail to reveal any pathological change to which importance can be attached, and also no history of any supposed exciting cause as being an etiological factor; and there being such a diversity of opinion as to the causative factors in the production of this disease, and not one explaining all the pathological phenomena connected with it—my experiments and observations led me to reason that a bacterium or its ptomain may be the chief factor in its production.

Indeed, only recently attention has been called to the contagiousness of diabetes mellitus by Ledieu, Naunyn, and others.

Diabetes mellitus, then, according to my theory, is the result of the pernicious influence of a specific bacterium or its ptomain in the organism, acting centrally on certain brain centres or peripherally on the glycogenic reservoirs.

The nervous system exercises a controlling influence on the normal production of sugar in the body. If from any cause, such as traumatism, neoplasm, continued worry or mental strain, poisons, etc., this controlling influence be impaired or abolished, the bacteria and their ptomains exert their deleterious influence.

My theory supposes the invasion of the organism by these bacteria, or their presence in it. In perfect health they are prevented from exercising their injurious influence by the normal resistance of the economy, or perhaps by some ferment physiologically produced by metabolic changes in certain organs of the body acting as an antitoxin against these bacteria.

If this presumption be correct, then the ingestion of a suitable bactericide in sufficient quantity to counteract the effect of this bacterium should manifestly show an amelioration of the pathological symptoms of diabetes mellitus.

After repeated experimentation I am able to report that the bichloride of mercury in suitable doses fulfils this indication.

My method of treating these cases is as follows: A history of the case is obtained and the patient weighed. The quantity of urine passed in twenty-four hours is collected, measured, the specific gravity taken, quantity of sugar estimated, and other abnormal characteristics are noted. If the urine fails to react to Gerhardt's test, the patient is then put on an antidiabetic diet for two weeks, during which time he takes the bichloride. I begin with a dose of one-twelfth of a grain three times a day, and in two or three days increase it to

one-tenth or one-eighth of a grain. In a week's time my patient is taking one-sixth of a grain three times a day, directly after meals, well diluted with water. This is the maximum dose. None of the symptoms of mercury poisoning showed themselves in any of my cases. A rather brisk catharsis takes place the first few days, especially if the patient previously suffered from constipation; and this diarrhœa I regard as favorable. At the end of two or three weeks my patients have shown a marked reduction of sugar and a decided improvement in their general condition. As soon as I have obtained this result, the dose of mercury is diminished until about one-fourth of a grain in divided doses is taken daily. Or I may still further reduce the dose. (The diet now is not so severely restricted.) A little bread and a tart apple are permitted.

The urine is examined daily or every other day for the first two or three weeks; that voided in the evening being tested.

As the percentage of sugar diminishes, the dose of bichloride is decreased accordingly and the diet is not so strongly restricted. From time to time the drug is suspended. Even though the sugar has entirely disappeared, I continue to give the bichloride, but in much smaller dose, about one-sixteenth of a grain three times a day.

Diabetics with syphilitic history are not included in this report. But I wish to mention that diabetic patients with a history of lues showed a more marked and rapid improvement under the mercurial treatment.

The following table (page 835), with a short *résumé* of each case, shows the efficacy of this method of treatment. In this table by restricted diet is meant a regimen in which all carbohydrates are excluded; by a mixed diet, that a limited amount of starchy food is allowed, such as wheaten bread.

Case I.—Mrs. M. W——, aged sixty years, has had diabetes mellitus since 1893, when the first symptoms showed themselves; she weighed one hundred and ninety-four pounds at that time. The disease began with severe itching of the genitals and the entire body, rapid emaciation, loss of appetite and sleep. These were the first symptoms noticed. All known remedies with a rigid diet had no marked effect. She began the bichloride treatment on June 20, 1898, when her urine contained 3.15 per cent. of sugar. She passed sixteen pints of urine daily. At the end of ten days the amount of sugar was reduced to 2 per cent., and the quantity of urine passed was five pints daily. Bichloride treatment was now suspended for one week, to be again continued at the end of that time in diminished doses of one-twelfth grain three times a day. On August 20th she had less than 1 per cent. of sugar, and passed only four and one-half pints of urine in twenty-four hours. She felt much stronger; there was no itching, the thirst had disappeared, and she had gained two pounds in weight. On October 11th she was entirely free from sugar and has remained so since, notwithstanding that treatment has been discontinued from time to time. A little bread was allowed during the latter part of the treatment.

Case II.—The patient had history of gall stones; he had great thirst, but no polyuria; he perspires very freely and suffers from headache; is constipated. He had been under treatment for four years without any alleviation. He began mercurial treatment, June 22, 1898. The urine then contained 3.25 per cent. sugar; six pints were passed. There was very marked improvement at the end of two weeks. The amount of sugar, July 1st, was 1.65 per cent., or about half what it was when he began treatment. In four months he gained fifteen pounds. On November 4th the gain was twenty pounds. Sugar amounted to only 0.3 per cent.; the patient passed four pints of urine daily, and felt as well as ever. He takes bichloride, one-sixteenth grain, twice daily.

Case III.—Mr. J. F——, aged fifty-five years; his was a very severe case. Acetone was present. The patient was haggard and morose. The disease began about seven years ago, with great thirst and severe pruritus. There was marked polyphagia. He lost weight gradually. Bichloride treatment was begun, June 25, 1898, with very bad effect. He had then 3.65 per cent. sugar, and passed eight pints of urine daily; specific gravity, 1.025. There were diarrhœa and rapid loss of strength. I was forced to give a smaller dose—one-thirtieth grain every four hours. This patient caused me much anxiety, for while the sugar diminished after treatment, the loss of strength and emaciation continued. A diarrhœa complicated the situation, and an acute lobar pneumonia of the left side developed on August 1st. Nevertheless the mercury was continued in the above-mentioned dose, but had to be suspended from time to time for a few days. Resolution was very slow. Then followed great prostration and loss of appetite. The percentage of sugar increased during the attack of pneumonia, but as the patient got well it rapidly diminished to less than 1 per cent. On October 17th he was entirely free from sugar and felt stronger and more cheerful. During all this time he had been taking bichloride, lately in larger doses. November 12th, there was no sugar at all and no trace of albumin.

Case IV.—C. H. A——, aged fifty-seven. This was a very interesting case. The patient was morose and hypochondriacal. He had large percentage of sugar, 5.15; specific gravity, 1.030; he passed sixteen pints of urine on June 20th, the first day of the bichloride treatment. Examination of urine showed acetone; hence carbohydrates were not excluded from his diet. He suffered from great weakness. In two weeks he had gained three pounds; the percentage of sugar was reduced to less than half, no acetone; he was cheerful and bright. The following three months he gained eleven pounds in weight. September 16th, sugar was 1.15 per cent., and bichloride treatment was discontinued for a time. November 17th, the gain was sixteen pounds; sugar, 1 per cent.; he passed four and one-half pints of urine every twenty-four hours. He eats some bread with each meal. As there is still 1 per cent. of sugar present, the patient is put on one-sixteenth grain bichloride three times a day.

Case V.—R. L——, aged forty-seven, came under observation April 3, 1898. There were great thirst, weakness, and severe gastric pain amounting to crisis; there were severe constipation and disturbed sleep. He passed fourteen pints of urine a day; specific gravity, 1.025; sugar, 2.65 per cent.; no albumin. From April 3d to July 1st, there was no improvement. July 1st, I began bichloride treatment. April 10th, he passed but six pints of urine; specific gravity, 1.022; sugar, 1.3 per cent.; his general condition was so much improved that a small quantity of bread was allowed at each meal. By this time he was taking one-twelfth grain of bichloride three times a day. September 15th, there was continued improvement; sugar, 0.65 per cent.; four pints of urine were passed daily. October 24th, there was no sugar nor albumin; specific gravity, 1.020; three and one-half pints of urine were voided this day. Bichloride reduced to one-sixteenth grain three times a day. November 12th, there was no sugar; specific gravity, 1.020; four pints of urine were passed; he has gained since July 1st seven pounds in weight and feels absolutely well and is very happy.

Case VI.—Mr. S——, aged forty-eight, an analytical chemist; his was a mild case. The patient came under observation, June 21st, because he had been refused by a life insurance company. His urine contained about 1 per cent. sugar. He had been losing flesh at the rate

of one pound a week for the past six months. He was put under a restricted diet and one-tenth grain bichloride three times a day. July 21st, there was 67 per cent. of sugar. Diet was still restricted. September 1st, the urine contained sugar, 0.2 per cent.; specific gravity, 1.020; he passed three pints daily. The patient was allowed mixed diet. He had not lost weight since treatment began. On October 12th, there was no sugar. The patient this morning ingested three ounces of white sugar as a test. Examination of the evening urine that day showed absolutely no sugar.

CASE VII.—J. K——, aged fifty-four, has had diabetes for seven years, and had been under observation for quite a long time before commencing specific treat-

Number.	Date.	Name.	Age.	Duration of Disease.	Began Mercury Treatment.	Quantity of Urine in 24 Hours. Estimated.	Specific Gravity.	Sugar Polarization.	Albumin.	Weight in Pounds.	Diet.	Remarks.

11	1898, Oct. 12th.	M. G.....	23	3 years...	Oct. 12th...	17 pints.	1.035	5.00	No....	140	Restricted....	Maximum weight, 180 pounds. Great thirst. Has never had less than two per cent. sugar while under treatment.
	Oct. 16th.	.....	..	.....	.....	16 "	1.032	4.50	" ...	140	"	No improvement.
	Nov. 3d.	.....	..	.....	.....	10 "	1.028	2.95	" ...	140		Treatment discontinued for a few days. Improvement marked.
	Nov. 16th.	.....	..	.....	.....	6 "	1.024	.80	" ...	150		Says he never felt better.

ment. Diet had a great influence in reducing the amount of sugar, which at times rose to 4 or 5 per cent. He had been under arsenical treatment for some weeks prior to July 13th, when I began with one-sixteenth grain of bichloride. At that time he was passing five pints of urine; specific gravity, 1.024; sugar, 1.65 per cent. He complained of inordinate perspiration, great thirst, and weakness. On October 5th he had but 0.4 per cent. sugar, absolutely no thirst, and passed about four pints of urine daily. There was marked improvement in his entire condition. November 4th, the urine contains no sugar; specific gravity, 1.020; the patient passes four pints of urine; he has no thirst, no diuresis, no diaphoresis. He has gained over two pounds, and feels perfectly well again. He takes bichloride, one-sixteenth grain, three times daily.

Case VIII.—A. P——, aged sixty-two; a most remarkable case, showing very rapid improvement; he has had the disease five years. He came under observation the first time, September 29, 1898, at which time he passed twelve pints of urine; specific gravity, 1.036; 4.1 per cent. sugar; no albumin. He weighs one hundred and seventy-four pounds, a loss of twenty-four pounds in six weeks. There were great and rapid emaciation, extreme thirst, severe itching, continuous headache, great weakness and languor. Gerhardt's test failed to reveal diacetic acid; no acetone present. I began with one-twelfth grain of bichloride and rapidly increased to one-sixth grain three times a day. October 6th, passed five pints of urine; specific gravity, 1.024; 2.75 per cent. sugar. He had less thirst, no headache, was more cheerful, though still very weak. October 14th, he passed four pints of urine; specific gravity, 1.018; 0.75 per cent. sugar; he has increased two pounds in weight. Mixed diet was prescribed; he feels a little stronger; treatment was ordered to be suspended for one week. October 27th, four and one-half pints of urine were passed; specific gravity, 1.020; 0.2 per cent. sugar. He has again increased two pounds, and is taking bichloride, one-sixteenth grain, three times a day. November 5th, he passed three and one-half pints of urine; specific gravity, 1.020; 0.2 per cent. sugar; he has gained five pounds since September 29th. November 21st, there was absolutely no sugar; specific gravity, 1 020; he feels very much better. Mercury was continued.

Case IX.—H. G——, aged fifty five; a very unique case, because the patient had been impotent for nearly three years After seven weeks of treatment, there was not only a reduction of sugar from 5.5 to 1.3 per cent., from passing twenty-nine pints to three and one-half pints of urine daily, with an abeyance of the most severe symptoms—such as great thirst, great weakness, and acetone in urine—but also a change from a condition of impotence to one of restored manhood. This case may demonstrate the contagiousness of this disease, for this man's wife has had diabetes for quite a number of years, and, as far as I can find, the most rigid examination to which I have subjected him fails to reveal the presence of disease in any of the organs to which this affection has been attributed.

Case X.—S. P——, aged sixty-eight, has had the disease four years, and showed very rapid improvement under bichloride treatment. He commenced treatment, September 13th, on which day he passed ten pints of urine; specific gravity, 1.030; 4 per cent. of sugar; no albumin. I began with one-twelfth grain of bichloride three times a day. October 13th, four and three-fourths pints of urine were passed; specific gravity, 1.024; sugar, 1.65 per cent. The patient gained two pounds in weight. November 9th, he passed four pints, specific gravity, 1.020; no sugar, no albumin; he has added two pounds more to his weight. I now allow him a little bread three times a day. November 16th, he passed three and one-half pints of urine; specific gravity, 1.024; no sugar. There was marked improvement in the general condition.

Case XI.—M. G——, aged thirty-two. This was a very serious case in a rather young individual. The disease was first noticed three years ago. He came under observation the first time on October 12th, on which day he passed seventeen pints of urine; specific gravity, 1.035; 5 per cent. of sugar; no albumin. He weighs one hundred and forty pounds. I ordered restricted diet and bichloride, which was run up to one-sixth grain three times a day. On November 3d he passed ten pints; specific gravity, 1.028; 2.95 per cent. sugar. He has increased eight pounds in weight. November 16th, he passed six pints of urine; specific gravity, 1.024; 0.8 per cent. sugar. He weighs now one hundred and fifty pounds, and says he never felt better. He still takes bichloride, one-sixteenth grain, three times daily.

Mr. Chairman and gentlemen, from the results of the treatment in the cases just cited, I feel justified in claiming for this drug a specific action in the reduction of sugar in diabetes mellitus. As the treatment and observations have not extended over sufficient time, I do not as yet feel warranted in claiming a positive cure of this disease. But as the results thus far have been so favorable, I see no reason, if the hypothesis as stated above—that this disease is due to a bacterial infection—be true, why we may not expect an ultimate cure. I would therefore ask that each and every one of you give this drug a fair trial in this disease; for it is only on accumulative evidence that we can base positive facts, and if your successes should be the same as mine, I think that we can then feel positively sure that the bichloride of mercury is a specific in diabetes mellitus.

40 East Sixtieth Street.

NEW METHOD OF CREATING A VAGINA IN A CASE OF CONGENITAL ABSENCE.

By ROBERT ABBE, M.D.,
NEW YORK.

Complete congenital absence of the vagina occurs sufficiently often to have come under the observation of most practitioners. It has heretofore baffled the ingenuity of surgeons to create a new one that would remain. We must distinguish between atresia or congenital closure of the outer or middle portion (where the uterus and the vaginal wall near it remain), and the entire absence of vagina with usually absence of uterus and ovaries. In the former, a surgical procedure will easily make a complete and enduring canal.

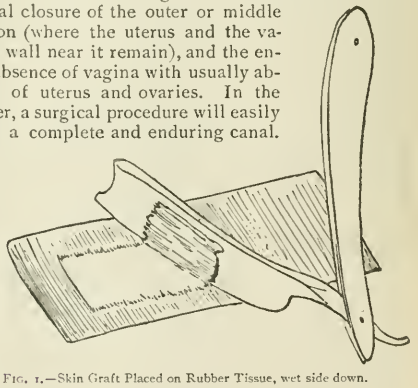

Fig. 1.—Skin Graft Placed on Rubber Tissue, wet side down.

In the latter, the attempt has often been made of opening the cellular plane between the rectum and the bladder, and by tampons—after a long period of granulation—trying to induce skin cicatrization to grow inward. The dimpled cicatrix that results has never been worthy of being called a success.

During the past two years two cases have come under my care. The first was that of a young country girl from Long Island, who sought her doctor's advice soon after marriage. He found what he supposed to be a very small orifice through a tough hymen, and introduced a blunt knife through it, splitting the posterior wall well back on the perineum. A gush of urine showed that he had entered the urethra and cut it completely backward. After a fortnight of wretched existence, during which the ignorant husband had frequent intercourse into her bladder in spite of her suffering, she was brought to me. Urine was not retained in the inflamed bladder. The genitals and thighs were excoriated by ammoniacal urine. There was an absence of vagina, uterus, and ovaries.

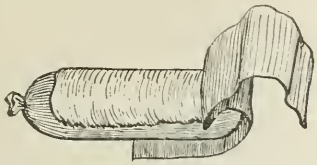

FIG. 2.—Skin Grafts Transferred to Stuffed Rubber Pouch, wet side up.

I restored the bladder wall and urethra by a plastic operation, making suprapubic drainage for four weeks—and thus she was as well as before marriage. I then split the recto-vesical space where the vagina should have been, and utilized the rather large labium minus on one side to make a lining for it, by dissecting free the edge toward the vagina and separating the two mucous surfaces so as to open it up into a long sheet with attachment only at the junction with the labium majus. The free edge was then stitched to the deepest point of the new vaginal space, and an iodoform-gauze packing placed within to hold it in contact with the raw surface. Thus a depth of two and one-half inches was lined on one side by mucous membrane. Excellent union took place, and for two months a vagina two inches deep was kept open by bougies. When she returned to her husband, however, it was found inadequate and the married couple soon separated.

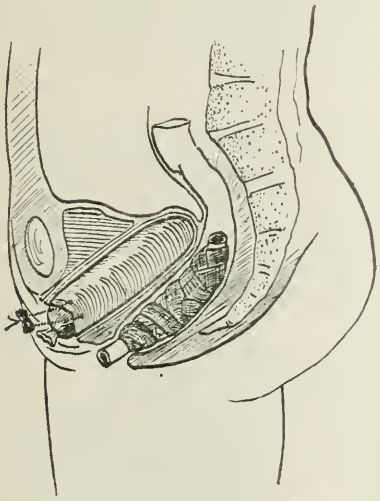

FIG. 3.—Graft-Covered Form Fixed in Place for New Vagina, gauze-covered tube in rectum.

Soon after, an attractive young lady of twenty-one years was brought to me with this history: Having become engaged to be married, she confided to her sister that she had never menstruated. They sought their family physician, who discovered that she had apparently no vagina. When brought to my office I found that every appearance of the external genitalia was perfect, except that from the meatus urinarius to the perineum was a blank wall. Rectal examination showed entire absence of uterus and ovaries.

I carefully planned and carried out the following operation: For several days the alimentary canal was made as empty as possible. A crescentic cut was made across the interlabial space, with concavity upward, thus getting a little shelf of mucous membrane below the urethra to divert escaping urine. By blunt dissection a free cellular space was readily created between the bladder and the rectum, to the depth of five inches. This was temporarily packed with sterile gauze to check oozing. Thiersch skin grafts were then cut from the thigh sufficient well to cover an ample plug made thus: A thin French rubber pouch, such as can be obtained at drug stores, was sterilized by boiling and stuffed with long strips of iodoform gauze to its full capacity. Upon this the skin grafts were spread with their wet sides outward and edges freely overlapping. Numerous small punctures had been previously made in the rubber after stuffing, so that the gauze contents would receive any discharge lurking about. A piece of rubber tubing, the size of one's little finger, wrapped loosely about with iodoform gauze, was now inserted into the rectum, with a view of permitting free exit of gas during the subsequent days of enforced constipation. Finally the graft-covered form was carefully passed into the new vaginal space, the walls of which were held apart by three deep retractors, which on removal allowed the fresh surfaces to come into closest contact with the wet surface of the grafts. To prevent the plug from being in the slightest displaced, two silkworm-gut stitches were passed across the vulva, transfixing the gauze-packed tampon, and tied over iodoform plugs at either side, as seen in the illustration.

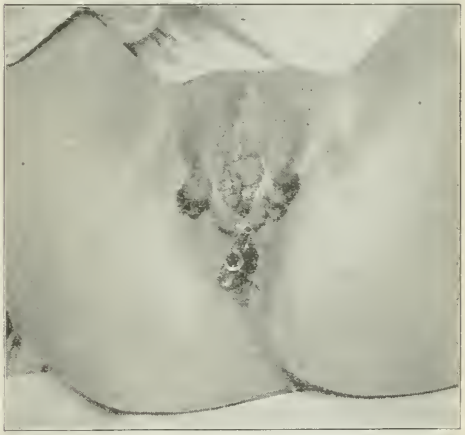

FIG. 4.—Appearance after Operation.

The urine was drawn every eight hours for a week, with such precaution that no cystitis resulted. The bowels were confined for ten days, without the slightest discomfort to the patient. Light diet was given. No febrile reaction whatever followed.

On the tenth day the retention suture was removed, the end of the plug cut, and the packing first removed before the rubber form. After cleansing, it was seen that the grafts had taken universally and a new lined cavity had been created, four and one-half inches deep.

The problem of preventing contraction now presented itself. For four weeks I kept the patient recumbent, packing the vagina with gauze liberally smeared with lanolin, and afterward, when the new skin was quite tough, dilating daily with large vaginal plugs and bougies, which were worn for a few hours at a time.

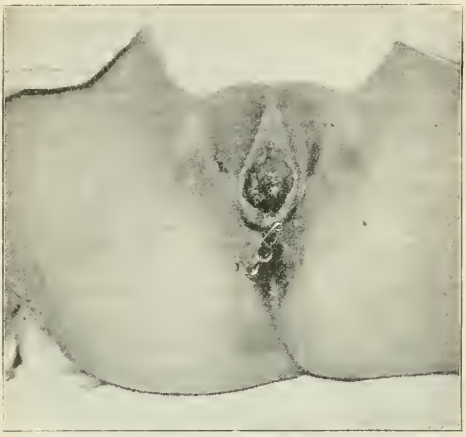

FIG. 5.—Tenth day. Retention stitch removed.

Ten weeks after the operation the patient married. She left the city for the summer, and was seen by me several times. When she began to go about, the gravitation of the abdominal contents tended to shorten the vaginal canal, and I saw that it would be necessary for her to wear a vaginal plug part of every day at least. Several varieties were tried, but nothing was so comfortable as a good-sized wax candle smoothed and rounded, and kept in by a T-bandage. Omissions of one or two weeks repeatedly allowed considerable shrinkage, but the renewal of the plug overcame it.

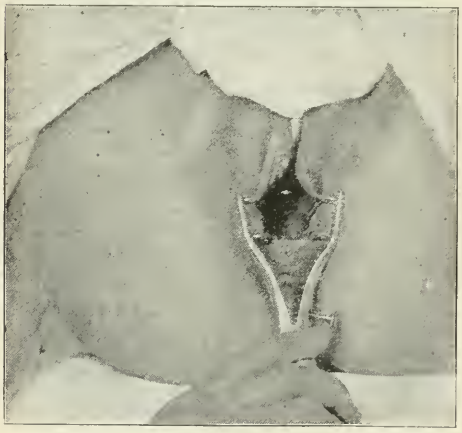

FIG. 6.—View Immediately after Removal of Plug. Speculum blade four inches deep

Inevitable stenosis by cicatricial contraction has reduced the original canal to smaller proportion, but, as it was made more than ample in the original design, it remains to-day a practical and competent canal, fulfilling at least one of its functions, and giving gratification to the mated couple. I have enjoined the continued use of the wax bougie for many months to come.

A FEW SPANISH WOUNDS.

By ELON O. HUNTINGTON, M.D.,
ASSISTANT SURGEON, UNITED STATES NAVY.

In our recent war with Spain the medical corps of the navy has had little to record in either a medical or surgical way. A few cases of heat prostration in the fireroom, as some vigilant blockader steamed away, under forced draught, after a bit of smoke or canvas on the horizon; an occasional contused hand, caught by the breech-block of a rapid-fire gun; or "wounded by the premature discharge of his own rifle," recorded of some unfortunate marine, include the greater part of the casualties. As the reading public knows, the wounds inflicted upon our jackies and marines by the enemy's fire can almost be counted upon the fingers of one's hands.

Marvellous as is this record, in view of the enormous damage done by our guns to the ships and men of the enemy, and cause for thanksgiving to a protecting Providence as it has been to every true American, it nevertheless has failed to meet the expectations of those medical officers who volunteered their services for the war in anticipation of a wide surgical experience, and to the surgeons of the regular service, looking for a harvest of operations.

After the destruction of Admiral Cervera's fleet on July 3d, however, there was an abundance of work for those into whose hands the wounded survivors fell. The absence of "first aid to the injured" measures on the Spanish ships, and the fact that many of the wounded were for hours in the water or unattended on the Cuban coast, together with the tearing character of the shell wounds, led to very general wound infection. This was in marked contrast to the clean Mauser bullet wounds with which our army surgeons had to deal, and which, in the great majority of cases, healed with the rapidity of small, clean, incised wounds.

It was my good fortune to be assigned to the care of the wounded Spaniards who were brought to the naval hospital at Norfolk soon after the battle by the ambulance ship *Solace*. That war was real and had its horrors was quite apparent, as stretcher after stretcher with its Spanish wreck was borne from the pier to the hospital.

Following the stretcher cases came those who were able to walk, wearing the only covering they possessed —namely, suits of pajamas, which were given to them on the *Solace*. Their helplessness and evident suffering made it no great effort to forget that they were enemies, and to treat them with as much care and attention as our own men received.

During the seven weeks of their stay in the hospital their behavior was all that could be desired. Only once was it necessary to discipline any of them, and that was in the case of a handsome young Don, who considered himself of somewhat finer clay than the rest, and refused to perform some light duty assigned to him as a convalescent. A very brief confinement on bread and water made him one of the most tractable of them all.

In addition to the wounds, of which each possessed one or more (one fellow from the *Vizcaya* cheerfully carrying a dozen as souvenirs of the battle), a large number were the victims of malaria. Temperatures of 105° F. were abundant. The paroxysms were easily controlled by quinine, however, in the majority of cases.

A detailed description of their various wounds would prove tiresome, I fear, but I may venture to outline a few which were of most interest to me. All save four of the men were wounded by fragments of shell, some escaping with a single fragment's light touch, others riddled with fragments varying in size from that of a pin-head to an inch or more in diameter. Search-

ing and enlarging sinuses for the discovery and extraction of these fragments formed the greater part of the operative work falling to me, most of the necessary amputations having already been performed by the surgeons of the *Solace* on her way north.

The effort of fragments to lodge as near a large artery, and still make the "miss as good as a mile," was apparent in a number of cases. In one boy (they were all boys, few being over twenty-two or twenty-three years old) was found a ragged piece of shell, the size of a silver dollar, lying against the inner side of the left femur, at about the junction of the middle and lower thirds, the artery being uninjured. This boy, who was at one of the guns on the *Vizcaya*, gave the credit of his retirement from action to the marksmanship of some gun-captain on the *Iowa*. He was sure the shot came from the *Iowa*, and described vividly in pantomime the bursting of the shell, the death of his comrades at the gun, and his own wound, which did not deprive him of consciousness.

In another case, a small fragment, making directly for the arch of the aorta, spent its energy in the production of a compound comminuted fracture of the upper extremity of the sternum and a compound dislocation at the left sterno-clavicular articulation. An alarming feature of this case was the frequent occurrence of a most intense spasmodic dyspnœa. The nature of the injury made respiratory efforts extremely painful, and the patient's condition, until relieved by morphine and glonoin, was a distressing sight. These attacks were accompanied by a marked torticollis, produced by the unopposed action of the right sterno-mastoid muscle, which persisted to a less degree during the interval between paroxysms. He had two or three such attacks daily at first, but they gradually became less frequent and the torticollis less pronounced up to the time of his discharge, when the latter was barely noticeable, and he had had no dyspnœa for some three weeks.

A shell exploded so near a fireman on the *Oquendo* that he was covered with powder burns from head to foot, but the only fragments of shell which struck him produced a slight scratch on the left buttock and a penetrating wound of the right knee-joint. Unfortunately pyæmia was the result of an effort to save the extremity after infection of the wounded joint had taken place.

A happier result for conservative treatment followed, however, in the case of a suppurating, compound comminuted fracture of the humerus and ulna at the elbow-joint. In addition to that wound the patient had received shell wounds of both legs, the thumb of the opposite hand had been torn away, with several scalp wounds, and a severe burn of the back and left side. His general condition was very low indeed; so conservatism was perhaps "Hobson's choice." At any rate, he recovered, his wounds healed, and he now has a fairly good elbow-joint.

The four cases which I mentioned as exceptions to the list of shell wounds were Spanish prisoners who were shot by the sentries on board the United States steamship *Harvard*, during the supposed mutiny, shortly after the battle of July 3d. Theirs were therefore wounds produced by small-calibre bullets at close range, and in the cases in which bone was struck very great damage was done.

A seaman from the *Oquendo* was shot in the right shoulder. The ball entered behind and internal to the head of the humerus, and shattered the right scapula just below its spine, some fragments being driven out through a ragged, irregular wound of exit, about three inches in diameter, directly above the vertebral column. The ball itself, instead of leaving by this wound, passed on beneath the left scapula and lodged behind and to the inner side of the head of the left humerus, from which situation it was extracted Necrosis of some fragments of the fractured scapula induced profuse suppuration in the tract between the wound of entrance and the central wound. This tract was laid wide open and the greater part of the scapula below the spine was removed. At the time of his discharge this tract was granulating well, the patient's general condition was very good, and he was able to use his right shoulder without pain, and with a fair degree of power.

In the second case, a ball entering at the inner side of the left thigh, just below the ilio-femoral fold, struck the femur and comminuted it for the extent of three or four inches, driving some of the fragments out through a wound of exit below the great trochanter, nearly as large as a man's hand. The patient's general condition was very poor when he entered the hospital, and his wound was suppurating freely. The verdict of a consultation was that an immediate amputation was contraindicated. A week's time was devoted to feeding and stimulation, in an effort to get the patient into a better general condition, if possible, to stand the operation. His condition did improve somewhat, but an amputation at the hip-joint proved more than a match for his resistance, aided though it was by salines in abundance and hypodermics *ad libitum*. He succumbed to shock after a temporary recovery from the anæsthetic.

A very painful condition was that of a fireman, who was wounded in the right buttock. The ball entered below and to the inner side of the great trochanter, and made an exit about two inches below and internal to the wound of entrance. Both wounds were healed when the patient reached the hospital. There was an area of ecchymosis, somewhat indurated, on the inner side of the thigh, over which he complained of slight pain, but his chief complaint was of sharp, almost continuous pain in the sole of the right foot. Examination of the foot showed no injury whatever, and there was no tenderness over the part. The pain in the foot was, however, real and severe, requiring large and frequent doses of analgesics to keep the patient quiet. His groans and cries disturbed the whole ward when he was allowed to come out from under the influence of the drug. The entire extremity was carefully examined with the fluoroscope, a clear view being obtained, with absolutely negative result. The condition gradually passed away, and when he left the hospital he no longer required the use of morphine. What caused the pain in the foot? Was it pressure of a hæmatoma in the thigh? was the great sciatic touched by the bullet? or was the pain in the foot independent of the gluteal wounds? It is my belief that the nerve was injured by the bullet in its passage through the buttock.

The fourth mutineer was a sailor from the *Oquendo*, who was shot in the right leg with such destruction of the part as to necessitate an amputation at the knee-joint, which operation was performed upon the *Solace*.

The majority of cases were of interest chiefly for the marked and rapid improvement in their general condition. Their shell wounds, serious though they were in many instances, became monotonous from their abundance. The men had been on short rations for a long time, and the vitality of all was greatly lowered. The effect of feeding and nursing was happily demonstrated to all concerned with their care; and when they sailed for home, though many of them lacked the normal number of arms and legs, they were a far healthier lot of Spaniards than when they sailed out of Santiago harbor to do or die for a lost cause.

Pernicious Vomiting.—Cocaine hydrochlorate, gr. ⅙ hypodermically once or twice daily, immediately before feeding.—Pozzi.

EYE LESIONS IN SOME DISEASES OF THE KIDNEY.[1]

By HENRY S. OPPENHEIMER, M.D.,
NEW YORK.

The eye shows lesions consequent upon kidney trouble, in every one of its vascular tissues. I say "consequent upon kidney trouble" deliberately, because formerly it was taught that certain eye lesions preceded troubles of the kidney. It is true that the presence of the eye lesion found by the ophthalmologist is often the first thing to call the attention of the patient and his physician to the existence of trouble in the kidneys. But, although a single examination for albumin may prove negative, it has been my experience that repeated and careful search for casts and albumin is sure to prove successful sooner or later. As to the frequency of the eye lesions which are observed in this connection, the retinitis albuminurica, with or without hemorrhages, is much the most common. But others are seen either separate or in connection with the retinal lesions.

Thus we see commonly in the nephritis of acute diseases, or in the later stages of the chronic ailment, the œdematous infiltration of the eyelids, especially the lower ones. The loose subcutaneous cellular tissue of these parts favors the spreading of serous exudations. Thus we frequently see œdema here, when it cannot yet be detected in other parts of the skin. It is apt to be transient, however, until we have pitting in the malleolar region. Again, I have seen cases in which œdema never appeared in the face, although great accumulations of serum had taken place in the abdominal cavity, etc.

The conjunctiva may become œdematous to the point of chemosis. An extreme and therefore rare case of this, in which the conjunctiva was elevated to the extent of leaving the cornea down in a depression (chemosis), is reported by Brecht.[2] This case had also detachment of the retina, which reattached itself later on.

Hemorrhages into the conjunctiva, sometimes in advance of the retinal affection, have been seen by Talko.[3] Samuelson[4] saw hemorrhages in both lower eyelids preceding a hemorrhagic retinitis albuminurica. Wharton Jones[5] has reported a case of extensive bleeding into Tenon's capsule, with protrusion of the eyeball and blindness, in disease of the kidneys with the hemorrhagic diathesis.

Troubles with the extrinsic eye muscles are not rare in this connection, and a search for albumin should be made in every case of non-traumatic paresis of eye muscles, which develops rapidly and seems to be due to lesions at the base or at the nerve roots. Finlayson[6] cites a case of interstitial nephritis with paresis of the right abducens muscle, which he was so fortunate as to have an autopsy upon. This revealed hemorrhages in the gray substance of the anterior portion of the cerebellum, near the median line, close to the fourth ventricle, and a third on the left posterior portion of the pons near the median line. Knies[7] gives three cases: (1) Paresis of abducens, the only eye lesion in a case of albuminuria, remaining after typhus and existing fifteen years. It recurred several times in a few months, and then the patient died; no autopsy. (2) A left-sided paresis of the trochlearis, with hemorrhages on the right optic disc, in cirrhosis of the kidney of indefinite duration. Death after six months; no autopsy. (3) A complicated ophthalmoplegia externa in a man, twenty-four years of age, with albuminuria—a remainder of typhus contracted two years before. First the right trochlear, then as this improved the internal rectus and the other muscles supplied by the oculo-motorius, became lame. Later there were attacks, lasting one or more days, of single and double ptosis. These pareses disappeared readily. The lameness of the right internus and rectus inferior lasted longest. Fundus and internal eye muscles constantly normal. Syphilis could be positively excluded, as far as this is ever possible. The patient was lost sight of. In most cases an extravasation about the nucleus or root of the nerves seems to be the cause of the paresis. In one case, however, Leber found sclerosed fibres in the nerves supplying the abducens muscle. This much for the external eye muscles.

The ciliary muscle, doing the work of accommodation of the eye, shows its weakness, as a rule, almost as soon as the general condition of the patient is sufficiently affected, in the reduction of the power of accommodation of the eye. In young patients, or in those with myopic eyes, this weakness is less likely to be noticed. Older persons, however, especially those with hyperopic eyes, are sure to come to the oculist for stronger glasses to compensate for this rapidly increasing weakness. Fortunately, so long as there exists no serious lesion in the interior of the eye, this is easily accomplished.

One of the less frequent eye lesions observed with kidney disease is iritis. Knies' reports two cases, neither of which showed anything unusual in its course. This seems to be the rule in the cases observed, and may explain the fact that so few cases have been reported. I have seen only one, and therefore conclude that they are rather rare. This, in a woman of sixty-seven, with hemorrhages in retina and albuminuria, developed a severe iritis, which, when atropine was used, though very cautiously, resulted in increased tension and secondary glaucoma.

Hemorrhage in the vitreous humor, either breaking its way through from the retinal vessels or having its origin from the more peripheral capillaries, is not an unusual occurrence in these troubles.

But by far the most important, as well as the most frequent in their occurrence, are the lesions we so commonly see in the retina, optic nerve, and choroid coat. I am aware that I am somewhat heterodox in associating the choroid with the retina in this connection. But I am well satisfied that in the severer processes the choroid is implicated in the affection of the retina. There are two reasons why the choroiditis in this connection is rarely mentioned. The retino-choroidal pigment hides, in a great measure, the process in the choroid coat; and, secondly, the exudation in the retina itself prevents the lesion of the choroid from being seen. But in the greater number of reports of anatomical and microscopical examinations of such eyes, my statements are borne out.

Retinitis albuminurica, or neuroretinitis albuminurica—for the optic nerve is very often more or less involved in some stage of the process—is so well known that I hesitate to describe it. We mostly see it when it is fairly pronounced, with its characteristic arrangement of whitish points, in a more or less complete stellate form, around the macula; with the retina hazy or whitish over the central part of the fundus, involving especially the region of the macula and nerve; the vessels perhaps partially covered with the exudation, and the veins larger than normal. Hemorrhages associated with this ophthalmoscopic picture are the rule rather than the exception. They may be few or very numerous. They are mostly flame-shaped or striped; taking these shapes when in the nerve fibre layer, as is commonly the case. But they

[1] *Loc. cit.*

may occupy other layers of the retina, and then take more or less circular forms. When we see the trouble at its beginning, it may be limited to a slight haziness of the retina in the central portion of the fundus, with a lessening of the light streak upon the vessels within the affected area, and perhaps the outlines of the optic disc a little indistinct or washed out. This may increase until, in the severer neuritis, we have an appearance resembling choked disc. The white spots appear gradually, and not always in the typical stellate arrangement. They may coalesce and thus cover a good part of the region occupied with its vessels. The fovea centralis in such cases will look bright red in the centre of this white or yellowish-white field. The periphery of the eye usually remains free, and this explains the fact that the patients very seldom become completely blind. The vision is, of course, reduced according to the severity and extent of the exudation.

As a rule, this affection is binocular, although many cases have been observed in one eye only. Sooner or later, however, the second eye is apt to follow its fellow in showing the lesion. The course of this disease depends upon that of the kidney trouble.

In acute cases, arising from the exanthemata or from pregnancy, we see quite a proportion of complete recoveries, although even in these some cases go on from bad to worse. The prognosis is always worse when hemorrhages are present, as we can assume the same condition of the vessels in the brain which we observe in the eyes. When the causal factor is removed, the blood becomes gradually absorbed, leaving perhaps some pigmentation behind to show its former site. The whitish exudation disappears very gradually, and completely only in cases in which the kidneys assume normal conditions and functions.

Dr. Bull reported to the American Ophthalmological Society, in 1886, one hundred and three cases observed by him, of which at the time of the report eighty-six had been fatal. Of these patients, fifty-seven died in the first year, eighteen in the second, six in the third, four in the fourth, and one in the sixth year. In four of these cases sugar was present as well as albumin. Of the four patients two died in eight months and one in fourteen months. Thus he shows that over half die the first year, and about three-fourths the second (73.4 per cent.). The ages of the patients were from five years to seventy-eight. In the progress of this inflammation there may be some temporary improvement; at times this can be made out with the ophthalmoscope, at others not. There may be new spots of exudation or hemorrhage, and some may disappear. The retina may become folded and even detached. Herter[1] reports a double retinitis with detachment, in a woman eight months pregnant; Anderson,[2] detachment of the retina in a child with chronic nephritis; Hirschberg,[3] double detachment in a man of twenty-two, with retinitis albuminurica. In pregnant women these detachments seem to occur more readily than in others, and tend to replace themselves often, but not always, at the end of pregnancy. Cases of permanent blindness remaining are reported (Fürst[4]); several cases after kidneys had healed (Weeks,[5] one).

Teillais[6] cites four cases of retinal hemorrhages in pregnant women, all of whom recovered after pregnancy; one of these had the complication of nose bleeding and hæmoptysis. As to the anatomical condition of retinitis albuminurica, we have, primarily, changes in the blood-vessels. The lumen of the smallest arteries and capillaries especially is narrowed through thickening of their walls; especially the intima is affected, which may lead to thrombosis and complete closure of the vessel. This can be studied through the ophthalmoscope, and in the retina it can be easily made out. But the condition extends to every vascular tissue of the eye. Hemorrhages occur from the veins and capillaries mostly. The œdema around these foci leads to the lifting and folding of the retina which have been observed. The white spots we see with the ophthalmoscope show to be fatty degeneration of the tissues and exudations. Some authorities have found exudations they describe as lardaceous, colloid, or amyloid, but the characteristic chemical reaction of amyloid tissue has never been obtained, so far as I know.

As a rule, the layer of rods and cones and the pigmented epithelium are not involved, excepting in severe cases.

The essential nature of this process appears to me to be consequent upon the changes in the blood-vessels. An irritant to the tunica intima exists in the blood, whether this be urea or some other substance of imperfect elimination, or any other poison, be it of scarlatina, malaria, diphtheria, syphilis, mercury, lead, phosphorus, alcohol, or what not. It irritates the blood-vessels, causing contraction of the arterioles and capillaries. This persistent irritation and contraction produce thickening of the coats of the vessels, lessening their calibre and throwing more work upon the left heart, thus in turn producing the hypertrophy of the left ventricle so constantly associated with chronic kidney disease. Now, then, we have a vitiated blood, increased arterial tension, diseased blood-vessels, and a hypertrophied heart. The condition affects the kidneys as well as the rest of the system. In the retina and the cortex of the brain, etc., we have terminal arteries, and, for lack of anastomosis here to supply the deficiency of circulation, the same as in other parts of the body, we are apt to have disturbances of nutrition and necrobiosis. In the retina the locus minimæ resistentiæ is the region of the macula, where fatty degeneration in the nerve-fibre layer, from imperfect nutrition, produces the typical stellate white figure seen ophthalmoscopically. The condition of the blood, the vessels, and the vis a tergo will determine whether we shall have hemorrhages at the beginning or later. Hypertrophy of the heart alone is in my opinion not sufficient to explain, as has been formerly attempted, the occurrence of these.

Thus we have seen occur, to recapitulate, from insufficient or vitiated blood supply, or from hemorrhages due to disease of the smaller vessels, œdema of the lids and conjunctivæ, hemorrhage in the conjunctiva, into the capsule of Tenon, into the orbital tissues and the eye muscles or their supplying nerves or trophic centres, inflammation of the iris, retina, and choroid coats of the eye, with hemorrhages into any and all of these, as well as into the vitreous—these conditions also extending to or sometimes beginning in the optic nerve. I shall not venture to go into the subject of treatment of these troubles. The treatment best for the kidneys is also that which holds out the greatest promise for the eyes. Now and then we are called upon to use (to fulfil local indications) a mydriatic, a counter-irritant, or perhaps massage, or electricity for a lame muscle; but, as a rule, the family physician treats my eye cases coming under this head.

I have left for consideration to the last the most serious disturbances of vision connected with renal trouble—uræmic amaurosis. It is an amblyopia developing in the course of acute nephritis, coming on gradually or, as in most cases, rapidly. We see it usually in the nephritis of the exanthemata, as scarlet fever, etc.; or in that of pregnancy. When it occurs in chronic nephritis, it is during an acute exacerbation, and warrants a grave prognosis. It is accompanied usually by headaches, nausea, and vomiting, and may occur during uræmic convulsions. Pulse hard;

arterial tension great. Urine loaded with albumin. There may be complete unconsciousness, and the patient may find himself blind on recovery from this; or he may be perfectly clear in mind and find darkness coming on rapidly, and, most often completely. The pupils are wide, as a rule, but may be contracted—the characteristic peculiarity being that, although the patient may be wholly insensible of any light sensation, there is usually reaction to light, even when the patient is unconscious. In the exceptional cases, when this reaction has not taken place, there have been inflammations of the optic nerves to account for its absence. This condition is always double sided. There may be retinitis with this amblyopia, but in such cases it has existed before the amaurosis, and continues after this has subsided, and has no influence upon it. In uncomplicated uræmic amaurosis there is usually no ophthalmoscopic change to be noticed. In a few reported cases there was narrowing of the arteries to be seen with the mirror, showing arterial spasm. The prognosis depends upon the condition of the kidneys. The patient may die in the uræmic attack. When this is recovered from, the vision usually returns in from twelve to seventy-two hours. The condition is clearly one of poisoning of the nerve centres, producing arterial spasm and consequent cerebral anæmia, with, perhaps, serous exudations. The reaction of the pupils to light proves this blindness to be of central origin. As to the frequency of uræmic amblyopia, I know of no statistics so conclusive as Dr. Bull's,[1] who observed it in thirty-seven cases out of the one hundred and three referred to above. The differential diagnosis between retinitis albuminurica and this amblyopia is so easy as hardly to need mention. The former is gradual, permits the patient to go about in reasonable health, and presents distinct retinal lesions. In this amblyopia the patient is found in bed, having become more or less suddenly and completely blind, with cerebral symptoms more or less pronounced, even to coma, and, as a rule, no lesion appreciable in ophthalmoscopic examination.

16 East Thirty-Second Street.

Progress of Medical Science.

The Abuse of the Mechanical Treatment of Uterine Diseases.—Dr. C. K. Flemming, in a paper on this subject, read before the Denver and Arapahoe Medical Society, October 25th, drew the following conclusions: (1) The vaginal speculum is capable, through lack of asepsis, of carrying infection into the vagina and thence to the uterus. (2) The uterine sound should have no place in the armamentarium of the general practitioner. (3) The results from intra-uterine medication are, to say the least, unsatisfactory, and may be decidedly harmful. (4) The rapid dilatation of the cervical canal is the ideal method, and the operation should be performed in the home of the patient or in the hospital. (5) The uterine curette should never be used in the office. (6) Pessaries are useful only in the treatment of displacements, are only palliative, and should not be used unless radical means are refused.

The Evolution of Ovariotomy.—Dr. A. Martin, in an address delivered at a special meeting of the British Gynæcological Society (*Pacific Medical Journal*, October), said: "I have spoken of vaginal cœliotomy, and you may wish to know through which cul-de-sac we should enter. Gaillard Thomas and the first operators, including myself, incised the posterior, and this method has been recommended by Mackenrodt, Löhlein, and others quite recently. Dührssen performed the operation through the anterior, and so do I now. Undoubtedly the posterior incision is nearer to the ovarian pedicle when the normal anatomical relations of the pelvis are undisturbed. But I think we obtain a much better view of the pelvic cavity through the anterior. After separating the bladder from the uterus and having opened the vesico-uterine pouch, we can easily insure them against injury. The uterus having been brought outside, half of the hand can then be introduced. Through this opening the pedicle of the ovaries is easily reached, because the ligamentum ovaricum proprium is stretched when the uterus is outside. When of normal size the ovary can now be seen, but if greatly enlarged by outgrowths only its lower segments. We can fix the pedicle with a good forceps and pull the tumor downward and forward. If it needs evacuation allow the fluid or other contents to escape without touching the peritoneum. After the tumor has been brought outside the pedicle can be secured with ease, which is done in the same way as by the abdominal method. After examination of the other ovary and the whole pelvic cavity, the operation is practically over. The uterus is now replaced in its normal position. When the wound is closed the peritoneum is included in the same sutures which close the upper sections of the wound, and if necessary, in cases of retroflexion, the uterus also is fixed to the vaginal wall. In young women it is advisable to pass these sutures not higher than two centimetres above the internal os. This will answer to prevent further displacement and insure safety in case of subsequent pregnancy. I must not forget to add that the uterus is easily freed in this way of its adhesions resulting from acute and chronic peritonitis, and secured by a correct vaginal fixation in proper position. It is generally known that the patients recover rapidly after this anterior colpotomy. Drainage I have not required in a single case out of my seven hundred and five."

The Depopulation of Cities Infected with Yellow Fever.—Dr Felix Formento (*New Orleans Medical and Surgical Journal*, October) concludes as follows: (1) General depopulating of towns and cities infected with yellow fever, however desirable, is not practicable. (2) Voluntary exodus of individuals and families is to be encouraged at the first breaking out of the disease. (3) During an epidemic, depopulating should be carried out under special sanitary precautions. (4) Depopulating of houses in which first cases occur, by removal of the sick to properly constructed hospitals and of the well to special camps of observation, and thorough disinfection of houses, are considered the most efficient measures for stamping out the disease at its birth. (5) Isolation of the sick and destruction or disinfection of discharges from the bowels and of all contaminated material, with disinfection of the premises, are the best means of limiting the disease. (6) All measures of repression of an arbitrary character are to be applied to a limited number of cases only. If they fail they should be discontinued, as they are an additional burden to the sufferings and hardships of the people.

Classification of Headache.—I. Diseases of the nervous system—(*a*) Neurasthenia; (*b*) hysteria; (*c*) meningitis purulenta and tuberculosa; (*d*) pachymeningitis hæmorrhagica interna and cervicalis hypertrophica; (*e*) hydrocephalus; (*f*) brain tumors; (*g*) circulatory disorders of the brain: hyperæmia and anæmia, arterio-sclerosis; (*h*) neuralgic headache: (1) neuralgia trigemina, (2) neuralgia cervico-brachialis; (*i*) migraine; (*j*) traumatic headache; (*k*) the so-called habitual headache. II. Diseases of the sense

[1] *Loc. cit.*

organs. III. Diseases of the digestive tract. IV. Diseases of the kidneys. V. Constitutional diseases —(*a*) anæmia; (*b*) chlorosis; (*c*) diabetes; (*d*) leukæmia. VI. Intoxications. VII. Infectious diseases. VIII. Rheumatism of the scalp.—Dr. Windscheid, *Public Health Journal*, October, 1898.

The Action of Drugs in Children.—Dr. J. B. McGee says that while as few drugs as possible should be given to children, when indicated they should be used freely. We should know what a drug cannot do as well as what it can do. In most children the tendency toward recovery in slight ailments is very strong. Medication should be simple. Medicine eliminated rapidly should be frequently repeated; such as alcohol, nitroglycerin, the ammoniacal salts, aconite, and belladonna. Digitalis is cumulative and should be given at wide intervals. Pills and powders are not easily taken by young children. Active principles and remedies in small bulk are to be preferred. Salol and sulphonal in pill or tablet may pass through the intestinal canal intact. Glycerin is a better vehicle than syrup, especially in summer. With the exception of opium and its alkaloids, larger doses may be given than are usually stated. The salts of sodium are to be preferred to those of potassium. Care is necessary in giving opium, with the exception of paregoric, one drop of which for each year is a safe dose. Dover's powder should not be given to children. Chloral is a good sleep producer. The bromides are very slowly eliminated. Sulphonal and trional are safe hypnotics for children. Belladonna is exceptionally well tolerated in children, and may be given in two-drop doses for each year, and even sixty drops a day have been given to a child two or three years old. Alcohol is one of the best heart stimulants and seldom disagrees with children. Strophanthus is to be preferred to digitalis. Caffeine and cocaine are not well borne, but strychnine is. Children stand the preparations of mercury and arsenic well. Cold is a good antipyretic, but phenacetin and acetanilid may be used, and also quinine in malaria.—*Medical Standard*, October, 1898.

Hysteria Virilis Simulating Chronic Intestinal Stenosis.—Dr. Strauss, of Berlin, mentions the case of a patient who, in the past eight years, had visited numerous hospitals throughout Germany for the relief of his intestinal disturbances, and upon whom laparotomy was twice performed (*Berliner klinische Wochenschrift*, No. 37, 1898). In neither instance was there a discoverable cause for the ileus, which was the indication for laparotomy. When recently the patient, a shoemaker, twenty-eight years old, came under the writer's observation, he appeared to be a very sick man; vomiting was continuous, he passed neither fæces nor flatus, and meteorism was marked. One day, during a typical hysterical attack, the meteorism, which during five months had remained unchanged, as regards the amount of abdominal distention, suddenly and completely disappeared; there was spontaneously a movement of the bowels.

Blood Cyst of the Sciatic Nerve.—W. K. Hatch (*Indian Medical Gazette*, September) reports the case of a man, aged forty, who for ten years had had a tumor on the back of his left thigh. There had been no injury to the part, and when first noticed the tumor was small and gave rise to no pain or inconvenience. It increased in size slowly and became painful, particularly on movement, about one month before the patient came under observation. The swelling was globular, firm, smooth, slightly elastic, movable from side to side, but not up and down, and the skin over it was healthy but shining. The tumor being dissected out, its surface was found to be slightly lobulated and of bluish color, and it was connected with the sciatic nerve. A few nerve fibres were carefully dissected off, and the sac was opened and then removed from the nerve. The sac was thin walled, and contained pure blood, hæmatoidin crystals, and a little fibrin. The wound healed readily, and no alteration of sensation or of motion resulted.

Staining of the Ganglion Cells.—The new method of staining the ganglion cells has the advantage over that of others, outside of Nissl's, in that it is applicable to all hardening processes. The technique is as follows: (1) Hardening of the preparation in alcohol or Muller's fluid or formol or Müller's formol. (2) Embedding in collodion or paraffin. Best in thin sections. (3) The sections are then washed and placed in the staining fluid (polychrome methylene blue, Dr. Grübler, Leipzig), where they are either allowed to remain twenty-four hours at the room temperature, or are heated over the water bath till steaming begins. (4) The sections are washed in distilled water. Strongly to fix the stain and to increase the durability of the preparation, it is advisable to keep the sections in frequently changed distilled water for twenty-four hours. (5) The differential stain is best made on the slide. The sections which have been placed on the slide are dried and then flooded with Unna's solution of glycerin-ether, which is allowed to remain on till there is a positive macroscopical differential stain between the gray and white substance (eight, fifteen, or twenty-five seconds, depending upon the thickness of the section). The superfluous fluid is removed and the section dried, either with filter paper or, better still, with a smooth cloth. (6) Wash several times with absolute alcohol, in order to remove the glycerin-ether and to make a clear differentiation. Dry. (7) Clear in ol. origani. In order finally to remove the alcohol, wash and rinse the slide several times in this oil. Oil which has been thus employed should be thrown away. (8) Mount in Canada balsam.—Drs. Frederick Luithlew and Joseph Sorgo, *Neurol. Centralbl.*, April.

Teething.—The eruption of the teeth is a physiologic and anatomic crisis.—White.

Diarrhœa of teething is natural.—Ellis.

The fact that this diarrhœic tendency lessens during the second and third year is in no way related to dentition, but due to the protective condition of the canal, which the development of the various secretions gives it. Free hydrochloric acid is known to be destructive to fungi up to a certain point; this, of course, the infant stomach has not. Since fermentation is in no way arrested, yeast fungi are found in large quantities in infant diarrhœa. And if physicians who attach importance to the theory of teething were to examine the food served to their diarrhœic patients, they would in numerous instances find it contaminated.—Dr. Frank H. Babcock, *Virginia Medical Semi-Monthly*, October.

Among the most common pathologic results of difficult dentition are certain affections referable to the cerebro-spinal system, eclampsia being one of the admitted results.—Smith.

When similar symptoms arise at each epoch of teething, and subside with the subsidence of the gingival turgescence, teething must be regarded as the cause.—Smith.

The evolution of the teeth is one of a number of developmental processes going on in the body, and organs and tissues are prone to disease in proportion to their normal or physiologic activity.—Carmichael.

Convulsions in teething arise from nervous excitement, from the pain and general disturbance.—Bouchut.

In teething the child is passing its first climacteric.—Love.

Serum Therapy.—Dr. Thomas Richard Fraser, in his address on medicine delivered at the last meeting of the British Medical Association, said: "Serum therapy has merely entered the first stage of its development, and already the results are of much value. The mortality of diphtheria has been reduced from forty to eight per cent.; the mortality of hydrophobia has shrunk at least from sixteen to one per cent.; the prognosis of tetanus has been deprived of much of its gloomy forebodings; the cure of pneumonia, of tubercle, of erysipelas, and of septicæmia, is on the eve of being realized; a complete demonstration has been obtained of the power of antivenins to prevent the toxic and lethal effects of venoms; and the experimental data are surely being accumulated for completing the greatest triumph of preventive medicine by the discovery of an antitoxic serum for the cure of smallpox."

An Antiseptic Dwelling-House.—Dr. van der Heyden, a bacteriologist, has had an antiseptic dwelling built in Yokohama. The walls of the structure are composed of large blocks and plates of glass. In one of the upper corners of the dwelling there is a small opening, so constructed as to give egress to the inclosed air, but not permitting the entrance of air from without. The fresh air, after having been filtered through cotton saturated with glycerin, is carried into the house by means of a large tube.—*Süddeutsche Apotheker-Zeitung.*

The Treatment of Pneumonia in Very Young Children.—Dr. L. Emmett Holt (*Medical News*, November 19th) concludes as follows: (1) No depleting measures are ever admissible. (2) Hygienic treatment, including fresh air, proper feeding, and intelligent care, is of the utmost importance. (3) No unnecessary medication should be permitted. (4) Many annoying symptoms may be relieved by local treatment, such as cough by inhalations, pain by counter-irritation, restlessness by the ice-cap, or sponging. (5) Stimulants should be deferred until demanded by the condition of the pulse. (6) High temperature is much more safely and effectively controlled by the use of cold than by drugs. (7) Greater caution is necessary in the use of powerful stimulants than is generally observed. (8) Rest is quite as important as in other serious diseases.

The Treatment of Pneumonia in Infants and Children.—Dr. Henry Koplik (*Medical News*, November 19th) says that treatment must be influenced by (*a*) the age of the patient; (*b*) the severity of the infection and the amount of lung involved; and (*c*) the condition of the heart. The mortality in the newborn and very young infants being very high, the selection of remedies in these cases calls for greater discretion than at a later period of life. At an early age in some violent cases the temperature is often subnormal, so that antipyretic remedies need not be considered. In such patients the high grade of toxæmia and the excessive heart action demand the first consideration. The subnormal temperature is also a very strong argument against those who contend that the cold-bath treatment is the sheet anchor against the spread of infection; in other words, the temperature is a measure of the infection present. This is not so. The treatment by means of drugs which serve to increase the production of leucocytes—phenacetin, for example—is at present a doubtful procedure. To reduce the pulse and to support the heart are the main indications. Small doses of tincture of digitalis and tincture of strophanthus are of especial value. The former is to be given in half-minim doses until the desired effect is attained; the latter seems to be better borne by the patient. Aconite and nitroglycerin are condemned; camphor, ammonia, caffeine, and musk also are not sustained in action. Strychnine given hypodermatically in doses of one-four-hundredth of a grain is very useful. Acute heart failure is best met by hypodermics of alcohol and ether; first the latter, then the former. Tepid or warm baths seem to have a stimulating effect by drawing to the skin surface the blood which has been driven into the interior, thus restoring the equilibrium. Poultices and cataplasm are nonscientific, and useless in any form of pneumonia. Opium is very badly borne, and only tends to deepen the stupor into which the poison of the disease has plunged the patients. Opium is distinctly contraindicated in weakly, idiotic, or semi-idiotic infants. Emetics are of questionable utility, for emesis is produced only at the expense of the heart. A temperature above 104° F. for two days is a plain indication for bathing or cold pack. Frequent baths of any kind are to be deprecated. The cardinal rule is never to repeat a bath, warm or cold, unless it is found that with the reduction of temperature, whether this be slight or marked, the heart action remains good. Never give baths when the temperature has started on a decline, temporary or permanent. Many cases have been treated successfully without baths; in these cases small doses of antipyretics are of great value. Infants, aged six months to a year, will bear from one-half to one grain of antipyrin or phenacetin, combined with digitalis in one-half-minim to one-minim doses. In infants in whom the pulse is good and respirations are not excessive, digitalis, strophanthus, or strychnine is rarely called for. The more we see of the type of pneumonia in which the heart is well sustained in action and the area of lung involved limited, the less we resort to alcohol. In fact it is of use only in asthenic cases. In many cases alcohol does harm by driving the heart, reducing appetite and the capacity for digestion. Finally, the patient should be isolated from other children, and especial attention should be given to constant change of air.

Buboes.—Reynaud, of Marseilles, highly recommends the treatment of ulcerating bubo by the thermocautery, brought to a white heat and held for five minutes at a distance of half an inch from the ulcer. The patients complain of a sensation which is disagreeable but not painful. The application is made once a day, and after the second or third time the wound is seen to become modified in its character and in a week is cicatrized. After each *séance* a piece of absorbent cotton, steeped in sterilized water, is applied to the ulcer.

Syphilitic Gummata in Dementia Paralytica.—Drs. Vallon and Wahl (*Deutsche Medizinal Zeitung*, October 27th) state that syphilitic manifestations during the course of progressive paralysis are very rare, even in those cases in which the post-syphilitic nature of the paralysis is beyond question. They report two such cases, however—one in a man of forty-one, the other in a man of thirty-eight; both patients presented a typical picture of dementia paralytica. During the course of the disease a suppurative gumma of the right tibia developed in the first case, and a similar gumma of the left femur in the second. In both instances the local affection disappeared entirely in a short time under mercurial inunctions and iodide of potassium; cicatrices formed at the site of the lesion. This antisyphilitic treatment had absolutely no effect upon the general symptoms of the dementia, a circumstance which appears to be the rule. This fact is of course not proof against the syphilitic nature of the progressive paralysis. On the contrary, the authors are thoroughly convinced that in the vast majority of cases the disease is syphilitic in origin.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, December 10, 1898.

THE OPERATIVE STATISTICS OF MAMMARY CARCINOMA.

JUDGING by what we read, there are not many subjects concerning which it is more difficult to draw satisfactory conclusions than upon the final results after operations upon carcinoma of the breast. The statistical evidence upon the subject appears to be susceptible of almost any arrangement, and almost anything can be proved by it. However, we are now certain that results in the last decade are better than those in the previous one, and better in two ways—a larger percentage of cases without recurrence after three years, and fewer local recurrences. The number of deaths from metastatic deposits is probably larger in proportion to the whole number of deaths from carcinoma starting in the breast. We have practically eliminated acute operative sepsis and "shock" as causes of death, and therefore need not consider them; and when we do have local recurrences they are often amenable to further operative work, so that in many such cases the actual cause of death is metastasis or direct involvement of the underlying pleura and lung by continuity of tissue. If statistics prove anything, they show that the more radical the operation the less often we shall see local recurrence. The work of Halsted and others thus far proves this point. When we remember that some of the operators of ten or twenty years ago showed sixty or seventy per cent. of local recurrence, and that Halsted offers us a series with only six per cent. of that form of recurrence, we cannot fail to be impressed. Of course immunity from local return has no bearing upon the behavior of any internal deposit. Our English confrères do not yet seem to be entirely convinced of the necessity of what they call the "complete" operation, and we believe that there are some even who do not admit the necessity of clearing out the axilla in all cases. We cannot understand this attitude, although it is well known that there are several varieties of carcinoma which vary much in malignancy and rapidity of growth. We are considering only operations done with the idea of effecting a cure. It is true that some "scirrhus" tumors are of very slow growth, and that their lymphatic involvements show little tendency to become extensive, but at present the clearing of the axilla and subclavicular fossa adds practically nothing to the operative risk, and may make a great difference to the patient. In such cases, which are commonest in old women, the very radical methods like Halsted's are probably not necessary unless the tumor is adherent to the muscle, and then if we operate at all we should be as radical as possible.

The question of definite cure of carcinoma of the breast is not an easy one to decide. Different series of operations have given percentages of immunity after from three to five years varying from seven to eight, up even to twenty. It seems hardly fair to put down as a recurrence an invasion of the disease after ten years and, *a fortiori*, after twenty, though this is done in some lists. Still there are some general conclusions which we are justified in drawing. We can say positively that early radical operations greatly reduce the percentage of local recurrences, but do not naturally have any effect upon metastases or lymphatic involvements which have already occurred; and from this we may infer that what we call "early" operations are not nearly early enough, and that metastatic deposits have been formed often, long before there is any objective manifestation of their presence. We must differentiate a metastasis from an involvement of an internal organ by continuity of tissue, which can occur only in an advanced stage of the disease. We are justified in concluding that in order to improve our percentage of "cures" we must have much earlier treatment and consequently earlier diagnosis, and the opportunities for the latter will come usually to the general practitioner, and not to the surgeon. We already know that by extensive removal we greatly diminish the chance of local return, and we are justified in supposing that by extensive and early removal we may often head off a metastasis. The laity ought to be taught that any tumor in the breast should be treated as a matter of great importance, demanding immediate attention from an expert, and this knowledge must in a large measure be disseminated by the general practitioner. It is often in the power of the latter to have such cases treated promptly by surgical means, and the opportunity should not be neglected. The question of diagnosis is not such an important one when we remember that an enormous proportion of tumors of the breast in women over thirty are malignant, and that on the doctrine of probabilities every tumor of the breast is malignant until proved innocent. If we can only get early diagnosis and treatment, the severity of our work on the chest wall will be diminished, but we consider the removal of the axillary and subclavicular glands an absolute necessity, if a permanent good result is to be expected. The amount of skin necessarily removed depends upon the variety of carcinoma and the direction of its most active growth, but this is a more important matter pathologically than surgically. The surgeons are justified in saying: Give us a chance, and give it to us early, and we will improve your statistics. Do not wait until you can feel enlarged glands in the axilla. Do not wait at all, and we will try to make the percentage of cures approach the best percentage of immunity from local recurrence after operation.

Influenza is beginning to assume epidemic form in and around New York. Thus far the cases have been of a comparatively mild type.

SEX IN CRIME.

A VIGOROUS article was contributed to one of the magazines a short time ago, endeavoring to show that woman is the physical equal of man. The view that she is mentally in no way his inferior has long been held by a large number of people. The great majority of persons, however, still retain the old common-sense opinion that woman, in spite of the evidence she has been affording within the past few years of her ability to shine in various branches of athletics, is not nor is she ever likely to be the successful rival of man in physical prowess. As to the comparative mental powers of the sexes, the question is a much more open one, some authorities contending that man in this respect does not excel his weaker sister, while the mass of testimony is against this judgment. Whatever the difference of opinion may be on the foregoing points, there never has been a valid objection advanced to the claim that in the excellencies of her moral attributes woman far surpasses the coarser male. The right of woman to this position is now challenged, and, in an article published in the *International Journal of Ethics*, Miss Frances Alice Kellor, of the University of Chicago, endeavors to convince her readers that their long-cherished belief in woman's moral superiority rests on no firm basis. Miss Kellor begins with these words: "Those who view superficially the psychical and physical differences existing between man and woman, and those who tenaciously hold the theory of separate creation, are the most ardent supporters of a belief which has become quite general, that woman was created from a finer clay, and is inherently more moral, more virtuous, and more æsthetic than man. Accordingly she is held to be less criminal, and apparently statistics sustain this view. Is woman's apparently less degree of criminality attributable to this congenital moral superiority, or is it due to sexual and social considerations and conditions over which she has no control, such as her having been selected as the anabolic organism, having had the burden of parturition placed upon her, and having been the favored sex in the progress of civilization? Have not these facts combined to render her life one of restricted activity and slavery, rather than one of freedom, activity, and independence; and are not the latter necessary elements for an extended and varied commission of crime? One prominent class of anthropologists considers woman as midway between child and man in her development."

It is then pointed out that in estimating the prevalence of crime for the purpose of comparison between women and men, statistics are misleading and manifestly partial to women, for the reason that women are less rigorously prosecuted, judgments against them when indicted are more difficult to obtain, and their punishments when convicted are less severe. Geddes and Thompson say that the greater amount of criminality in man is remotely due to his more katabolic nature. The most interesting part of Miss Kellor's paper is that which treats of the distinctively biologic considerations, and among them it is shown that women are physically incapable of committing many of the crimes with which men are charged, and they therefore resort to subtle rather than to violent methods. Woman's incentives to many crimes differ from those of men, being due to emotional causes rather than to those arising from economic, social, and political conditions, and this because woman's emotional nature has been developed to a greater extent. The criminal age in woman is less than in man, depending upon functions peculiar to women. This operates particularly in such crimes as abortion, infanticide, etc. Attention is called to the fact that women possess less sensitive organisms than men, as evidenced by the greater fortitude with which they endure pain and privation; and, lastly, the causes leading to a greater prevalence of crime among unmarried women are explained thus:

(1) Maternity operates to a greater extent than paternity in preventing crime.

(2) The sexual indifference of women, particularly mothers, in whom passion is held in abeyance by the demands and drains of motherhood, operates to prevent crime.

(3) The greater predominance of religion among women, owing to their more superstitious natures and unwillingness to yield faith to reason.

(4) Married women are less subjected to the influences incident to a struggle for subsistence, their energy being largely given to domestic and social duties.

The article is throughout suggestive and well expressed, and the subject is one that could be properly entered into only by a woman. The sex problem is daily looming larger before our eyes, women are entering into competition with men in every branch of life, and, as many think, unduly usurping men's duties, so that it is well that the matter should cease to be regarded from a sentimental standpoint, but should be judged fairly and squarely upon its merits.

News of the Week.

A Death from Football Injuries occurred the first of this month in Athens, Ohio. The victim was the quarter-back in the Ohio University eleven.

Scarlet Fever in an Institution.—The officers of the board of health have established a quarantine against the House of Industry in this city, owing to the presence of three cases of scarlet fever among the inmates.

Mitigating City Noises.—Boston objects to discords, and the police of that city have therefore issued an edict that all the street organs must play in tune or not at all. In accordance with this ukase all the hurdy-gurdy players and organ-grinders of the city were summoned one day last week to grind out their full quota of tunes before the music committee of the city, the police board, and invited guests with musical ears. The music-dispensers whose machines were out of tune were told that they could get no licenses until their organs had been put in tune again, and, mean-

time, they were warned not to play on the streets. If now the police will publish another regulation enforcing the tuning of all the pianos and forbidding the playing upon them except at specified hours, the Bostonese will be the envy of all with ears and nerves.

Dr. P. J. McGowan, of this city, surgeon of the New York Naval Reserves, serving during the late war on the *Yankee*, was presented with a loving-cup by a number of medical friends on Thanksgiving-day.

Born on the Top of a Street Car.—Dr. E. A. Lightburne writes in *The Lancet* that he was called a few days before to attend a woman who was about to be confined on the top of a tramcar in Bow-road, London. On getting there he found the car on a siding and surrounded by a cordon of police to keep the crowd at a respectful distance. With the assistance of the police matron and a bull's-eye lantern everything passed off very satisfactorily, the woman being safely delivered of an infant weighing eight and one-half pounds.

Small-pox in Cuba.—The latest reports from Cuba announce that the epidemic of small-pox in Holguin and Gibara has been checked as a result of the thorough and efficient sanitary regulations established by Dr. Woodson. Vaccination and isolation have been strictly enforced. In Holguin alone two thousand cases have been isolated and eight hundred persons vaccinated. By order of Colonel Hood notices have been posted in various towns in explanation of the purpose of vaccination, since in numerous instances opposition was met with among the more ignorant natives.

Obituary Notes.—Dr. Charles H. Hammett, of Washington, D. C., died at his home in that city on November 22d, of chronic nephritis, at the age of sixty-three years. He was a graduate of the medical department of the University of Georgetown in the class of 1856, and was formerly health officer and coroner for the District of Columbia.—Dr. Eugene Marie Berjot, of New Orleans, died in that city on November 27th, at the age of eighty-two years. He was born in Paris and was a godson of Lafayette. His father was a member of the French Assembly which condemned Louis XVI. to death. He served as a surgeon in the French army in Algeria and afterward practised for a time in Cuba. About thirty years ago he removed to New Orleans, where he had since resided. After settling there, he obtained, in 1869, a degree from the New Orleans School of Medicine, since extinct.—Dr. D. A. McTavish, of West Bay City, Mich., died at his home in that city on November 17th, of tuberculosis, after an illness of several months' duration. He was born at Glencoe, Ontario, in 1855, and studied medicine in Toronto and Edinburgh. He settled first in Kawkawlin, Mich., in 1882, but removed to West Bay City in 1887, and practised his profession there up to within a few weeks of his death.—Dr. Edwin H. Pierce, of Christiansburg, Va., died suddenly in a hotel in this city a few days ago. He had come to New York to take a course of post-graduate study.—Dr. William Molesworth, of Brooklyn, died at the Long Island State Hospital after an illness of nearly two years. He was born in Ohio sixty-eight years ago, and practised his profession in that State until 1874. He then came to New York and went into business.

Midwifery in New York.—According to the one hundredth annual report, recently issued, of the Society of the Lying-in Hosptial, out of the 51,117 births reported by the board of health for the year ending October 1, 1898, in the borough of Manhattan, 23,892 mothers were dependent on the care of midwives, and only 27,225 were treated by physicians.

Spread of the Plague.—A cable message from United States Consul Gibbs at Tamatave, Madagascar, received in Washington last week, announced that the bubonic plague had appeared at that place.

Measles in the Hebrew Orphan Asylum.—On November 5th, measles broke out among the inmates of the Hebrew Orphan Asylum in this city. Fifteen of the children, between six and eleven years of age, were attacked and were isolated in the asylum hospital. A quarantine was also established against the institution. The repressive measures were successful, and it is now stated that all the children have recovered and no new cases have developed for several days.

School-Board Physicians.—The president of the board of education recently announced the appointment of a number of physicians to examine physically applicants for teachers' licenses. According to the new regulations of the board, these physicians will number ten for the boroughs of Manhattan and the Bronx, two for Queens, two for Richmond, and five for Brooklyn. They are to be appointed in November of each year, and the certificate of one holds good in all the boroughs. The fee is not to exceed $3, and is to be paid by the board of education, instead of by the applicant as heretofore. The following is the list: Manhattan and Bronx—Drs. Samuel M. Brickner, A. M. Jacobus, Vanderpoel Adriance, Alexander Lambert, P. J. Lynch, Matthias Nicoll, Jr., J. R. Tillinghast, Nathan B. Van Etten, Josephine Walker, W. Gill Wylie. Brooklyn—Drs. D. G. Bodkin, Fred E. Hamlin, Frank R. Newman, J. H. Raymond, W. S. Searle. Queens—Drs. W. J. Burnett and J. C. Wharton. Richmond—Drs. William Bryan and George P. Jessup.

A Plague Scare in San Francisco.—Alarm was caused recently in San Francisco by the report that a death from the bubonic plague had occurred in Chinatown. The report was started by the Chinese, who were terrified by the death of three of their countrymen of pneumonia. They thought the disease must be the plague and that it was sent to them in punishment for the building of a tower on the Hall of Justice near by. So when a fourth death occurred the Chinese were sure the plague was upon them, and they communicated with the city authorities in the hope that the municipal building would be razed to the ground. Thus they believed the evil spirits would be placated and Chinatown saved from the plague.

The board of health officials made an autopsy and found that the cause of death was nephritis and that there was nothing whatever to indicate plague.

Maintaining a Nuisance on Barren Island.—The mayor has called the attention of the board of health to a report made to him by a special committee of the Anti-Barren Island League, regarding the nuisances there. Complaints have been made that the business carried on at Barren Island has been of such a character as to be a public nuisance and the cause of sickness to people and damage to property near by. The mayor asks the board of health to take the matter up in time so that the nuisance can be abated before the warm weather, and also that those affected (if an order of removal is made) may have an opportunity to secure other locations.

The Health of the Army has improved greatly since the cool weather set in and the flies have perished. According to reports received by the surgeon-general the last of November, the hospitals at Chickamauga, Lexington, and Jacksonville have been closed. The general hospital at Fort McPherson, Ga., has only 200 patients remaining, and reports 423 vacant beds. The Josiah Simpson Hospital, at Fort Monroe, has 400 vacant beds. The general hospital at Fort Myer, Va., has 350 vacant beds and only 162 patients remaining. The hospital at Fort Thomas, Ky., which recently received the sick from Camp Hamilton, reports 371 in hospital and 103 vacant beds.

Dr. Guiseppe Sanarelli, the discoverer of what has been assumed to be the microbe of yellow fever and also of a serum proposed for the cure of the disease, has been offered by the Italian minister of public instruction, Dr. Baccelli, at the suggestion of the medical faculty of the university, the chair of hygiene in the University of Bologna, left vacant by Professor Roncati.

Typhoid Fever prevails extensively among the troops at Honolulu, reports dated November 23d stating that there were over three hundred cases there at that time.

Health Conditions Better at Manila.—A despatch from General Otis, commanding at Manila, states that there has been a noticeable improvement in the health of the troops during November. On the last day of that month the percentage of sick was $10\frac{1}{6}$ as against $12\frac{1}{5}$ on October 31st. The deaths during November were twenty-six, during October forty-five. One-third of the present sick are suffering from typhoid and malarial fever, one-sixth from intestinal troubles, and in the remaining fifty per cent. the ailments are slight in character.

The Health of the Empress of Germany. — An English weekly society journal which is usually well informed has the following in its issue of November 5th: "A very grave rumor—which I mention with all reserve—is creeping about to the effect that the real reason for the journey of the German Emperor and Empress to the Holy Land is to be found in the fact that the Empress has fallen a victim to consumption, and that nothing but a prolonged visit to a particularly mild climate can save her life. To outward appearance there seems to be some foundation for the story. For two years the Empress has been gradually losing weight and strength. She now weighs but one hundred and twenty-four pounds, and she was until lately a tall, finely built woman."

Conditions at San Juan, Porto Rico.—The commandant of the naval station at San Juan, Porto Rico, calls attention to the poor sanitary condition of the station. He recommends that measures be taken to prevent sickness, and says that it is important that the government make sanitary improvements before undertaking to put the station in better defensive condition.

The Condition of Havana.—The death rate in Havana continues very high, four hundred and forty deaths having been reported for the week ending November 24th. Dr. Brunner, sanitary inspector of the United States Marine Hospital Service in that city, reports that he cannot account for the continuance of the enormous death rate under the weather conditions existing. While the city is filthy and dirty in the extreme, he cannot see that the native population should be unusually affected by such a condition of affairs. An effort is to be made at once to clean the city, and General Greene has had a long conference with Marquis Esteban, mayor of Havana, regarding street cleaning. It was decided that the refuse should be loaded in scows, towed out to sea, and dumped several miles away. A sufficient number of scows and lighters are to be sent there by the United States Government for this purpose. President McKinley has also authorized from available funds the expenditure of $50,000 for cleaning the city, so as to make it as healthful as possible for the residence of soldiers and citizens. The cleaning will be done according to the recommendations which would have been made by the late Colonel Waring, had not his death forestalled a formal report to the War department. Most of the papers which Colonel Waring had intended to incorporate in his report have been secured by the War department, and they are said to form a very good basis on which to proceed with the sanitary arrangements at Havana from a scientific standpoint.

Koch's Disappointment.—The *British Medical Journal* quotes from *La Tribuna* of Rome a somewhat amusing story about Koch, who has been studying malaria in the hospitals of the Eternal City. In the Santo Spirito he came across a patient with pernicious malaria, admitted apparently in a dying state. He asked that "this body" might be kept for his examination. The next day he went intending to make the necropsy, and was amazed to find a living man sitting up in bed to all appearances cured. The "corpse" greeted the professor with a significant smile. The cure had been wrought by the intravenous injection of quinine, according to Professor Baccelli's method.

Reviews and Notices.

A Text-Book of Materia Medica, Therapeutics, and Pharmacology. By George Frank Butler, Ph.G., M.D., Professor of Materia Medica in the College of Physicians and Surgeons, Chicago, etc. Second Edition. Royal 8vo, pp. 860. Philadelphia: W. B. Saunders. London: Rebman Publishing Company. 1898.

The matter here presented has been too finely elaborated for the requirements of the acting physician, and much has been inserted which the student, bent upon speedily acquiring a knowledge of pharmacy and materia medica, does not need. Certain scientific publications should be prepared with the view of giving to the student or to the practitioner what each most needs, and when the attempt is made to accomplish this in one and the same work the result is often unsatisfactory to both. Materia medica is one of the subjects which might well receive separate treatment for the two classes of readers. A careful scheme has been mapped out and adhered to in both portions of the work, which results in a certain monotony of headings, definition, etc. Accuracy and method have been placed before literary attractiveness.

Such advances as have been recently made in pharmacology and the physiological action of remedies are noted in the present edition. In place of the chapter on definitions there has been substituted one on the untoward effects of drugs; a question well worthy of discussion. Serum therapy has received further attention and is brought up to date. Naturally, the great bulk of material is in the nature of compilation.

Diseases of Women. A Manual of Gynæcology. By F. H. Davenport, A.B., M.D., Assistant Professor in Gynæcology, Harvard Medical School; Assistant Surgeon to the Free Hospital for Women, Boston. Third Edition, Revised and Enlarged. With 156 Illustrations. Pp. 391. Philadelphia and New York: Lea Brothers & Co. 1898.

The third edition of this manual differs from its predecessors more especially in the fact that the author has added surgical methods of treatment to the non-surgical. He continues to omit most of the pathology and rare conditions of the subject, thereby making the work better adapted to students and general practitioners. It is a practical, concise, well-illustrated volume.

The recent researches of Prof. J. Whitman Williams, of the Johns Hopkins University, published in the *American Journal of Obstetrics*, upon the question of the presence or absence of pathogenic germs in the vaginæ of pregnant women, serve to reconcile the various contradictory reports which have for the last few years been brought before the profession.

In view of the fact that his conclusions are the reverse of what he formerly believed, they have an added interest. His later observations have shown that hitherto many published reports, among them his own, are valueless simply because a faulty technique had been employed, and that when cultures were taken with regard to the prevention of contamination of the vagina, especially by the mucus from the hymen, none of the usual pathogenic cocci could be demonstrated, thus substantiating the claims of Krönig. He has found this to be true, whether the secretions were normal or abnormal. Yeast, the staphylococcus epidermidis albus, an anaerobic streptococcus, and what he considered the gonococcus were present, but inasmuch as these are not found in puerperal septicæmia, his conclusions do not seem to be overthrown. He admits that gonococci may extend, during the puerperium, from the cervix into the uterus and tubes, and does not deny that in very rare instances the vagina may contain bacteria which may give rise to sapræmia and putrefactive endometritis by auto-infection, but claims that this fact remains yet to be demonstrated. Death from puerperal infection he ascribes to a lack of aseptic preparation of the physician, the nurse, or the external genitalia, and the infection always is due to external causes.

No more potent evidence could be found against meddlesome midwifery, the ante-partum douche, and unnecessary digital examinations. Most certainly, if auto-infection is impossible, we should try to avoid the slightest chance of introducing germs by the hand and by instruments, or, what is more to the point, of conveying them from the septic vulva into the vagina. Nature has supplied mothers with the necessary antiseptic protective secretion, upon which our art cannot improve; rather do our antiseptic fluids seem positively harmful. The plea that we should cultivate greater skill in diagnosis by external palpation, and that when digital examinations are unavoidable be extremely careful in cleaning the vulva as well as the hand, certainly gains added force in view of these recent investigations.

The Gospel According to Darwin. By Woods Hutchinson, A.M., M.D. Chicago: The Open Court Publishing Company. 1898.

The purpose of the author of this work has not been to present a new religion, but rather briefly to outline some of the influences affecting human hope and happiness. The term Darwinism has been used in a broad sense, and an effort is made to show that the good predominates over the evil in this life and that the natural is as wonderful and admirable as the supernatural. The thinking reader, of whatever religious conviction, will find little to condemn and still less to which to take serious exception in these pages. Though at times outspoken and unequivocal, the author maintains throughout his arguments a reserve and delicacy of expression, indicative of a desire to offer no offence, for, as he says, "Darwinism has no quarrel with religion, only with its excesses." The author, as a physician and man of scientific methods, stands out prominently in many chapters; and one is impressed at almost every page with the wide range of reading and the thoughtful consideration of personal experience and observation which the writer must have devoted to the preparation of these essays. The omnipotence of good, the holiness of instinct, the beauty of death, love as a factor in evolution, courage as the first virtue, the strength of beauty, the value of pain, are all chapters filled with germs of thought and gems of expression, whose effect should be only beneficial to the reader, whether or not the logic which they clothe is accepted or acceptable. The work of two hundred and forty pages is well written and entertaining throughout, and physicians should be especially interested by it for other reasons than that it is by one of their own profession.

The Essentials of Histology, Descriptive and Practical. For the Use of Students. By E. A. Schäfer, LL.D., F.R.S., Jodrell Professor of Physiology in the University College of London, Editor of Histological Portion of Quain's "Anatomy." New Fifth Edition, Revised and Enlarged. With 392 Illustrations. Philadelphia and New York: Lea Brothers & Co. 1898.

This manual of minute anatomy by the editor of the histological portion of Quain's "Anatomy" has long been favorably known both to teachers and to students. While its main purpose is to furnish practical directions for the microscopical examination of the tissues, it serves also as an elementary text-book of histology, presenting the essential facts of the science in an attractive way, and shorn of the discussions of conflicting theories and vague hypotheses that needlessly complicate the study for beginners. The subject matter is divided into forty-six lessons, each prefaced by easily comprehensible and explicit directions for the preparation of the material under consideration, and fully covering all of the ordinary technical methods.

The excellence and profuseness of the illustrations obviate the necessity for wearisome pages of letterpress, the many schematic drawings being well calculated to facilitate an understanding of the more complex structures. Altogether the book fulfils a distinct purpose, and we do not know of a better one to put in the hands of the beginner, while the more advanced worker will find it a useful synopsis of laboratory methods.

Renal Growths. Their Pathology, Diagnosis, and Treatment. By T. N. Kelynack, M.D., M.R.C.P. Lond., etc. Illustrated. Edinburgh and London: Y. J. Pentland. New York: The Macmillan Company. 1898.

The author of this work upon "Renal Growths" has made a very excellent contribution to the mass of literature which has accumulated in the last twenty years upon this and allied subjects. In his first chapter he gives very good reasons for the difficulty in arranging a thoroughly satisfactory classification of the neoplasms of the kidney, and presents us what he considers to be the arrangement which is least objectionable; that is, Newman's. This appears to be the best yet given, and is certainly a useful one. The most important tumors of the kidney, sarcoma and carcinoma, are thoroughly discussed, and our knowledge of the subject is well arranged

rather than greatly increased; much useful statistical information is added. Many cases are cited, and it is a pleasure to note how often the names of Americans appear in the bibliography of the subject. There are an important chapter upon disease of the adrenals and many illustrations, most of them photographic reproductions which are fine specimens of the printer's work but of doubtful didactic value. In that part of the book devoted to treatment, all that has been done in this line of work is described, and in spite of many discouraging results we are glad to see that the author is not pessimistic, and that he feels justified in hoping that with earlier and more accurate diagnosis the number of cures after operation will increase.

A Clinical Text-Book of Medical Diagnosis for Physicians and Students. By Oswald Vierordt, Professor of Medicine, University of Heidelberg, etc. Authorized Translation with Additions, by F. H. Stuart, M.D., etc. Fourth American from the Fifth German Edition, Revised and Enlarged. Philadelphia: W. B. Saunders. 1898.

The appearance of a new edition of so well known a work as Vierordt's "Medical Diagnosis" needs hardly more than passing comment. The book is excellent in every way and its new edition brings it up to date. Its position is so well established as a book of reference among medical men that we need not go into details as to its good qualities. There are nearly two hundred illustrations in this edition, which are useful additions to the text, and the work of the translator has been well done. All the sections of the book are good, but we might specify that on the nervous system and that on the digestive organs.

Retinoscopy, or the Shadow Test. By James Thorington, M.D., Adjunct Professor of Diseases of the Eye, Philadelphia Polyclinic, etc. Second Edition, Revised and Enlarged. Philadelphia, P. Blakiston, Son & Co. 1898.

This little manual deserves a second edition and will undoubtedly pass through many more. It presents a clear, terse, and thorough exposition of an objective method of determining refraction errors which is deservedly increasing in popularity. In our opinion the author is amply justified in declaring that its great value in nystagmus, young children, amblyopia, aphasia, and in examining illiterates and the feeble minded, cannot be overestimated, and we agree with him in reminding those who attempt retinoscopy, fail, and ridicule it, that the fault is behind and not in front of the mirror. The book is well printed and usefully illustrated.

A Treatise on Aphasia and Other Speech Defects. By H. Charlton Bastian, M.D., F.R.S. New York: D. Appleton & Co.

The attention that aphasia is now attracting is shown by the fact that no fewer than five exhaustive treatises on this subject have been published in the English language within as many years. Dr. Bastian is well known to students of language the world over. His contributions, the "Physiology of Thinking" and the "Brain as an Organ of Mind," put him, a generation ago, well to the fore as a profound and philosophic thinker. The present volume will materially enhance that reputation. Although some of his contentions are at variance with the beliefs of many of the most trustworthy exponents of the genesis of speech, the vast majority of his conclusions are in keeping with the teachings of modern physiology and psychology. Bastian believes that the word centres are four in number: visual, auditory, glosso-kinæsthetic, and cheiro-kinæsthetic (writing centre); and his hypotheses and argumentations are based upon such existence. This view has been warmly contested by Collins in his recent work, the "Genesis and Dissolution of the Faculty of Speech," which was reviewed in these columns a few months ago. In that book the existence of a specialized centre for writing was impugned; nor do we see that Bastian has proved his point concerning its existence. Although its position is definitely depicted in his diagrams, yet his words on page 18 seem strangely at variance: "The situation of the cheiro-kinæsthetic centre cannot be localized with nearly so much confidence. The tendency for some years has been to follow Exner, who believes it to be situated in the posterior part of the second frontal gyrus, though, as we shall see later, the evidence in favor of this localization is at present almost non-existent." In the light of this frank statement it is not easy to comprehend, when no evidence is brought forward to show the allocation of such a centre, the author's insistence upon its existence.

The book abounds in a wealth of illustrative cases; it will prove a veritable mine for workers in this field, and one that will repay careful and studious examination. It is replete with most suggestive thought, and it cannot fail to mark an epoch in the development of the subject which it treats.

Therapeutic Hints.

Phthisis.—Inhalations of formaldehyde mixed with carbonic-acid gas.—Cornil.

Typhoid Fever.—Banana diet is recommended, because it is easily digested, almost wholly absorbed from the stomach, and is very strengthening.—Ussery, of St. Louis.

Impacted Cerumen.—Peroxide of hydrogen acts rapidly in disintegrating the solid cerumen; in a few minutes after its use the wax can readily be removed from the ear by syringing.—W. D. Turner.

Tapeworm.—

℞ Olei tiglii ..... gtt. i.
Chloroformi ..... gtt. xxx.
Glycerini ..... ʒ i.
M. S. Give at night on an empty stomach; on the following morning give a dose of castor oil.

Cough in Measles.—

℞ Sweet spirits of nitre ..... ʒ ij.
Muriate of ammonia ..... ʒ ss.
Dover's powder ..... ʒ i.
Simple syrup ..... ʒ iij.
M. S. Shake well. Dose. A teaspoonful to a tablespoonful.
—J. D. Ebert.

Antiseptic Powder.—

℞ Pulv. camphoræ ..... 5 parts.
Pulv. bismuthi subnitrat ..... 20 "
Pulv. acidi salicylici ..... 20 "
Pulv. iodoform ..... 55 "
M. S. Apply to wounds and ulcerous surfaces.
—Cazozzani.

Sore Nipples.—

℞ Ichthyol ..... ʒ i.
Lanolin ..... ʒ i¼.
Glycerin ..... ʒ i¼.
Olive oil ..... ʒ iiss.
M. S. Apply.
—Oehren.

Diarrhœa.—

℞ Tr. opium ..... ʒ ss.
Tr. rhubarb ..... ʒ ss.
Comp. tr catechu ..... ʒ i.
Ol. sassafras ..... ♏ xx.
Comp. tr. lavender ..... q.s. ad ʒ iv.
M. S. One teaspoonful every four hours for adults.
—Loomis.

Burns and Scalds.—

℞ Acidi salicylici ..... ʒ i.
Olei olivæ ..... ʒ viij.
M. S. Apply to the burn, covering with lint.
—Bartholow.

Fetid Chronic Laryngitis.—

℞ Potassii permanganatis ..... gr. ij.
Aquæ destillatæ ..... ʒ ij.
M. S. Use in atomizer several times daily.
—Sajous.

Aortic Stenosis.—

℞ Liq. potassæ ..... gtt. x.
Tinct. veratri viridis ..... gtt. v.
Syr. zingiberis ..... ʒ ss.
Aquæ ..... q.s. ad ʒ i.
M. S. Use three times a day.
—DaCosta.

Laryngeal Tuberculosis.—

℞ Zinc chloride solution ..... 2–5 per cent.
S. Use by the sclerogenic method of interstitial injection.
—Castex.

Mercurial Stomatitis (Salivation).—

℞ Acidi lactici..... ℥ xv.
Magnesii carb..... ʒ i.
Ol. menth. pip..... gtt. x.
M. et ft. pulv.

Or:

℞ Acidi salicylici..... ʒ ss.
Magnesii carb..... ʒ i.
M. et ft. pulv. S. The teeth should be carefully cleaned several times a day with one of the above powders.

—Otto Roth.

"Rotterinum."—

℞ Acidi citrici,
Thymoli.....āā gr. iss
Acidi salicylici..... gr. x.
Acidi boracici..... gr. xlv.
Zinci chloridi,
Zinci sulphocarbolatis.....āā gr. lxxv.
M. et ft. pastilli No. iv.

This is a disinfectant and antiseptic mixture, officially recommended in Bavaria as a substitute for carbolic acid and corrosive sublimate. To make a proper strength solution dissolve one pastil in a quart of water.—Roth.

Exophthalmic Goitre.—Symptoms of exophthalmic goitre are believed to show a marked preference for the right side of the body, especially in the early stages of the disease. Fitzgerald, of Dublin, who has attempted to explain this preference, believed the tachycardia to be also a right-sided symptom, because the right vagus is probably more concerned with the inhibition of the heart than the left, and also because the heart "soon after its appearance in the embryo projects to the right side, where it comes into relationship with the corresponding vagus."—Victor Miller.

Dysmenorrhœa.—A mixture of caffeine, potassium bromide, and tincture of gelsemium, administered for a few days before menstruation, is of much value in the treatment of dysmenorrhœa.—H. Talley.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 1, 1898.

Edward G. Janeway, M.D., President.

Nomination of Officers.—*Presidents*, Drs. William H. Thomson and Egbert H. Grandin; *Vice-President*, Dr. Herman Knapp; *Trustees*, Drs. E. G. Janeway and A. Jacobi; *Committee on Library*, Dr. A. Caillé; *Committee on Admissions*, Drs. N. J. Hepburn, J. W. Brannan, Reginald H. Sayre; *Treasurer for the Trustees*, Dr. W. F. Cushman; *Five Delegates to the State Society*, Drs. J. H. Huddleston, Egbert Le Fevre, Louis Faugères Bishop, A. P. Zemansky, George H. Cocks, J. Arthur Booth, Emil Gruening, W. A. Ewing, James Ewing, W. W. Gilfillan, and Richard Wiener.

The meeting was in charge of the section on ophthalmology and otology.

Certain Functional (Chiefly Hysterical) Conditions of the Eye.—Dr. B. Sachs read a paper with this title. He said that hysteria at the present time was recognized by symptoms so positive that one could positively say that the disease was hysteria and nothing else. In the opinion of some there was in hysteria a distinct though functional derangement of the entire nervous system. According to others, hysteria was a psychical derangement. The distinctly volitional and purposive movements were most subject to hysterical derangement. When hysteria affected the peripheral parts of the body there might be sensory or motor disturbances. The chief symptoms were: (1) An altered mental state; (2) palsies, with or without contractures; (3) subjective and objective disturbances of sensation, such as hyperæsthesia and anæsthesia; (4) hysterogenic zones; and (5) typical convulsive attacks, occurring at irregular intervals. True hysteria, in the opinion of the speaker, was after all an infrequent disease, although it was on the increase because of the influx of a foreign population, in whom it was much more common. The deep reflexes were never lost in hysteria, nor were the electrical reactions markedly altered. Great variability in the symptoms was a strong argument in favor of the hysterical nature of an ocular affection. An unusual combination of ocular symptoms was also suspicious. The pupillary reflexes should theoretically be beyond the control of the will, but a number of observers had reported disturbances of these reflexes in purely hysterical subjects. But it must be remembered that hysterical subjects might also suffer from tabes or from syphilis.

Hysterical Motor Affections.—Among the spastic conditions produced by hysteria were mentioned spasm of convergence, internal squint, and myosis. Conjugate deviation of both eyes was commonly observed in hysterical seizures, but it was rare for it to persist for any considerable period of time. Hysterical ptosis might be the result of spasm or paralysis. In his own experience hysterical ptosis was as frequently due to spasm as to palsy. The question of the existence of hysterical paralysis of the external ocular muscles had given rise to warm controversies among ophthalmologists. He had already presented a patient exemplifying this affection. The patient was a man, fifty-one years of age, who suddenly lost his vision while at the funeral of a friend. A complete examination of the man did not reveal any palsy in any other part of the body. The only other symptom was a complete left hemianalgesia. A few weeks ago it was discovered that the ptosis had entirely disappeared, and that he could move his eyes much more freely in every direction. The photophobia had entirely disappeared and the hemianalgesia was nearly gone. He had been treated last May by hypnotic suggestion, but he attributed his improvement to the fact that during the summer he had stumbled and received a considerable shock.

Hysterical Sensory Affections.—Among the sensory affections of the eye due to hysteria were: concentric limitation of the visual fields, disturbance in the perception of color, amblyopia, and amaurosis. Concentric limitation of the visual field was one of the most common of the stigmata of hysteria. Lasting hemiopia is certainly an extreme rarity in hysteria. If the diagnosis of hysterical amaurosis was to be upheld, several conditions must be established, *e.g.*, the ophthalmoscopic findings must remain negative for a prolonged period of time, organic disease must be excluded, and there should be present other signs of hysteria. The existence of the unilateral form of hysterical amaurosis was acknowledged by all. The speaker said that in his own experience he had met with considerable difficulty in making the differential diagnosis between hysteria and retrobulbar neuritis.

Dr. H. D. Noyes said that in his experience he had not often met with cases of muscular trouble which he could distinctly assign to hysteria. How strongly mental impressions alone could influence a patient in his assertions of blindness had been very forcibly brought to his mind some years ago in the case of a boy, ten years of age. While coming from Boston the boy had received a slight blow over the eye, and no amount of assertion could convince him that the vision was not destroyed on that side, although the ophthalmoscopic examination was entirely negative. The vision of the other eye had already been impaired by organic

disease. By bandaging the supposedly blind eye and insisting upon the boy getting around as best he could with his organically diseased eye, he was cured within three days. Dr. Noyes said that he did not consider the differential diagnosis between hysterical amaurosis and retrobulbar neuritis so very difficult. Pflüger had recorded cases of hysterical hemianopsia with the symmetrical segmental defects which pointed not to the chiasm but to the occipital lobes as the probable source of the trouble. These cases might exhibit no ophthalmoscopic appearances, and, in the course of time, disappear. Among his own cases he could recall three instances of hysterical amblyopia. These were described. There could be no question that in these cases of hysterical amblyopia central vision was impaired.

Dr. C. L. Dana said that he had entertained some scepticism regarding the reality of the affections forming the subject of the paper. He was of the opinion that there could not be hysterical paralysis of any of the muscles which could not be dominated by an idea; one could not, for example, conceive of hysterical paralysis of the phrenic nerve. He had just looked over his records of forty-five cases of hysteria in which there could be no doubt about the existence of hysteria, and in which he had made notes of the ocular conditions. Of this number there were twenty-three presenting marked ocular symptoms, the most characteristic one being concentric limitation of the visual field. In none of them had he observed anything like paralysis. Among the whole forty-five cases there were only three in which decided muscular affections of the eye were noticed. In some there were diplopias, such as resulted from the slight muscular insufficiencies occurring in neurasthenic conditions. In his own experience, therefore, there had been no such thing as hysterical ophthalmoplegia, and, if it existed, it must be very rare. The hysterical ptoses that he had seen had been very easily dispelled. He believed hysteria to be a disease of the mind having its seat in the cortex of the brain, and especially in the associative centres of the cortex. From this theoretical conception of the disease it seemed that it was next to impossible for one or two eye muscles to become affected in the manner referred to. It was another matter with hysterical sensory affections. In hysterical limitations of the visual field it would be noted that the field was almost invariably larger on one side than on the other. Hemianopsia might persist for months after a migraine, without there being any connection between it and hysteria. Hysterical blindness of one eye he had seen.

Dr. Herman Knapp said that he had never met with a case of hemianopsia which was not either imaginary or the result of some disease. This brought up the question of conscious and unconscious simulation. A very important class was that of nervous asthenopia with concentric limitation of the visual field. These patients could not read well for any length of time, and the limitation of the field varied rapidly. When concave glasses were placed before these eyes the vision was greatly improved. If convex glasses were substituted, the patients did not see so well, but better than without any glasses; and when the two kinds of glasses were placed before the eyes at the same time, the vision was immediately made $\frac{20}{20}$. It would seem, therefore, that these persons must labor under some peculiar nervous impulse. In these cases there was no conscious simulation, and they recovered rapidly if assured that there was no organic disease present.

Dr. Thomas R. Pooley said that this discussion reminded him of the remark made by the astute clinician, Dr. Stokes, of Dublin, that there was no nervous symptom which might not, and did not, occur without any appreciable symptom of the nerves, brain, and spinal cord. Dr. Pooley said that he was unable to see what a hysterical lesion was. It seemed to him very difficult to assume that a lesion which must be situated far back, and be the result of only a hysterical condition, should affect only the extrinsic muscles of the eye. He had observed a paresis of the abducens, which was said to be the result of hysteria. In one of these cases, presenting distinct hysterical manifestations in other respects, there was a strange hesitancy in the movement of the muscles as the eye followed his finger. In another case there were, in addition, diplopia in both outer fields of fixation and nystagmus. It was his belief that there was great difficulty in distinguishing between what had been termed hysterical amblyopia and neurasthenic amblyopia, with restriction of the field of vision. These cases presented not only concentric limitation of the field of vision, but also a limitation of the color field, but not according to the rule. There were also transient scotomata, evidently the result of exhaustion of the retina. It was this rapid exhaustion of the retina which seemed to be the cause of the phenomena observed in these so-called hysterical cases. He believed with Dr. Knapp that there was no true blindness in these cases of supposed hysterical amaurosis; certain it was that these patients could find their way about in a space to which they were not accustomed.

Dr. Edward D. Fisher said that in functional nervous diseases it did not seem that one would be apt to find the eye affected. Almost all hysterical paralyses came on suddenly and without adequate cause, and the resulting paralysis was more severe than was observed when the cause was an organic lesion. It was difficult to conceive of the paralysis of a group of muscles, except when acting in pairs.

Quinine Amaurosis and Brain Tumors.—Dr. E. G. Janeway said that he had once seen a patient who gave a history of having become blind immediately after taking forty grains of quinine. He had made the autopsy in that case, and had found a glioma of the walls of the third ventricle of the brain. Having searched the literature of the subject at that time, he had been led to the opinion that tuberculous meningitis and other organic diseases had been responsible for many cases that had gone into the literature as examples of quinine amaurosis.

Dr. Emil Gruening said that a competent ophthalmologist should not be led into making a diagnosis of quinine amaurosis when the condition was really due to a tumor of the brain, for the symptoms of the former were sufficiently distinct and characteristic. He had no theories to offer as to the existence or non-existence of hysteria. In one case of supposed blindness in a teacher a cure was effected in three days by giving him a shower-bath twice daily.

Dr. Sachs said, in closing, that he had no desire to pose as an apostle of hysteria, but hysteria was a reality, and the oculists who had spoken had apparently not taken the trouble to look for the hysterical stigmata in their cases.

SECTION ON OBSTETRICS AND GYNÆCOLOGY.

Stated Meeting, November 25, 1898.

E. B. Cragin, M.D., Chairman.

Fibroma of the Uterus—Mistaken Diagnosis.—Dr. Balleray presented a fibroma removed from a woman, twenty-nine years of age, who had been married five years and had never had any children. She had always suffered at the menstrual periods, and since her marriage this pain had been more severe, and associated with attacks resembling those of catalepsy during the first twenty-four hours of each period. There was also considerable pain in the back. Ex-

amination under ether showed a tumor pressing on the rectum, but decidedly movable. It was thought to be a fibroma of the ovary, but when the abdomen was opened it was discovered that the growth was connected with the uterus. By making a double flap it was not difficult to extirpate the tumor. The case was presented chiefly because of the error in diagnosis.

The Early Diagnosis of Cancer of the Uterus.—Dr. Balleray also presented a uterus which he had removed two weeks before from a patient fifty-seven years of age. She had had only three or four attacks of bleeding from the vagina before coming under observation. The diagnosis was cancer of the cervix. This was the sixth case of cancer of the cervix that he had met with during the past year, and she was the youngest of the group, the oldest having been sixty-seven years old. This series of cases was interesting as tending to show that the family physician was now more alive to the early diagnosis of this condition than formerly. All of the patients had done well since the operation. He also referred to a woman, sixty-one years of age, in whom the cancer had not been recognized by her physician until the case was beyond operation. Her medical attendant had not only failed to discover the true nature of her trouble, but had jokingly remarked that she was becoming young again, as her courses had returned, and he would advise her to be married once more.

Tuberculosis of the Endometrium.—Dr. Philander A. Harris exhibited the uterus and appendages removed because of a diagnosis of tuberculosis of the endometrium. The patient was a woman nearing the menopause who had borne children. He had first seen her about eleven months ago, at which time there had been a cyst in the vagina, three or four inches in diameter. This had been removed, but she still complained of a feeling of discomfort in the pelvis. About three months later she began to menstruate excessively, the period being prolonged, and there being also some "spotting" between the periods. She was curetted last June, and the material was examined by Dr. Otto Ramsay, who reported the presence of tubercle bacilli. About two months unavoidably elapsed before the speaker had another opportunity for a careful examination, and then he had found an exudation on the right side of the pelvis, which had not been there in June. In view of the microscopical diagnosis he had, after consultation, removed the uterus and appendages.

Gall-stones Removed by Operation.—Dr. Harris also exhibited three gall-stones which he had removed from the gall bladder of a woman, forty years of age. The bladder was distended and its walls were thickened. The operation was done after the patient had suffered from pain and fever for about three weeks. She had previously had mild attacks of biliary colic. The bladder was sewed to the incision. Bile was discharged for about four weeks, and then the wound healed permanently.

Malignant Disease of the Uterine Body.—Dr. H. J. Boldt presented a fresh specimen showing malignant disease of the body of the uterus. The patient was fifty-six years old, and she presented the clinical features of a fibroid which had undergone carcinomatous degeneration. The diagnosis of fibroma of the uterus had been made not only by her attending physician but by another prominent gynæcologist of this city. On bimanual palpation a tumor, rather larger than the head of a child, could be felt. In the middle portion, anteriorly, was a softer area, which was taken to be a degenerating spot. On opening the abdomen the mass was found to consist of the uterus, with firmly adherent intestine, and above this was a mass of omentum which was rolled up into another hard tumor. This explained the error in diagnosis which had been made by three different gynæcologists.

Aneurism of the Uterine Artery.—Dr. Paul F. Mundé reported a case of aneurism of the uterine artery, which, so far as he knew, was unique.

Vesico-Utero-Vaginal Fistula—Unusual Complications.—Dr. Mundé also reported this case. (Both of these cases will appear in a future issue.)

Suburethral Abscess.—Dr. Mundé reported a case of suburethral abscess—*i.e.*, an abscess forming in the urethro-vaginal septum. He had not been able to find in any of the older books any mention of an abscess in this peculiar locality. Kelly, however, speaks of it, and states that the first operation for this condition was done in 1747. The patient of Dr. Mundé was a multiparous woman, seen by him last September. She complained of scalding urination, and of a mass which protruded through the labia. Examination revealed a swelling in the urethro-vaginal septum, about the size of an egg, having a smooth, tense wall. On pressing it, there was a spurt of irritating urine from the urethra. It was at first supposed to be a urethrocele, but on reference to Kelly's books the true nature of the condition was made clear. Mention of suburethral abscess had also been made in a recent book by Dr. Dudley. The treatment consisted in making a free incision through the sac of the abscess in the septum, washing it out with bichloride solution, curetting the cavity, then swabbing with iodide of phenol and inserting a drainage tube. The tube was left in for about two weeks. The abscess cavity completely healed.

Dr. P. A. Harris said that he desired to place on record a case of suburethral abscess brought to his attention about one year ago by Dr. Scribner, of Paterson. While the question of operation was being considered the abscess ruptured, and since then there had been a sinus discharging pus.

Dr. Robert L. Dickinson said that he had photographs of two such cases. One of these had been operated upon through the vagina. The route of infection became evident in these days of careful study of the urethra and bladder. He had noticed on removing Kelly's urethroscope from a bladder that very day that a drop of pus had escaped from the mouth of a gland in the urethro-vaginal septum. It was evident that if this opening became plugged, an abscess would develop in this situation.

Dr. Cragin remarked that he had met with a case of suburethral abscess similar to the one described by Dr. Mundé.

Functional Neuroses and their Relation to Diseases Peculiar to Women.—Dr. Hermann J. Boldt read this paper, in which he discussed only those neuroses which might be considered as purely reflex. The bountiful nerve supply of the genital organs being borne in mind, sufficient reason could readily be found for the causation of functional neuroses. He looked upon these neuroses as the result of a depraved condition of the nerve substance which could not be demonstrated anatomically. A woman predisposed by heredity to hysteria was more apt to develop it if her pelvic organs became deranged than if this did not occur. The more common occurrence of these neuroses at the present time might be explained in various ways. Weak and delicate girls were crowded with studies, and their intellectual training was pushed at the expense of their physical development. Young women impeded respiration by tight lacing, and interfered with the circulation in the lower extremities by wearing too tight garters. Hysteria might be termed a "cerebral neurosis," and its development required a proper soil. The predisposing soil being placed in the brain through heredity, physical or mental exertion, psychical disturbances, over-indulgence in alcoholic beverages, sexual excesses, or lesions occurring during childbirth might furnish the exciting cause. Psychical

disturbances certainly did their share toward the development of functional neuroses. It was wellnigh impossible to determine how much influence a coexisting pelvic abnormality had upon such a neurosis until such a patient had been under observation for some time. The functional neuroses of the skin associated with menstruation were quite prominent—*i.e.*, acne, rosacea, urticaria, etc. In this connection a case was cited in which a young girl suffered from menorrhagia and a troublesome eczema at each menstrual period. Examination showed no pathological condition to explain her excessive bleeding. In another case which he had observed, there was a reflex vasomotor neurosis dependent upon a displaced ovary. The chief features were that at her first menstruation, when thirteen years old, a purple discoloration had appeared on the upper extremity, with swelling of the right leg and foot. The limb became cold at the beginning of each menstrual epoch, and continued so during the period. There were differences in the measurements on the two sides, and the superficial veins and capillaries of the affected side were greatly distended. The severe pain in the right inguinal region, particularly during menstruation, was considered to be due to an enlarged and prolapsed right ovary. She was entirely cured of her dysmenorrhœa by correcting the malposition of the ovary, and with this the skin lesion disappeared.

Among the psychoses observed in women melancholia and hypochondriasis, occurring during the menopause, were prominent. These neuroses usually disappeared within a year or two after the climacteric. The speaker said that he had met with two such cases in which the condition was dependent upon the occurrence of an illegitimate pregnancy, as was shown by its prompt disappearance when the unfortunate girls were married to their seducers. The neurotic condition associated with nymphomania was well known to all physicians. He had seen one instance completely cured by the removal of the clitoris; on the other hand, he had reported several failures after this operation in this class of cases. Pelvic inflammation by pressure on the nerves caused changes in the circulation of the pelvis, and, reflexly, produced an evil impression on the nervous system. Displacements of the uterus might cause the most intense neuroses. A case was recalled of malposition of the uterus associated with marked suicidal mania. As habitual vomiting, tachycardia, cardialgia, and similar conditions sometimes disappeared after dilatation of a narrow cervical canal, the correction of a uterine displacement, or the cure of a diseased endometrium, we would not deny the connection between the neurosis and the lesion. Among the rarer forms of reflex neuroses was that in which the patient felt a painful sensation in the back or abdomen, and occasionally an attack could be produced by pressure on a pelvic exudate. Among the vasomotor neuroses the speaker mentioned hemicrania and that form of goitre occurring during pregnancy. In the majority of gynæcological patients the digestive system suffered. The differential diagnosis between gastric neurasthenia dependent upon pelvic derangement and so-called nervous dyspepsia was made by the fact that in the latter there was pain radiating over the entire abdomen and extending up even to the neck and head, when pressure was made over the epigastrium, which was not the case in gastric neurasthenia dependent upon pelvic derangement.

Medicinal and Hygienic Treatment.—Speaking of the treatment of these conditions, Dr. Boldt said that it was a serious error to give a long course of gynæcological treatment to neurasthenic patients having only a minor pelvic lesion, unless most careful attention was paid to the general health. In this class of cases he had found the bromide of gold and arsenic exceedingly useful. When given in doses of five drops, gradually increased to fifteen or twenty drops daily, the percentage of hæmoglobin rapidly increased. This medicine also had a decided effect on the inflammatory condition of the ovary, as he had frequently demonstrated during the past twelve years. Correction of the habits and diet, and exercise were necessary if one would successfully cope with the chronic constipation usually present in these cases. Abdominal massage was exceedingly useful here, but to be successful the physician must give specific instruction as to the mode of performing it. In arranging the diet, preference should be given to foods containing phosphorus, fat, and iron, unless there was some distinct contraindication. Patients afflicted with functional neuroses were benefited by appropriate physical exercises.

Surgical Treatment.—The surgical treatment, though exceedingly important, should never be employed except under the most positive indications, especially in patients exhibiting a marked hereditary taint. Only a very small percentage of such women had been benefited by castration. He deprecated operating for the cure of hystero-epilepsy or any other form of functional neurosis, unless it was possible to recognize some pathological lesions apparently directly connected with the neurosis. In three obstinate cases of migraine in which he had operated because of disease of the ovary, he had noted that the migraine had been cured by the operation. He asserted that more harm than good had resulted from oöphorectomy in cases of functional neuroses, and the same remark was applicable to such operations as curettage, trachelorrhaphy, and perineorrhaphy.

Influence of Cicatricial Tissue.—Dr. Bache Emmet felt that the paper expressed views which were becoming more and more generally adopted. With increasing experience he had been led more and more to separate pelvic diseases from those affecting the nervous system, although there could not be any doubt about the anatomical relations between the two. The keynote to this difficult subject was to be found in the consideration of the general nutrition. He was inclined to place a little more stress upon the part played by cicatricial tissue in affecting the nervous system at large. This was especially observed in connection with the cervix. He was often surprised at the slight disturbance produced in cases in which the ovaries were embedded in cicatricial tissue. By bad ligaturing the surgeon sometimes inflicted serious damage, and caused the patient much subsequent discomfort. Oftentimes the patient would complain of ovarian pain on one side only, and yet the abdomen being opened it would be observed that the ovary on the painful side was not nearly so much bound down by adhesions as the other one which had given rise to no discomfort.

True Reflex Neuroses Rare.—Dr. Edward D. Fisher said that, despite the talk about specialism, the paper gave evidence of the truth which was constantly forcing itself upon us—*i.e.*, that the true specialist must have a good knowledge of the whole system. In the majority of cases of functional neurosis one had to deal with an organ which was functionally ineffective, probably because of malnutrition or some condition of toxæmia. These states were ordinarily removable. A direct reflex from any part of the body, producing a neurosis, must be extremely rare; in the so-called functional neuroses one was confronted mainly with a depraved state of the system. Mention had been made of the neuroses observed about the time of the menopause. These were best explained by the abnormal state of the blood at this critical period of life. If a person were kept without sleep for several days one would observe the development of a series of hallucinations just as marked as the

so-called neuroses under consideration, and yet they would promptly disappear as soon as the proper amount of sleep was secured. Again, nymphomania and masturbation never produced disease directly, but they did produce exhaustion, which was most keenly felt by the nervous system. He did not believe that masturbation could give rise to insanity. Pelvic disease, in a similar way, might give rise to certain nervous symptoms—the so-called functional neuroses. No reflex action was necessary to explain such cases; the answer was found in the existing malnutrition. Dr. Fisher said that, in his experience, after the removal of the ovaries the result had not been satisfactory in cases of epilepsy or hystero-epilepsy.

Dermatological Neuroses.—Dr. L. Duncan Bulkley mentioned the case of an unmarried woman, thirty-two years of age, in fair health, who complained of some irregularity in her menstrual functions. A few days later he found her in a darkened room, suffering from intense photophobia and great nervous excitement. She stated that she had consulted a gynæcologist who had applied caustic to an erosion of the cervix. In addition to the photophobia there were marked congestion of the eyes and severe orbital neuralgia. A month later she went to another prominent gynæcologist, and the same phenomena were repeated after the local treatment. If they had occurred but once the speaker would have considered it a mere coincidence. So many of his patients had complained that their skin diseases were worse at the menstrual epoch that he had kept a number of notes regarding these facts. He had noted in about twenty cases of eczema the aggravation or recrudescence of the eruption at the time of menstruation. One very intelligent woman suffered greatly from eczema of each hand every month for eight years. The patients ranged from twelve to forty-four years of age. The phenomenon was observed with about the same frequency in single and married women. In two cases of seborrhœic eczema the eruption was lessened instead of being made worse by the occurrence of menstruation. He had also noticed that the degree of pruritus was influenced by menstruation. All physicians were acquainted with the close relation between acne and the menstrual function. One of the most remarkable of the skin neuroses connected with the uterine function was a form of general herpes developing during pregnancy, and disappearing after the uterus had been emptied. A kindred matter of some interest was the frequency with which patients complaining of painful or irregular menstruation were relieved during the administration of alkaline diuretics, given with the object of benefiting the cutaneous lesions. In most of these cases he had had no idea of the physical condition in the pelves of these women, but the good results had been explained by Dr. Etheridge, of Chicago, and by others, on the ground that this line of treatment caused a freer action of the kidneys.

A Therapeutic Hint Regarding Headache.—In connection with the common complaint of vertical headache and flushings in women he called attention to a fact learned by experience, although not yet explained, that the internal administration of full doses of strong nitric acid (five drops, three times daily, suitably diluted) almost invariably gave prompt and complete relief.

Ovaries Should Not be Removed at Random.—Dr. Mundé said that in 1886 he had read a paper on this subject, and had reported a number of interesting cases. These were briefly referred to again. Among them was a case of persistent supraorbital neuralgia in an unmarried woman, which had resisted all the usual treatment, but had yielded promptly to the correction, by the wearing of a pessary, of a retroversion of the uterus. Another was a woman who had been under the care of various neurologists and alienists for a mental derangement, but who recovered after a quack had discovered and relieved a displacement of the uterus. Dr. Mundé said that when he had reported these cases he had been quite severely criticised by foreign journals for having made misleading statements; but he was prepared, even at the present day, to stand by these assertions. He thought a little too much stress had been laid upon the part played by cicatricial plugs in lacerated cervices, although when they were situated high up their influence might be more worthy of attention. When the usual modes of treatment for these nervous conditions failed to give relief, it was right and proper for the gynæcologist to make an examination and do what he can, even if only in a tentative way, toward saving the person from becoming a confirmed invalid. So far as the removal of macroscopically normal ovaries was concerned, for the relief of such conditions as hystero-epilepsy or hystero-catalepsy and real insanity, he wished to be put on record as being exceedingly conservative. Before doing such an operation he would wish to be convinced that the neurologist had exhausted all his resources; yet he made this statement in the face of the fact that he had performed six successful operations in cases of this kind. The fact should not be lost sight of, however, that ovaries which appear normal macroscopically often prove, on microscopical examination, to be diseased. The operation known as "normal ovariotomy;" or Battey's operation, he believed should be one of the past—that is, if done for the indications laid down by Battey.

Nourish the Cortical Centre.—Dr. S. Baruch said that he agreed thoroughly with the reader of the paper in the statement that the connection of functional neuroses with pelvic derangements was still problematical. About fifteen years ago, when the wave of peripheral irritation swept over this country, and so many women were unsexed, it was quite remarkable that no one suggested that men should be unsexed. In 1890, the late Dr. Loomis had arranged for a symposium on this subject in the Academy of Medicine, and, in spite of the fact that the opinions expressed at that time were almost unanimously against this indiscriminate removal of ovaries, the slaughter went on. On the occasion referred to, he had stated that the only case of epilepsy that he had ever seen cured had been by the removal of an enchondroma from the nasal septum. There had never been an attack of epilepsy since that time. He was of the opinion that the removal of the ovaries, the repair of the lacerated cervix and perineum, and the correction of malpositions of the pelvic organs acted beneficially by improving the general health, *i.e.*, by permitting walking and other modes of exercise, by relieving pain, and by removing sources of infection. With the improvement of the general nutrition he believed the nutrition of the cortical centre was improved, and hence the good result. Many cases of neuroses were referred to him for hydriatic treatment as a last resort, and they recovered under hydrotherapy, not from any specific effect, but simply from the influence which it exerted on the general health and on the nervous tone. All efforts should be directed toward improving the general condition, and this should include moral, medicinal, and physical treatment, conducted in just as systematic a manner as the physician would employ in the treatment of any serious acute disease, such as pneumonia.

Dr. W. B. Pritchard said that he believed there was such a thing as a reflex neurosis. He had often thought that in a large number of cases of supposed reflex neurosis dependent upon pelvic disease there was a primary cause back of both the pelvic condition and that of the nervous system. In his opinion,

operations were comparatively rarely indicated in these cases, and it was encouraging to note the increased tendency toward conservatism on the part of the operative gynæcologists.

Neuroses after Oöphorectomy.—Dr. E. E. Tull spoke of the form of neurosis arising from the legitimate removal of diseased ovaries. The existence of such nervous manifestations made it seem to him desirable, whenever possible, to leave one ovary, as it appeared, in a certain number of cases, capable of preventing these unfortunate sequelæ.

Interesting Illustrative Cases.— Dr. E. C. Savidge referred to the case of a widow, forty years of age, who married for the second time, and had an abortion at six weeks. She then developed an aggravated pruritus and an eczema, which were treated by an eminent dermatologist without benefit, and she was not relieved until he had curetted her. Another case was that of a woman who had had an epileptic attack, with an aura, almost every month. The speaker said that after having treated her for six months with bromides he removed a small cyst from one ovary, with the result that the patient had had no more attacks. Another similar case was that of a negress with a marked retroflexion, who was quickly cured by the use of purgatives and the tamponade. Still another case of this kind was cured by the application of leeches to the cervix. In a case of nymphomania coming under his observation he had curetted the uterus and removed a polypus from it. This restored the equilibrium of her sexual nervous system.

Dr. Boldt closed the discussion. He said that while undoubtedly the main point was to improve the general nutrition, nevertheless if there was a marked local abnormality we could not expect to bring about a complete cure without treatment directed toward that local lesion. He was sorry to say that castration was still performed in cases marked chiefly by severe pain and nervous excitement.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, November 28, 1898.

S. O. Vander Poel, M.D., President.

Inaugural Address of the President.—Dr. S. O. Vander Poel, the newly elected president, in his inaugural address stated that he should steadfastly avoid conducting the business of the society in the interest of any particular clique or faction, and would endeavor, as far as possible, to eliminate what was known as "medical politics."

The Medical Aspect of Life Insurance.—Dr. Vander Poel then took up the special subject of the medical aspect of life insurance. He said that the physician who believed that, if he were a good medical practitioner, he should be a good examiner for life insurance would soon have his mind disabused of this fallacy on beginning the actual practice of this special branch. The physician must entirely change his usual point of view.

Sub-Standard Lives. — Family physicians often wondered why life insurance companies rejected persons who, although having slight cardiac disease, were likely to live nearly as long as persons without such impairment. The reason was to be found in the fact that all the actuarial calculations had been made on selected lives, and these "sub-standard lives" could not be safely insured except upon the experience based upon large groups of such lives. Unfortunately this had not yet been done, although Dr. Oscar H. Rogers had been working upon this gigantic, but immensely important, task for the past six years. He hoped soon to publish the results of these labors. This investigator had studied about ten thousand cases, and in a somewhat novel manner, *i.e.*, by studying the death records of the company with which he was connected, along with the other records. These studies had included such impairments as rheumatism, albuminuria, albuminuria associated with Bright's disease, cardiac disease, glycosuria, excessive body-weight and underweight; and, as a result, this company had been placed in a position to extend the benefits of insurance to a large number of persons hitherto denied them. It must always be borne in mind that the mental state of the applicant for life insurance is entirely different from that of the patient coming to his regular medical adviser, and, consequently, the medical histories obtained by insurance examiners are very different from those recorded by ordinary medical practitioners. It had only been quite recently in this country that the companies had been willing to insure impaired lives, although this had been done in England under certain limitations. Any insurance company, carefully managed and insuring only normal lives, should succeed in business. For example, at the age of thirty-five, a company could afford to lose nine deaths per thousand the first year, and nine deaths of the remainder for the second year, etc., but the same company would lose money if there were only three additional deaths per thousand. It was evident that the proportion of deaths in the later years should be about the same as in the earlier ones, and it was because of this necessity that insurance companies were so conservative about accepting persons apparently suffering from slight and unimportant albuminuria, it not being possible to affirm that, in considering large numbers of lives, the death-rate on such impaired lives would not be greater in the later years.

Cuban Malarial Fever.—Dr. William H. Thomson read a paper with this title. He said that at the beginning of his service at the Roosevelt Hospital on September 1st, he found in his wards sixty cases of Cuban malarial fever among the soldiers, who had contracted this disease at Santiago. The majority of them had been in the hospital since August 17th, and the duration of the illness before coming to the hospital ranged between twenty and forty days. In all the cases that had been treated first with quinine, and in a large proportion of the total number, there had also been a free use of Warburg's tincture and of arsenic. Subsequently thirty-nine more patients had been admitted, making one hundred in all, besides a group of mixed malarial and typhoid-fever cases. Of the number referred to, sixty-three were actively febrile, the temperature ranging from 103° to 107° F. Of these, forty per cent. had chills, with the usual succession of symptoms, but with true intermissions in only ten per cent. The chills were irregular rather than periodic in the remaining thirty per cent. They seemed in some cases to be double tertian and in some double quartan, but in all of them the paroxysms of rigors were very irregular. The remaining sixty per cent. of the febrile patients had no chills, and the fever pursued a very variable course. The plasmodium malariæ was found in ninety per cent. of all the cases, but in some not until after repeated examinations. The commonest form was the crescentic, but there were also many actively mobile extra-cellular bodies, very small and round in contour. Masses of pigment were often seen free in the field of the microscope. Only one separate flagellum was detected, although possibly more might have been detected if more time had been given to the examinations. The most prominent features in these cases were the anæmia and great prostration. The anæmia appeared to be quite independent of enlargement of the liver and

spleen. The liver was enlarged in not more than five per cent., and the spleen was enlarged in about fifty per cent. In the great majority of the cases, during the febrile stage, there was scarcely any delirium, but instead there was a characteristic taciturnity. It was upon this particular symptom that the effect of the medicinal treatment, to be afterward referred to, was most marked. Sixty-five of the patients were treated for sixteen days by careful feeding and nursing. They were also given quinine, from thirty to sixty grains daily, or Warburg's tincture in doses of half an ounce, three times a day. Others were treated with arsenic. The general results of such treatment had been quite unsatisfactory. The best results from quinine were in the small number of patients showing periodical remissions. The Warburg's tincture seemed more effective than quinine. Arsenic appeared to be of very doubtful benefit. Cold baths were used in six cases of high temperature, but the patients did not bear them well, and the temperature was not controlled thereby.

The Most Successful Antimalarial Medication.—The treatment which gave by far the best results consisted in the administration of fifteen grains of quinine, fifteen grains of powdered ginger, and half an ounce of paregoric, twice a day—in the forenoon and afternoon. Under this treatment the patient received an equivalent of three grains of opium each day. This plan was tried on forty-seven patients, all of them actively febrile, and eighty-four per cent. severely so. Fourteen febrile patients, of whom sixty-five per cent. were severe, were treated with Warburg's tincture alone as a control experiment. In twenty-two, or forty-seven per cent. of the number who took the paregoric, there was a fall of the temperature to normal within twenty-four hours, and it did not rise again. The treatment was continued from eleven to fourteen days, and the patients were then discharged. In ten patients, or twenty-one per cent., from thirty-six to forty-eight hours were required to reduce the temperature to normal. In three the treatment failed to control the fever. One of these, however, had a colitis, to which his continued fever seemed to be mainly due. No relapse was recorded in any patient taking the paregoric treatment after the temperature had once been reduced to the normal. In five cases, or 10.6 per cent., the paregoric treatment could not be continued because of the nausea excited. They were then given quinine and ginger alone, and they recovered, but relatively slowly. Six out of the forty-seven proved in time to be cases of mixed infection with malaria and typhoid fever. There were only two patients who showed the effect of opium: the remainder not only were not drowsy but seemed to be aroused from their stupor by the treatment.

Comparison with Warburg's Tincture.—Of the fourteen patients treated with Warburg's tincture, in two, or fifteen per cent., the temperature was reduced in twenty-four hours. Both of these were patients who had been recently admitted, and who had been treated with quinine previously. In twelve, or forty-five per cent., the time required to break the fever varied from forty-eight hours to ten days. In seven of the cases the Warburg's tincture failed to control the fever after ten days. All of these patients recovered in about twenty-four hours under the paregoric treatment. Of the remaining thirty-nine out of one hundred, twenty-six were admitted as convalescent, and without any fever. They were all extremely anæmic, and the plasmodium malariæ was found in eighty per cent. They were all given the paregoric, quinine, and ginger treatment, and with as good general results as in the febrile cases. In the delirious afebrile cases the paregoric seemed to act especially well. Both from the blood examinations and from the clinical features, Dr. Thomson said that it was evident that the Cuban malarial parasite belonged to the æstivo-autumnal type, and that its cycle of development in the blood was very irregular as to time. This would seem to indicate that the action of quinine is only secured at certain stages of the life history of the parasite, and emphasized the practical benefit of administering this drug at certain times. In the more or less continuous forms of malarial fever it seemed to lose much of its effect. When, therefore, the physician had to deal with an infection not having definite remissions, quinine was still valuable if given at proper times, but increasing the dose in these cases seems only to make matters worse.

Quinine with Aromatics and Opium.—For many years he had been accustomed to prescribe quinine with an equal quantity of ginger, and had obtained better results in our common agues than with quinine alone. Opium had been known to be of benefit in the treatment of malarial fevers since the time of the ancient Greek and Roman physicians. In this century it had been highly praised by Dixon, of South Carolina, as a remedy for breaking the cold stage. Sir William Roberts, who served on the commission in India which investigated the method of treating malarial fevers by the use of opium, maintained that the anti-malarial properties of opium were due to its alkaloid, commonly called narcotin, but which, he said, was better described as anarcotin. This alkaloid constituted a considerable proportion of the drug, varying in different samples of good opium from one-fourth to two-thirds of the percentage of morphine. Sir William O'Shaughnessy in 1838 had reported one hundred and thirty-eight cases of malarial and remittent fevers treated by opium, with ninety-five per cent. of cures. This had induced the Indian authorities to institute further experiments, and as a result anarcotin was prepared in quantity and distributed to the medical depots throughout India. Sir William Roberts claimed that anarcotin was scarcely inferior to quinine, and in some classes of cases was actually superior to it. The speaker said that it was a question whether or not the beneficial action of the paregoric treatment was due to the presence of anarcotin; he was inclined to believe that the opium acted as a stimulant, thus enabling the system to cope better with the malarial infection. It was because of its superior stimulating properties that he had chosen the paregoric preparation of opium. Certainly in the majority of the cases the drug acted as the reverse of a narcotic, and rather as a general cardiac and nervous stimulant.

Typhoid and Malaria.—The cases of mixed infection with typhoid fever and malaria ran the usual course of typhoid fever, and they were treated without any quinine. Two of the patients, after being fairly convalescent from the typhoid fever, had had an attack of chills and fever, which had soon yielded to the paregoric treatment. During these attacks the plasmodium had reappeared in the blood. Three of the patients died, and, strangely enough, all from an unusual cause, *i.e.*, intestinal hemorrhage. As this accident had occurred only once in one hundred and fifty cases at the Roosevelt Hospital, its occurrence in these three cases led to close investigation of the previous history. This elicited the fact that all of these soldiers had insisted upon continuing at drill for some time after they had been taken ill.

Artificial Nauheim Baths.—Twelve of the patients were given the artificial Nauheim baths, and twelve other patients, as nearly as possible in the same condition, were used as a control. In every instance the effect of the cold Nauheim bath was to lower the temperature for a longer time than the simple cold bath. The stimulating cutaneous impression of the carbonic acid gas also seemed beneficial, although the nurses

complained of the prickling it produced on their hands.

Intestinal Irrigation.—Nine patients were treated by intestinal lavage every afternoon, six pints of normal saline solution being administered at a time through Kemp's irrigator. For two days before beginning this treatment careful observations were made as to the quantity of urine excreted. During the irrigation treatment the patients were given the same quantity of fluid as on the two days of preliminary observation. In seven patients the urine was increased from ten to twenty ounces daily. There could be no question that the other symptoms were also improved, so that these few observations should at least encourage one to give the treatment more extended trial. The object of the treatment was to diminish the well-known toxicity of the blood in typhoid fever.

Dr. Wickes Washburn said that he had had under his care some of these patients before they had been transferred to the Roosevelt Hospital. He described the deplorable state of many of these men on reaching the Montauk camp, and explained the fact that many of them had collapsed in the streets of New York City after having been discharged from the Montauk hospital, by saying that some of the cases showed a most persistent tendency to relapse. For instance, one patient, who had been discharged from Camp Wikoff on August 29th, had had a relapse as late as yesterday. In the cases complicated with diarrhœa he had found opium beneficial.

Dr. J. F. Chmelicek said that he had had about six hundred and fifty of these patients under his care. His routine treatment for the malarial fevers had been to administer five grains of quinine with half a minim of oil of black pepper. He had also met with fatal cases of intestinal hemorrhage in persons who had persisted in keeping on their feet long after becoming ill.

Cuban Fever Plasmodium.—Dr. Robert L. Watkins illustrated the different forms of plasmodium by means of lantern projection.

The following committees were appointed: Committee on Hygiene—Dr. George B. Fowler, chairman, Dr. J. W. Brannan, and Dr. John S. Thacher. Committee on Discipline—Drs. Gorham Bacon, Thomas W. Bickerton, and H. Holbrook Curtis. Committee on Audit—Drs. Prince A. Morrow, H. A. Griffin, and Beverley Robinson.

Surgical Suggestions.

Operation in Fractured Patella.—There is one precaution to be observed—namely, to handle the tissues as little as possible, and then with instruments in preference to the fingers, and, most of all, to do the handling yourself.—Haynes.

For Facilitating Cicatrization in Granulating Wounds, Abscesses, etc.—Direct upon them, at a distance of twenty inches, a jet of steam at a temperature of 127° F. Ulcerations that were resistant to other treatment rapidly heal under this measure.—Beyer, *Deutsch. med. Woch.*, February 24th.

The Pain of Lithiasis.—In lithiasis of the bladder or cystic duct the pain is sharply located in the right hypochondrium; jaundice is usually absent, and when present is usually due to suppuration or to location of the stone near the junction of the common and cystic ducts; a tumor is usually present.—H. J. Cowan.

Fracture of Nose.—When the bridge has been depressed, elevation may be attempted by a Sir Astley Cooper director. Thrust a pin from side to side through the nose, and put a piece of cork on each projecting end of the pin, pushing the pieces together until the bridge is sufficiently elevated. The bony deformity does not tend to disappear, so that if it is desired to remedy it it should be done at once.—G. G. Davis, *Annals of Surgery*, October.

Cold Abscesses.—The method of choice in the treatment of cold abscesses is the injection of iodoform in oil, ten per cent. If this fails, use oxygenated water. —Redard.

Fracture of Patella.—In laying down indications for treatment, Dr. Martin (*Archiv. Méd. Belges*, June) says arthrotomy followed by bony suture is the only plan capable of re-establishing in its integrity the extensor apparatus of the lower limb. (1) It should be employed in young subjects, free from all taint. It is not prudent to attempt it after the fiftieth year. (2) Diabetes and albuminuria are decided contraindications. Syphilis, gout, alcoholism, and cachexias call for serious deliberation. (3) There should be made out a separation of three centimetres, with marked exudation into the joint, causing ankylosis to be feared. Bloodless operations suffice for mild cases. These will be massage and early mobilization if the hæmarthrosis is but slight and the separation scarcely noticeable. Dutch physicians let their patients walk at the earliest possible date. In the intervals of manipulation the fragments are kept together by a compress bandage or strappings. Better results are to be obtained by waiting ten or twelve days for the swelling to subside, and then causing digital approximation of the fragments and retention by plaster bandage, interrupting the immobilization to carry out several *séances* of massage to prevent muscular atrophy. (4) The patient should be warned of the risks and be allowed to choose according to his profession, etc. (5) Arthrotomy and suture should be undertaken only in a rigorously aseptic operating-room. This rule is as imperative as in laparotomy.

Intracerebral Injections in Tetanus.—In the matter of prognosis tetanus and diphtheria stand together; all depends on early diagnosis and early therapeutic intervention. Although the authors Heckel and Reynès (*Presse Médicale*, No. 74, 1898) report but one attempt at intracerebral medication, and although the subject succumbed after receiving respectively two and one-half and three and one-half cubic centimetres of antitetanic serum in the substance of the brain upon the two sides, still they advocate the procedure and adduce the following indications: (1) Eradication of microbic foci when visible, limited, and operable. (2) Subcutaneous injection of antitetanic serum, which prevents new diffusion of the toxin through the blood. (3) Intracerebral injection, which guarantees the nerve cells against all subsequent chemical combinations with the toxin.

Recent Experience with Advancement of the Recti Muscles.—Dr. C. H. Beard (*Journal of the American Medical Association*, October 8th) concludes a paper as follows: "The more I study the anomalies of the ocular muscles, the more I see and the more I do, the stronger becomes my conviction that muscular advancement is the only operation—not the only treatment—but the only operation, not only for all forms of strabismus, but also for the strabic tendencies. De Wecker, of Paris, in a recent magnificent paper on the results of strabismus operations (*Annals d'Oculistique*, January, 1898), recommends advancement whenever binocular single vision is the end in view, and tenotomy, or tenotomy and advancement, when the ultimate aim is a cosmetic result. A stronger indorsement than this of advancement as the best procedure in all cases could hardly be conceived."

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

DR. ORD'S BRADSHAW LECTURE—A THICK SKULL—THROMBOSIS OF HEPATIC VEIN—THE PUBLISHING SEASON—SOME BOOKS—SIR R. THORNE'S HARBEN LECTURES — THE DEATH OF MR. FREDERIC — MANSLAUGHTER FOR "CHRISTIAN SCIENTISTS."

London, November 11, 1898.

The Bradshaw lecture for this year was delivered yesterday by Dr. W. M. Ord, who took for his subject myxœdema. His own researches on this disease will be familiar to your readers. On this occasion he passed lightly over its pathology, as it will come before the College of Physicians next year in Dr. George M. Murray's lectures. The diagnosis was touched with a master's hand. Dr. Ord said that round one well-defined picture are to be found forms more or less obscure, in part because of incomplete development of the whole series of symptoms, and in part also by reason of curious modifications constituting alliances with diseases to which the term myxœdema cannot be applied with propriety. In regard to the thyroid, he pointed out that it is not always that the gland is found reduced. If enlarged, that state may be brought about by new growth. Moreover, the history of some cases points to enlargement having preceded the contraction and atrophy.

In some cases symptoms of exophthalmic goitre have preceded the myxœdema, and the lecturer seemed inclined to think that we shall come to recognize an early stage of hypertrophy, with or without signs of Graves' disease. Not that all cases of enlargement are followed by atrophy, but he found, as no doubt others have done, that some enlargement is much more commonly observed than formerly in young women brought for treatment on account of anæmia and various nerve disorders.

As to treatment, the only one is thyroid gland. Dr. Ord prefers it fresh and minced when the patient will take it or it can be regularly obtained; next to this he prefers the extracts of the whole gland; next the B. P. dried and powdered gland. He admits the convenience of tablets, and their efficacy. Some of these are made of the whole gland, others of extracts.

Professor Curnow showed at the Pathological Society, on the 1st inst., a remarkably dense skull, weighing two pounds ten ounces. He had mentioned the existence of this at the previous meeting in the course of remarks on a specimen of acromegaly, to which I referred in a former letter. This skull is dolichocephalic and prognathous; the ridge of origin of the temporals and the insertion of the masseters are very strongly marked, unlike European skulls; the frontal sinuses are large; there is no enlargement of the pituitary fossa. Dr. Curnow said it had been supposed to be an Australian skull, but it certainly was not. He thought perhaps it might be African, but could not be more precise; it seemed a normal skull, with strong racial peculiarity. It is certainly not acromegalic.

At the same meeting there were two specimens of that rare condition, thrombosis of the hepatic vein. In both there were cirrhosis and some indications of inherited syphilis, but not enough evidence to make this conclusion clear. No doubt the state may be due to a variety of causes. One of these specimens was from a man of twenty-five, the other from a boy of thirteen. In the conversation a case was referred to occurring in a child seventeen weeks of age, reported in "St. Bartholomew's Hospital Reports." Dr. Rolleston remarked that in the specimens exhibited the changes seemed to be more marked at the orifices of the hepatic veins, perhaps causing first stenosis and then thrombosis. He had seen in one case thrombosis extending in from the inferior cava. Osler had described a case of the kind, and Delépine one in which thrombosis arose from rupture of a softened cirrhotic nodule into the vein. Some cases reported as diffuse sarcoma in children are probably syphilitic cirrhosis.

The publishing season is in full swing. Already a number of books are claiming early perusal to make room for others promised shortly. Some are strictly scientific and professional; others appeal to a wider circle, but have a special interest to us on account of the subjects, the authors, or other points.

Thus Emin Pasha began his wonderful career as a doctor, and his life in two bulky volumes abounds in scientific as well as general details of his explorations.

Sir George Robertson's "Chitral: the Story of a Minor Siege," is attractive for a similar reason, and is a lively account from the inside.

"Under the African Sun," by Dr. W. J. Ansorge, is announced as forthcoming, and as the author is a sportsman as well as a government officer in Uganda, he will doubtless tell us much of native life in Central Africa and perhaps add to our knowledge of that region's natural history.

Dr. Weir Mitchell's new story, "The Adventures of François," is now in full circulation on this side, and claims attention when from heavier volumes or stress of work we turn a weary effort toward relaxation.

"Clifford Halifax, M.D.," is the title of another promised story by Mrs. L. T. Meade, and I am told it will refer to "Christian scientists" and other quacks.

"Disciples of Æsculapius" is to be the title of a work left by the late Sir B. W. Richardson, which will be published shortly. It consists of biographical sketches of eminent physicians.

A life of the late Dr. George Harley, F.R.S., by his daughter, Mrs. A. Tweedie, is another announcement, and one in which I feel interest from my knowledge of the late physician.

Turning to works of a heavier character, I take up the first volume of Schäfer's "Text-book of Physiology." It consists of more than one thousand pages, royal 8vo, with three colored plates and some ninety figures. The writers of the several articles are representative men, and the editor himself contributes two. When complete this will be a veritable cyclopædia of physiology.

Another book of the cyclopædic order is "The Hygiene and Diseases of Warm Climates," a bulky illustrated volume of one thousand pages, edited by Dr. Andrew Davidson, and contributed to by Sir Joseph Fayrer, Drs. Manson, Macnamara, Notter, Cayley, Lousins, Sternberg, and other authorities.

Clifford Allbutt's "System" will soon be completed; but we are not at the end of these ambitious publications, for there is a project in Edinburgh for an "Encyclopædia Medica," which, it is asserted, will be a complete and authoritative medical library, covering the entire field of medicine, surgery, and midwifery, including "every subject likely to be of use to medical men." A large promise this,—but I have no desire to restrict it or to question the ability of Edinburgh to fulfil it. The work is intended to be comprised in twelve volumes, of five hundred pages, royal 8vo. There will be a good deal of condensation required to compress into the proposed compass all the promised material.

A new journal came out on the 15th ult., the *Medical and Surgical Review of Reviews*. It consists of abstracts of papers from other sources. Several attempts have been made to found such a journal, but none has succeeded.

Sir R. Thorne Thorne, K.C.B., is delivering the

Harben lectures this year. His subject is the administrative control of tuberculosis, and he shows from statistics that the deaths from all forms of tubercle are decreasing. The difference between the fifties and the first half of the nineties amounts to over thirty-six per cent. Much of this reduction of mortality is accounted for by pulmonary consumption, which is itself reduced by forty-five per cent. On the other hand, the diminution among infants and children is far less. Sir Richard assigns the first place among administrative measures which have contributed to this result to those which give ventilation and sunlight to dwellings. Nearly as important are draining of subsoil and other sanitary improvements. Infection by meat he considers is not extensive, for the general consumption of meat has increased and tuberculous disease has diminished, and that too at the ages when most meat is consumed. With milk it is different, for tabes has increased in infants under one year. Sir Richard dealt with this in his second lecture on Wednesday, and showed that it had gone on hand-in-hand with a steady and heavy increase in the use of cows' milk, the English being almost the only civilized people to consume their milk uncooked. Boiled for a single instant, the danger would be met, and thousands of infantile lives might be saved by this simple precaution.

The inquiry into the death of Harold Frederic ended on Tuesday in a verdict of manslaughter against Mrs. Mills, the "Christian scientist," and the woman who sent for her and influenced the deceased, and who seems to have controlled him. At the request of the jury the inquest had been adjourned for a week, in order that they might have the benefit of the coroner's summing up of the whole case. In the course of this he made some strong observations on the criminal folly of neglecting to employ medical aid.

On Sunday Canon Eyton denounced "so-called Christian science" from the pulpit in Westminster Abbey. He knew Mr. Frederic personally, but he cannot imagine how he should have consented to the course he did. He says the curious feature of the growth of credulity in these times is that it is taking place alongside of an enormous expansion of education. He laments the lack of common sense which lets apparently well-informed people swallow any new quackery just as they swallow "patent pills by the handful, without the least regard to the condition of their body." The "only remedy for the terrible growth of credulity is to teach people to think, to use their brains, to widen their mental processes."

On the other hand, Mrs. Mills has professed to pity the ignorance of the public, and expressed her willingness to "let erring mortals have their little day before they accept her faith."

SHOCK AND SALINE INFUSION; SOME CORRECTIONS.

To the Editor of the Medical Record.

Sir: In your issue for November 12th inst., appears as the leading article an essay by Dr. Thomas F. Reilly, upon "Technique and Use of Saline Infusions"—of all subjects one of the most interesting to me.

The paper is a very able study of the topic, and is well calculated to awaken in the mind of the general practitioner a further interest in a great and neglected weapon for good.

I am quite sure that Dr. Reilly has meant, also, to deal justly with all writers and workers in the experimental field whom he honors by quoting. Nevertheless, as he has, but certainly without intention, done the writer some small injustices, both of commission and of omission, I will venture to ask so much of your space as may suffice to make plain this fact.

Under the heading of "Methods of Introduction" of the saline solution he says: "Dawbarn has successfully used a modification of this (intra-arterial) method, which consists of the injection of the solution into a large artery through an aspirator needle thrust directly into the vessel. On account of the danger of sloughing the intra-arterial method is seldom employed."

Here the context would make it plain that Dr. Reilly assumes that Dr. Dawbarn's technique has been proven to have such a danger. In reality this is incorrect. Dr. Reilly can, I believe, mention no published case in which sloughing has followed my technique. I have followed with care each reported case—and there have now been quite a number—and no one has as yet had an ill result from selecting the common femoral artery for needling (the only vessel upon which I have advised this) instead of opening a vein and using a cannula.

One need not doubt the safety of this if he reflects upon the method of treating aneurism (inoperable by pressure, ligation, or the usual plans) advocated by Professor Macewen, of Glasgow—which is needling the affected artery. A dozen, more or less, of needles are inserted into the diseased vessel. With one of these the opposite wall is slightly scratched. All are left in place, let us say, twelve hours, during which time they aid in producing a plastic deposit, thickening the wall of the sac, within. Ten days or a fortnight later this procedure is repeated; and perhaps a third time. And the plan is safe, as a rule. Now, if a *diseased* arterial wall will bear such needling as this, and repeatedly, without sloughing, we need not fear that a *sound* artery may not tolerate a single needle for a single half-hour.

It is worth remarking, *en passant*, that in Ballance and Edmunds' great work upon Arteries, the statement is made that there is no stouter vessel than the common femoral. Its coats are actually as thick as those of the abdominal aorta. This fact of course increases the safety.

If a surgeon cuts across the radial artery at the wrist, inserts a cannula, and uses infusion in this way, it may very possibly have been followed occasionally by sloughing. But such a technique should not be confused with my method, of needling the femoral artery.

I hope my original article made plain the fact that I prefer—for a surgeon—the vein and transfusion cannula, with scalpel and retractors and forceps for aid. But my object was to point out and prove that if instruments were not at hand one could still both easily and safely administer intravascular saline infusion. Every doctor has a hypodermic; every household either a Davidson syringe, a fountain syringe, or a long rubber tube and tin funnel. And with syringe and hypodermic needle it is easy to infuse salt-solution into the common femoral—an artery which is at least large enough to contain a lead-pencil, and which is easily felt pulsating beneath the finger unless the patient be actually at point of death. In a fat subject a superficial cut may be needed, unless one has a longer (aspirating) needle. The needle is introduced slowly with a boring, gimlet motion, until a trickle of bright blood wells up it. Then, holding it firmly, slip over its base the rubber tube, with the saline solution already running, and have some one tie a thread about it. The needle should be firmly held throughout the introduction of the infusion fluid.

If a fountain syringe or rubber tube and funnel be employed with the needle, we must remember that the reservoir needs about six feet of elevation, when gravity will suffice to empty it. But if it is much lower than this (as the writer has proven upon dogs) the intra-

arterial pressure may still be great enough, after even a severe bleeding, actually to force the arterial blood up the needle and into the tube, instead of the current being in the reverse direction.

An advantage of this intra-arterial technique is the fact that the flow must be slow through the hypodermic needle; and thereby the sudden overwhelming of a tired heart by rapidly introduced injection-fluid in large amount (as through a cannula in a vein, by a beginner in such work) is prevented. This is rather a common mistake, I am sure.

If the patient be not in immediate jeopardy of death from loss of blood, inversion and pouring a couple of quarts or more of hot salt-water into the large gut through the rubber tube or the tin funnel are wonderfully effective. The blood greedily drinks up what it needs, and the heart is further stimulated by the heat. But if the circulation is so feeble as to make it questionable whether water poured into the bowel will be taken up by the circulation, then, in addition to the rectal method, let us use the intravascular; venous preferred, arterial if short of tools.

Of course, by a hypodermic needle fastened to a syringe we may also use hypodermoclysis. This is slower than any other method, however, in its effects. The lymphatics are not very speedy in permitting the diffusion of water entering the connective tissues. This last plan is of especial use, however, in babies with severe diarrhœa. In this disease the heart is often exhausted by pumping too thick blood—blood from which much of its water has been purged away. We cannot readily enter a vein in such little ones; the femoral artery, too, being but small in them, would not be easy to find by needle. The purging would in great measure prevent the retention of water given by the rectum (though this does good by cleansing); but hypodermoclysis, at a dozen or more points, an ounce or so at each, is of utmost value. I published in the MEDICAL RECORD of November 12, 1892, a case of severe cholera infantum so treated, successfully. At that time I could find the use of saline infusion for infant diarrhœa alluded to in only two instances, one German, one French, which were there quoted.

Under the heading, "Preparation of Solutions," Dr. Reilly copies without adverse comment a most dangerous bit of advice from Messrs. Bosc and Vedel; namely, that "ordinary water is non-toxic, not very destructive to the red corpuscles, and might be used in an emergency."

Let me assure the doctor that if he tries this upon a patient there will be a funeral. Nowadays every one knows that at least a litre, and from that to two litres, is the ordinary amount of saline solution proper to inject intravascularly to treat hemorrhage or prevent shock, or both. If any one injects, of plain water, more than a very little, however, the water, devoid of sodium chloride, dissolves the hæmoglobin out of the red discs, disintegrating them and killing the victim at once. Perhaps a quotation from an experiment of mine at the Columbia University physiological laboratory may emphasize this point, which surely needs emphasis (see MEDICAL RECORD, January 2, 1892).

"On May 15, 1891, I operated on a large dog, weighing before bleeding 16.77 kilos. On the one-in-thirteen hypothesis (of blood to body-weight) his weight of blood would have been 1,290 gms.; or, allowing for the specific gravity of blood, about 1,222.75 c.c. The cannula of the mercurial manometer was inserted into the right carotid. The right femoral was used for bleeding; the left femoral for injection of the hot salt-solution. Professor Curtis superintended the working of the kymographic needle. Dr. F. J. Brockway assisted me. We drew 563 c.c. of blood."

Upon attempting to replace this, and a smaller subsequent bleeding, by the salt-solution with which, at various temperatures I was experimenting, "a mistake —a most interesting and instructive one—was made. Dr. Brockway and I each supposed that the other had added the salt to the hot water; whereas in fact neither had done so. And within a minute after receiving a considerable amount of this plain-water injection the animal died." Previous dogs, bled to an equal degree, had done beautifully and recovered under saline infusion. Hence we were much puzzled until Professor Curtis asked if the salt had been added, and stated that without it water in considerable amount will kill almost as quickly as prussic acid—and in the way already named.

A little further on in his article Dr. Reilly, under the same heading of "Preparation of Solutions," makes another remark to which I must take respectful exception. "The temperature of the (saline) solution should be about 100° F." Now, if there is anything which I have proven, by experiments in the Columbia laboratory, and published long ago, it is that the proper temperature is 49° C. (120° F.), or as hot as the average hand can bear. This degree of heat is safe, and is very stimulating to the flagging heart, and restores the tone to the muscular tunic of the vessels. So recently as last winter, in the same physiological laboratory, Dr. Robert Coleman Kemp repeated my experiments of some seven or eight years ago, and re-verified their correctness. His statements were published in the MEDICAL RECORD early this autumn. We both used the mercurial manometer and kymographic tracings after saline infusion at various degrees of heat. In giving saline infusion I am careful to keep the reservoir wrapped in a large towel, to avoid rapid cooling, as I wish to maintain the temperature at or near 120° F.

But I would say a word of warning against Athansin's conclusions, quoted by Dr. Reilly. There must be a fallacy somewhere, when he says: "In animals, at least, solutions having a temperature of 165°–175° F. can be safely used." Upon reference to Kirkes' "Physiology," eleventh edition, p. 846, it will be seen that globulin coagulates at 70° C. (158° F.); and Dalton, seventh edition, p. 80 affirms that serum-albumin clots at 72° C. (162° F.).

It will be noted, however, that both 158° F. and 162° F. are about 40° F. hotter than the hand can support—as above stated. So that the temperature I advise is a long way from being unsafe.

In conclusion, I beg to make a few comments upon Dr. Reilly's views of shock. I am pleased to see that thereon we agree entirely respecting the extreme value of saline infusion, and especially as to its exhibition in the *prevention* of shock which from weakness of the patient beforehand, or severity of bleeding, or length of operation, is to be feared. If we thus strike the first blow—if we thus use the ounce of prevention —we save many a patient. But if we wait for the shock to strike the first blow, and then begin our saline infusion, it will often be too late.

I would respectfully make the claim that I am the originator of the use of intravascular saline infusion for the prevention of shock. A careful search of the Index Medicus and the New York Academy of Medicine library justifies this statement. The three surgeons quoted by Dr. Reilly under this heading published their remarks respectively December 12, 1896; March 15, 1898; and January 22, 1898—as stated by him.

This plan of prevention of shock has been in use (as dozens of doctors can testify) in my clinic since the autumn of 1891; as a consequence of some months of experimental work upon dogs, with hot saline vascular infusion after bleeding; testing intra-arterial pressures, at differing temperatures of the injected

fluid, with instruments of precision, and under the kind supervision of Professor Curtis, in the Columbia University physiological laboratory, during the winter and spring of 1890–91. So far as is known, other surgeons did not until later adopt this plan against shock; and it is commonly ignored even to-day by a majority of physicians. Nothing upon the *prevention of* shock is said in certain surgical text-books recently published in this city, in Rochester, in London, and elsewhere, so far as I have read; and several of these books do not even seem to value saline infusion at all highly.

In evidence as to priority is submitted a brief quotation from the writer's paper read before the surgical section of the New York Academy of Medicine, November 9, 1891, and published in the MEDICAL RECORD, January 2, 1892: "Whoever has noted the vigor with which unstriped muscle, everywhere, reacts to the use of heat—for example, the much stronger and decidedly more permanent uterine contractions which result from hot postpartal injections as contrasted with cold ones—must believe it probable that such unstriped muscle, forming as it does a most important tunic of the blood-vessels, would be greatly aided by hot saline infusion in regaining its lost tone. Perhaps, too, the central sympathetic centres would feel and respond to this stimulus. Now, since a more vigorous cardiac action (for the heart, though not unstriated, responds to the heat), accompanied by a somewhat restored vascular tone, would go far toward recovery both from hemorrhage and its attendant shock, I have felt that the experiment was well worth trying." (I had tried it as a preventive of shock only upon dogs, before the paper was written.)

Again, a quotation from the writer's article in the MEDICAL RECORD for November 12, 1892: "And why would it not be well, at the end of any and every operation grave enough to make shock a probable result (though, because of the ether, not yet at hand), to inject subcutaneously (*i.e.*, intravascularly) a quart or two of hot salt water? It would be painless, the patient not yet being out of anæsthesia. It would certainly be harmless. And I believe it would do much to prevent, by maintaining filled blood-vessels, otherwise fatal shock from developing. It seems not improbable that we shall ultimately see this done as a matter of routine, after all severe operations." At that early date the writer had tried the method in but very few instances, to prevent shock, using a half-litre or more within the vessel and as much more in the cellular tissues; and could not, of course, speak, as all can to-day who have used it, with absolute certainty as to its value upon human patients.

In the *Medical News* this autumn was published an article upon the "Post-operative Use of Saline Injections," by Dr. Eugene Boise, and which had been read before the American Gynæcological Society. This article covered much the same ground as that of Dr. Reilly. I merely mention it here in order to say that the week following (see *Medical News*, September 24, 1898) Dr. Boise wrote as follows: "On reading my article . . . I am struck with my omission therefrom of all reference to Dr. Dawbarn, of New York, to whom the world is indebted for the first suggestion of the intravenous use of decinormal saline solution as a preventive of shock. Dr. Dawbarn also first demonstrated that for such purposes the temperature of the solution should be high—115° to 118° F.—and thereby perfected one of our most valuable and reliable therapeutic measures."

In conclusion, just a word as to the repetition of saline infusion. Many times I have read of surgeons using it once upon a given case, and reporting a temporary good effect, but that subsequently the patient died of the shock. Now, of course, no method can save all cases of every dangerous disease; but common sense would teach us that if a dose obviously does good it should be repeated, while the same indications call for it. Of late I regularly use, just as heretofore, the hot intravascular infusion when shock is to be feared; and then elevate the foot of the bed upon a chair, and give the same solution, alternate hours, by bowel, through Kemp's rectal tube, which enables one to do this easily and without soiling the bedding. I keep this up so long as threatened or existing shock demands it, plus strychnine, or other medicinal means, until the pulse remains lower than 120 beats per minute; and I am confident that patients are thus saved who would succumb to shock after a grave operation or severe loss of blood, were the infusion to be used but once.

ROBERT H. M. DAWBARN, M.D.

105 WEST SEVENTY-FOURTH STREET, NEW YORK CITY.

THE INFLUENCE OF DIET ON CONSTIPATION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The paper and discussion on "Habitual Constipation and Its Non-Medicinal Treatment," before the section on medicine of the Academy, which you epitomized in the last issue of the MEDICAL RECORD, has for me an interest very personal and direct; is, indeed, a veritable *argumentum ad hominem*. The physician who is never sick is to be envied, yet in the treatment of the sick he may labor under a certain disadvantage. I once heard of the remark of a very distinguished physician, to the effect that in dyspeptic conditions it was unnecessary to discriminate in eating; let the dyspeptic eat whatever his appetite craved.

I do not know of more fallacious advice, and can only account for it from the fact that the one who gave it was the picture of health, with probably never a dyspeptic symptom in his life. So it is with this very wretched condition—constipation. He who has been a victim to it ought to be a little better prepared to gauge its causes and its cure than the man perfectly healthy in this respect.

I do not deny that drugs may be sometimes useful in habitual constipation, but to my mind they are in the main a delusion and a snare. In this view I am, I believe, in accord with the author of the paper.

I recognize well the fact that all cases cannot be treated alike, and yet, according to my experience, the chief causative factors of constipation are indiscretions in eating and drinking, and its cure depends mainly on the correction of excess. When one considers the evils that flow from overeating—the imperfectly oxidized food products—the derangement of the excretory processes and the interference with peristalsis from toxic causes—one finds it not very difficult to believe in this causation. In my own case I find that the less I eat—within bounds and broadly speaking—the better I am, and to my mind the method that will in most cases hit the mark is a restricted diet according to individual idiosyncrasies—plenty of exercise and fruit—especially apples, the king of fruit.

I have a relative, now ninety-six years of age, with a fair degree of mental and physical vigor. My earliest recollection of him is as a semi-invalid, with the symptoms of dyspepsia and constipation predominant. After the age regarded by many as old, he learned what the majority fail to learn—the virtues of a simple and moderate diet, rightly adapted to his special needs. A considerable portion of this diet consisted of apples taken, not spasmodically, but morning, noon, and night, and at all seasons when attainable. Not a few claim that they are unable to eat apples because of the indigestion and flatulence

occasioned. Those who are thus unfortunately debarred must get along without this health-giving fruit, but I am very strongly of the opinion that the majority who hold this idea are simply laboring under a misapprehension. Among a number who have quite overcome this habit of constipation by courageously and persistently following out a course of prescribed dietetics, occurs the case of a female patient in the practice of a friend of mine, to whom I had lauded the virtues of the apple. This patient claimed that apples had always disagreed with her, producing flatulence, indigestion, and a host of unpleasant symptoms.

He induced her to begin by eating immediately after each meal a portion of a small apple; this portion to be increased a little day by day. She now takes after each of her simple and restricted meals from two to three apples, not only without discomfort but with the greatest relief to her former constipated habit.

Dr. Lockwood, the reader of the paper, remarks that faradization had been a grievous disappointment to him; and to a certain extent I agree with him. While it is by no means valueless as an adjunct to proper hygienic measures, the galvanic current, applied according to the following method, will give better results than faradization. A conical metal electrode, about two centimetres in diameter and four or more in length, and connected with the negative pole, is introduced just within the rectum, while the other and indifferent electrode is applied externally, preferably on the abdomen. With a current of from five to ten or fifteen milliamperes, according to each individual case, interruptions are made at intervals of three to five seconds for a half-dozen times more or less. It will be observed that the impression made is greater at the opening of the circuit than at the closing; just the contrary of what occurs in purely external applications through the high resisting media of the epidermis. It will be further remarked that in many if not the majority of cases these applications are followed not only by a distinct desire for a passage but by an actual movement of the bowels.

PROSTATECTOMY—A CLAIM OF PRIORITY.

To the Editor of the Medical Record.

Sir: In your issue of November 19th, Dr. S. Alexander is quoted as describing a perineal prostatectomy under the heading of "His Method of Enucleation," which, as nearly as I can understand, is identical with my own, described in the Medical Record, August 6, 1892.

I am satisfied that I was the first to describe and publish this method of operating upon hypertrophied prostates. Interested readers, by referring to the above number, under the heading of "A New Method of Removing the Prostate Gland," will find the operation credited to Alexander described in detail, with an illustration from a photograph showing the line of incision. I know of no one prior to this time attempting total enucleation. The operation there described was reprinted in the *British Medical Journal*, August 17, 1892, and in the *Medical Annual*, 1893, and is a matter of history. I studied, planned, and executed the new method independently and without knowledge of the work of any others, if there be, along the same lines. Professional courtesy demands that Dr. Alexander should properly credit my work. A reprint of my article with a personal letter calling his attention to my operation was mailed him shortly after the appearance of the publication in the Medical Record. As late as 1895 Dr. Alexander appears before the members of the New York Academy of Medicine and describes essentially, according to published reports, the operation with which I should have been credited. Again I wrote him, this time asking that he give me the date of his first operation and anything that he had published on the subject in question. I also called his attention to my claim for priority. At no time have I been able to get a response from Dr. Alexander, and I am driven to take this method to find out what his claims for originality are and in what respect they differ from my own.

With me, and as far as I have been able to learn, the semicircular incision in front of the sphincters and behind the transversus perinei carried from the middle of one tuber ischium to the other, the separation of the rectum from the membranous urethra, and the uncovering and enucleation of the prostate through this route is original. I await enlightenment.

John S. Pyle, M.D., LL.B.

2123 Ashland Avenue, Toledo, Ohio,
November 23, 1898.

THE "SURGICAL NURSES" FROM THE ACADEMY.

To the Editor of the Medical Record.

Sir: My attention has been called to a letter from Dr. Dawbarn, in the Medical Record for November 26th, in which he laments the fact that the register for nurses, at the New York Academy of Medicine, is not under the supervision of a competent medical man. He tells us of the ignorance and stupidity of some of the women sent out as "surgical nurses" from the bureau of the Academy, and doubt not that many other surgeons could testify to the unfitness of these persons for the work which they undertake to perform. Unquestionably some guarantee should be given to the profession of the character and qualifications of the nurses registered at this bureau. But how is this to be accomplished? Dr. Dawbarn does not tell us. He makes a suggestion, however, and that is that the bureau should send out as "surgical nurses" only those who are graduates of New York training schools. Is this discrimination against graduates of training schools outside of New York City a just one? Is all the concentrated wisdom of the nursing profession centred in the heads of the representatives of that guild who are graduates of New York schools only? It may be, but of this the writer is not convinced. He has seen graduates of New York training schools who had about as much expression in their faces as they might be expected to have in almost any other portion of their anatomy. He has seen many whose appearance would lead him to infer that they might be very proper persons to scrub the floors of the wards, but that they ought hardly to be trusted to perform the responsible duties of a trained nurse, especially a surgical nurse.

He has seen the hatchet-faced, lantern-jawed female, whose very presence was enough to turn milk sour, waiting upon a nervous invalid whom she managed to stroke against the grain every time she attempted to do anything for her.

On the other hand, he has seen the rotund, squabby, bumptious young dame, with a swagger resembling that of a Bowery swell, rustling about a sick-room in a manner calculated to give a susceptible person a rigor; or prancing about an operating-room, turning things upside down with an abandon characteristic of the proverbial bull in the china shop. We do not believe that the mere fact of graduating from a New York training school makes a woman an ideal nurse. Nurses are born, not made. To become a first-class nurse a woman must possess the nursing instinct, must

have a natural aptitude for the work of her calling. This is a commodity which, unfortunately, the training schools (even in New York) do not always have in stock. The schools do not furnish information and brains too; they are forced to do the best they can with the material at their command, and the result is some of the half-baked specimens of whom (or which) Dr. Dawbarn complains. If there are as many incompetent nurses registered at the Academy as Dr. Dawbarn's statement would lead us to believe, we think that the responsibility for this state of affairs rests on the shoulders of the superintendents of the various training schools in New York, for the New York graduates must outnumber those from other schools in the proportion of three to one at least. This condition of things will continue as long as the training schools continue to take as pupils women who have no adaptability to the calling of a trained nurse. If a young woman is intelligent, well educated, loves her work, and applies herself to it diligently, she will make a good nurse, and it will make very little difference whether she graduates in New York, Oshkosh, or Philadelphia. G. H. Balleray, M.D.

New York, December 1, 1898.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 3, 1898:

	Cases.	Deaths.
Tuberculosis	150	159
Typhoid fever	64	16
Scarlet fever	115	5
Measles	136	2
Diphtheria	156	24
Laryngeal diphtheria (croup)	20	11
Cerebro-spinal meningitis	0	2
Chicken-pox	38	0

Lunatics in Ireland.—The forty-seventh report of the inspectors of lunatics in Ireland, published at the end of September last, states that the total number of known insane in Ireland on January 1, 1898, was 19,590, as against 18,956 in 1897.

Memory in Idiots.—Among cases of extraordinary memory in idiots Morel cites an idiot who remembered the date of the funerals of all the persons who had died in his parish within thirty-five years, with the names of those who had taken part in these funerals. Morel also cites the case of an idiot who could not count up to twenty, but who knew the names of all the saints in the calendar, with dates of their respective feasts.

Man was Not Always a Flesh-Eating Animal.—Primitive man originally subsisted on a diet consisting purely of fruits and roots; but though fructivorous by instinct and by reason of the conformation of his digestive organs and dental system, in which respect he is nearly allied to the apes, which are all fruit-eating animals in their natural state, he soon became omnivorous from necessity, and his stomach readily adapted itself to every kind of food. If the Darwinian theory be accepted and the descent of man from simian ancestors be granted, we have further argument in support of the fact that flesh-eating was the outcome of civilization and climatic necessity rather than of natural craving. Exposed at the epoch of the great extension of the glaciers, which at one time covered all our mountains, to the hardships of an inclement climate, man required something more nourishing and heat supplying than the vegetable diet which sufficed for him in a higher temperature; and in the palæolithic age we find him not only destroying animal life, but provided with and utilizing the means of cooking the victims of his rough-hewn knife and spear.

On the Use of Poisons by Suicides and Murderers.—Sir. J. Crichton Browne when delivering the inaugural address before the Pharmaceutical Society, Bloomsbury Square, London, a few weeks ago made some interesting remarks on the above subject. He referred at length to the use of poisons by murderers and suicides, and said that notwithstanding the discovery of new poisons which, when taken into the body, could defy detection, even in a most minute post-mortem examination, homicides still clung to the old-fashioned and clumsy methods of human destruction. Nicotine poisoning had been resorted to in only one known case of premeditated malice, and then a man was murdered in less than six minutes, and the post mortem failed to detect the slightest trace of poison in the body. There were organic poisons well known to medical men which could be used with impunity without the slightest fear of detection, but they were rarely or never used illegitimately. A connoisseur of poisons could, by keeping his own microbes, slaughter hundreds of innocent people, without the slightest fear of his crime coming to light. For a long time to come, he thought murderers would continue to stake their necks on such old methods as arsenic and strychnine poisoning, which was a remarkably lucky thing for society.

Reading Aloud.—Reading aloud as a mere physical exercise is of great importance and efficacy. Cicero in some one of his letters speaks of curing himself of troublesome and alarming weakness by reading aloud for some hours every day. Certain temperaments are influenced by it, as actors are affected by their own playing. It is said of Madame Testa that she would come home from the opera and sit in a passion of tears at the recollection of what she had been acting. It was entirely unaffected. She would say she knew it to be idle, but that she "could not get the thing out of her head."

Health Reports.—The following statistics concerning small-pox, yellow fever, cholera, and plague have been received in the office of the supervising surgeon-general of the Marine Hospital service during the week ending December 3, 1898:

		Cases.	Deaths.
Small-Pox—United States.			
Michigan, Detroit	November 12th to 19th	Present.	
Ecorse Township	November 12th to 19th	Present.	
New York, New York City	November 19th to 26th	3	1
Pennsylvania, Philadelphia	November 28th	5*	
* Imported from Norfolk, Va.			
Small-Pox—Foreign.			
Belgium, Antwerp	October 29th to November 5th.	9	4
Italy, Rome	October 1st to 8th	..	1
Russia, Moscow	October 29th to November 5th.	12	2
Odessa	October 29th to November 5th.	3	1
Odessa	November 5th to 12th	5	1
St. Petersburg	October 29th to November 5th.	7	
Warsaw	October 29th to November 5th..	..	2
Yellow Fever—Foreign.			
Columbia, Barranquilla	October 22d to 29th	2	2
Barranquilla	October 29th to November 5th.	..	3
Mexico, Vera Cruz	November 10th to 17th	..	3
Vera Cruz	November 17th to 24th	..	8
Cholera.			
India, Madras	October 15th to 21st	..	11
Plague.			
Austria, Vienna	October 22d to 29th	..	1
Bokhara, Samarcand	November 6th	Epidemic.	
India, Bombay	October 18th to 25th	..	109

The United States Consul at Odessa, Russia, reports plague present at several localities in Central Asia, and advises restrictions on shipments of wool to the United States via Black and Caspian seaports.

THE ABDOMINAL WOUND.[1]

BY A. C. HEFFENGER, M.D.,

U. S. NAVY,

MEMBER STATE BOARD MEDICAL EXAMINERS, NEW HAMPSHIRE; NEW HAMPSHIRE MEDICAL SOCIETY, STRAFFORD DISTRICT MEDICAL SOCIETY, ETC.

IN selecting a subject for the annual presidential address, I have sought to present to you one, not only of deep interest to the abdominal surgeon, but of vital importance to the profession at large.

Modern surgical technique is undergoing constant evolution, and therefore to give skilled operative assistance, and assume intelligent charge of the after-treatment of a laparotomy case, the general practitioner should make annual trips to the metropolitan surgical centres, which, unfortunately, but a limited number can afford either the time or expense to do.

The object of this paper, therefore, is to lay before you in a plain, practical manner the methods now in vogue with the best abdominal surgeons in the country. It is not possible in a paper of this length to go thoroughly into the entire subject, or to give the individual opinions of various men, so that in the main only general principles relating immediately to the abdominal wound will be considered.

Preparation of Patient, Surgeon, and Assistants.—When it is decided that an abdominal section is to be done, preparation of the operative field is the first thing to demand our attention, and this is divided into two portions when time and circumstances will permit.

If the operation is to take place in the morning, the patient receives the preliminary preparations during the afternoon of the preceding day.

First a thorough, warm bath is given, in a tub if possible, after which a proper drying with sterile towels is effected, a clean night robe put on, and the patient placed in bed and given a hot sublimate vaginal douche.

Next a practically sterile table is placed at the bedside of the patient, upon which should be found green soap, scrubbing-brush, alcohol, ether, sublimate solution (1:1,000), razor, gauze-sponges, sterile towels, a large abdominal dressing of gauze or cotton recently steamed or baked, abdominal binder, and safety pins.

A rubber sheet is now placed under the patient, and the abdomen well exposed from the ensiform cartilage to the pubis. The skin of the exposed region is next thoroughly lathered with green soap, and all hair carefully shaved off. More soap and the scrubbing-brush are next applied, the brush being used gently, and the umbilicus well attended to. Gauze sponges wet with sterile water are then used to remove all soap from the skin. Now, before completing the preparation, the surgeon or nurse should carefully sterilize his or her hands, and with a gauze sponge finally mop the skin with alcohol, ether, and corrosive sublimate solution 1:1,000, in turn, after which the abdominal dressing and binder are carefully applied, the rubber sheet is removed, the night robe readjusted, and the patient made as comfortable as possible. Delicate patients will often require stimulants immediately after undergoing this ordeal.

The following day, when the patient is well anæsthetized and on the operating-table, another vaginal douche is given, and the temporary binder and dressing are removed. The chief surgical assistant, with sterile hands, applies green soap and water with a gauze sponge to the entire abdomen, carefully looking to the umbilicus, and watching for eczematous points which may harbor infection.

Following this, the skin is well mopped with alcohol and ether, a sterile laparotomy sheet placed over the patient, and sterile towels are placed over the chest, across the lips, and on either side of the operating-field.

While the patient has been undergoing this final preparation, the surgeon and his assistants have been making themselves thoroughly aseptic. The arms should be bared above the elbows, and, with the collar and cravat removed, the hands, arms, face, and neck should be thoroughly washed with green soap and sterile water. The hands are then again lathered with soap and well scrubbed with a nail-brush for five minutes, great care being taken to clean thoroughly under and around the nails. The hands and arms are then immersed in a strong solution of potassium permanganate, bleached in a solution of oxalic acid, immersed in alcohol, and finally rinsed in sterile water. An operating-cap of sterile cotton is then put on, and the operating-gown, with elbow sleeves, donned. If the instruments, sponges, ligatures, and sutures are all ready, the operation can immediately be proceeded with.

Position of Patient, Surgeon, and Assistants.—All operations involving the pelvis are best done in the Trendelenburg position, as the intestines thus gravitate away from the working-field, leaving a good view of and free access to the interior of the pelvis. Operating in this position, the surgeon faces the foot of the table, being on the left side of the patient. The chief assistant stands immediately opposite, while the second assistant stands near the foot of the table on the left side. The instruments are placed beside the first assistant, and the suture materials, needles, and ligatures are in charge of a special assistant near the surgeon's left arm.

The Incision.—The surgeon begins the incision within the hair of the pubis, and with quick and delicate force divides the skin and part of the subcutaneous fat with one stroke of the knife for about an inch and a half in the median line, toward the umbilicus. The second stroke of the knife lays the fat open well down to the tendon and increases the length of the incision to the extent the character of the case will probably require. In fat women a long incision is required, as the depth of the wound increases the difficulties of manipulation in the cavity. In large uterine tumors, the incision should begin much higher up, and the peritoneum opened midway between the pubis and umbilicus, as they are apt to drag the bladder high up in the abdomen where its liability to injury from the knife would be great. If more room is needed, the incision is carried up to and beyond the umbilicus, passing to the left of the navel and avoiding the

[1] Presidential address before the Strafford District Medical Society, Dover, N. H., October 12, 1898.

suspensory ligament of the liver. While dividing the tissues down to the linea alba, several small arteries are cut and are grasped with hæmostats, which are thrown to one side of the incision. The linea alba is seen as a white line between the recti muscles, and the knife should enter as nearly as possible in its course. Under the linea alba will be found the subperitonal fascia and fat, which varies greatly in different subjects. In thin, greatly distended abdomens, scarcely any will be seen, while in very fat cases there may be an inch or more encountered before the peritoneum is reached.

This is picked up by the surgeon and chief assistant with mouse-toothed forceps, and carefully divided with the knife till the peritoneum is reached. The peritoneum is then picked up by each with forceps, and moved freely to be sure that no adhesions are under the line of incision, and, when found free, is carefully incised with the knife till an opening large enough to admit the forefinger is made. The knife and forceps are then put aside, and the index finger of the surgeon is inserted into the cavity to make sure there are no intestinal or omental adhesions, and that the bladder is well out of the way. If everything is free, the peritoneum is cut, with the fingers of the left hand as a protecting guide, to the full extent of the rest of the wound. It will now be found that as a rule hemorrhage from the small vessels divided during the steps of the incisions will have ceased, and the hæmostats may be removed. If, however, there should still be some bleeding after removal of the hæmostats, small catgut ligatures should be thrown around the hemorrhagic points, and cut short.

The abdomen now being opened, we shall assume that the various intra-abdominal steps have been successfully accomplished, and the time has come to close, or partially close, the wound, as the case may indicate.

Drainage.—Before closing the wound the question of drainage must be considered; and here let me state that whenever possible the drain should be dispensed with, for it is a source of danger in itself, both while in place and upon removal. Tubal drainage immediately following operation is now condemned by practically every one, and gauze alone is used by the best surgeons. It becomes firmly adherent to the sides of the wound and to raw surfaces in the cavity, and its removal is attended with much pain and more or less hemorrhage. It has been proved that a greater mortality results in drained cases than in a similar number and character of undrained ones. The peritoneum is capable of absorbing and destroying far more germs than has been previously supposed, as the following conclusions by various investigators show, and which may be found in Kelly's book on operative gynecology.

1. Large quantities of fluids may be absorbed by the peritoneum in a remarkably short time (Wegner).

2. Minute foreign particles are carried from the peritoneal cavity through the diaphragm into the mediastinal lymph vessels and glands, and thence into the blood, by which they are transmitted to the organs of the body, especially those of the abdomen, and later appear in the collecting lymph glands of these organs (Muscatello).

3. The leucocytes are largely the bearers of foreign particles from the peritoneal cavity (Muscatello).

4. There is normally a current in the peritoneal cavity which carries fluids and foreign particles toward the diaphragm, regardless of the posture of the animal, although gravity greatly favors or retards it (Muscatello).

Drainage should be limited to infected cases, or those in which the streptococcus undoubtedly exists. Simply because large raw surfaces are left, or there is mild capillary oozing, a drain should not be used, for, as previously shown, the peritoneum is quite capable of taking care of the fluids from such sources, and if eight to ten ounces of normal salt solution be left in the cavity, there is reasonable surety that they will be kept harmless until absorbed.

Of course, all hemorrhage and oozing should be stopped, if possible, before closing the wound, and those cases in which practically only peritoneum is left, will, *ceteris paribus*, give the best results.

The manner of putting in a drain will vary slightly, according to the degree of drainage demanded. If a large area is to be drained, the pieces of gauze should be folded into ribbons about eighteen or twenty inches long and an inch and a quarter wide. These strips are loosely packed in coils over the desired area, and the free ends brought out at the lower angle of the wound. The ends should be so marked that the top ribbon may be removed first. If but a small drain is needed, the umbrella drain is best. It is made by simply folding a half-dozen layers of gauze like a folded umbrella. The apex is placed at the bottom of the point to be drained, and the raw end lies in the lower corner of the wound. In removing this drain pull out the central fold first, then the others in order, till the outside piece is left. This, being firmly adherent to the sides of the wound, must be gently twisted around to loosen it, and then pulled out.

Dressing.—The dressing over the drain and wound consists of several layers of sterile gauze and cotton, and extends well beyond in all directions. It should be removed with forceps, under strict asepsis, as often as saturated.

Closing the Incision.—The best method of suture after laparotomy is still an open question, with many strong opinions for various forms of technique. Kelly holds that all buried sutures give the best result, and advises suturing the peritoneum with a continuous catgut suture, the fascia with interrupted mattress sutures of silver wire, the fat by a continuous in-and-out catgut suture, and finally the skin by the subcuticular catgut suture. In this method there are no sutures to remove, and Kelly claims for it "a firm closure, freedom from stitch-hole abscess, diminished liability to hernia, and simplicity of after-treatment."

If the wound is aseptic, its surface free from hemorrhage, with little traumatism of its edges, and the tension of the silver sutures has not been too great, this happy outcome may be realized.

Besides this ideal closure, however, there are various other methods very popular with individual surgeons. The simple through-and-through interrupted silkworm-gut suture has a host of advocates throughout the whole country, while a continuous catgut peritoneal suture, interrupted catgut or silver-wire fascia sutures, with interrupted silkworm-gut sutures for fat and skin, is also much in vogue. On the best method of suture after laparotomy, the MEDICAL RECORD, July 17, 1897, copies from the *Indian Medical Gazette*, February, 1897, the following: "La Torre (International Congress in Geneva) says: 'A good abdominal scar depends upon three main factors: the location of the incision, the suture material, and the method of suturing.' Bantock: 'Bacteria take no part in the production of pus. They are the result and not the cause of the condition. Suppuration of the abdominal wound or of the suture tract does not originate from the introduction of germs or adult bacilli into the wound, but is the sequence of necrosed tissue in the wound and excessive tension of the sutures. The ordinary interrupted suture suffices in most cases, but in very fat subjects it is advisable to close the peritoneal cavity with continuous sutures, while the rest of the wound is united by two layers of interrupted sutures. Silk is the best material for interrupted sutures, while, for

the continuous, catgut (not chromic-acid gut) is preferred.' Byford: 'Avoidance of wound infection and injury to the tissue during operation is of prime importance. A median incision is advised. First unite the peritoneum, next fascia and muscles, and finally the skin. Use interrupted sutures of silkworm gut.' Edebohls: 'The resistance of the abdominal scar depends upon a broad surface of contact. Divide the fibrous covering of the recti and in the subsequent closure of the wound the peritoneum is first united, next the two recti muscles are sutured together, and the suturing of the fascia and skin completes the operation. Use chromic-acid catgut for all but skin sutures.' Wylie: 'Hernia in the linea alba is frequenly the result of abscesses, often caused by an excessive tension of the sutures. An exact suturing of the fascia is necessary; this should never be done by continuous sutures, which would carry infection throughout the whole wound.' Pozzi and Engström also lay great stress upon an accurate union of the same anatomical structures. Coelho considers deep silk sutures the best method, while Latzko demonstrates a series of microscopical sections of an abdominal scar which show that deep sutures unite many structures not anatomically related to each other, while a careful suturing of fascia to fascia and muscles to muscles, etc., leaves a hardly distinguishable scar."

The question of suture material might be gone into at great length, but practically silk, plain and chromicized catgut, silver wire and silkworm gut are those most generally used, and individually I am using now only plain catgut of various sizes and silkworm gut. Before tying the sutures be sure that all hemorrhage has ceased, otherwise there will be hæmatoma, with subsequent suppuration if the blood is not evacuated or absorbed. When hæmatoma is found to exist, the edges of the wound should be slightly separated at once, the blood squeezed out, and the wound then firmly held together with adhesive strips, and a compress applied. Hæmatoma is most apt to occur when the wound is sutured in layers, owing to the difficulty of firmly closing the fat adjacent to the fascia. I have called this line in laparotomy "the post-operative blood space."

In through-and-through suturing I have never seen hæmatoma, and since discarding silk, and using the non-capillary silkworm gut sutures in the skin, wound troubles in non-drained cases have been exceedingly rare.

How long a wound should remain sealed before inspection is necessary, will depend upon the nature of the case. If it is a drained case, the dressing is changed whenever saturated, or in any event after forty-eight hours. In non-drained cases, it is my custom to remove the dressings on the fifth day, and carefully inspect the stitches. If all is well, I re-dress and wait till the tenth day, when all sutures are removed, the wound is washed with sterile water, dusted with boracic acid, and a light dressing put on. If stitch trouble or infection in the line of incision is going to occur, it will probably take place between the sixth and tenth days, so that careful observation of temperature and pulse should be noted during this time, and the patient interrogated as to pain or unusual soreness in the line of incision.

Primary as well as secondary wound trouble should be carefully watched for, though it is of very rare occurrence, and is due to very septic suture material, or virulent infection of the wound from other causes. In these cases there is a rise of several degrees in temperature during the first twenty-four hours, and upon removing the stitches murky serum or forming pus will be found. The wound should be thoroughly disinfected with a 1 : 1,000 solution of bichloride of mercury, or decinormal salt solution at a temperature of 110° F., and subsequently packed with iodoform gauze.

In pulling open these wounds within the first forty-eight hours, very firm union will be found to exist in the non-infected parts. Indeed I have been surprised to find that after removing all sutures the wound not only remained firmly adherent, but quite decided force was necessary to break it apart. It would seem from this that sutures are left in as a rule longer than necessary, and that in a perfectly aseptic case they could be removed after seven days without fear of trouble, and we all know that they cannot be dispensed with too early when once their work is done. Though suppuration of stitches or in the line of incision is generally ushered in by rising pulse and temperature, such is not always the case, especially if hæmatoma has occurred, for in cases in which the dressing has not been removed for ten days, because everything apparently was going well, the wound has been found separated and bathed in pus upon its final removal. In consequence of this fact, I make it an invariable rule to remove the dressing on the fifth day, and, if all is well, re-dress every forty-eight hours till the stitches are removed and it is evident no wound trouble is likely to occur. Assuming, however, that stitch-hole abscess or suppuration in the line of incision is going to occur in a given case, we shall probably find a rise of two or three degrees in the temperature, and the pulse will run up to 100 or 120; pain in the region of the wound is complained of, and upon removing the dressing hard, brawny areas will be felt on one or both sides of the wound, which are sore upon pressure, and may or may not be red according to the depth of the septic focus. The wound should be separated at once at the nearest point to the focus, provided the induration extends fully to its edges, and pus will be found to exude. If the focus is around a stitch remote from the line of incision, the stitch is removed, being cut on the non-infected side, and pulled through toward the infected side, thus avoiding carrying septic matter across to the healthy side. This rule should be observed in removing all sutures that look tainted on one side or the other. The septic stitch having been removed, and pus found freely flowing, the hole should be well opened with the knife, and the abscess cavity evacuated and washed out. These abscesses usually form in the superficial layers of the fat from skin-suture infection, though they may occur in the muscular layers, and present a genuine abscess of the belly walls. These latter cases require free incisions, ample drainage, and frequent flushings with antiseptic solutions, such as bichloride of mercury, 1 : 3,000, or decinormal salt solution. Peroxide of hydrogen I do not recommend in wound lavage, on account of the power it has of forcing its way into the tissues, and suddenly carrying septic matter into the areolar tissue and fat before destroying it. In this manner it is liable to cause a large suppurating phlegmon.

Peritonitis resulting from wound abscess is exceedingly rare even in the most violent mural forms, owing to the simple fact that the peritoneum unites very quickly and firmly, and forms a highly resistant shield before pus is generated.

Kelly gives the following causes of post-operative wound complications: "Unnecessary handling of the wound, rough retraction of its edges and prolonged pressure with metal retractors, carelessness in checking bleeding in the incision, strangulation of large bits of tissue by ligatures, and the use of sutures penetrating the skin in closing the incision."

To these causes must be added the normal presence of many pyogenic germs in the skin, which are likely to take on active genesis when in contact with air.

Remlinger states that many of these germs are found in the deep layers, and has demonstrated in

these layers the staphylococci albus, aureus, and citreus, the streptococcus pyogenes, and the coli bacillus. When the wound is firmly healed, whether by primary or secondary union, the question of its ultimate support demands consideration.

Personally, I have never had hernia or even a weak wall occur in any case, but I think it good practice to advise the use of an abdominal supporter for six months or a year, according to the length of the incision and the character of the union. All supporters should have perineal straps to hold the front and centre well down, and should be well cut up over the hips to allow the front to come down into good supporting position.

Portsmouth, N. H., October, 1898.

A CHEAP CURE FOR APPENDICITIS.

By T. J. HUTTON, M.D.,

CHICAGO, ILL.,

FORMERLY RESIDENT PHYSICIAN, LONG ISLAND COLLEGE HOSPITAL, BROOKLYN, N. Y.; BRIGHAM HALL PRIVATE HOSPITAL, CANANDAIGUA, N. Y.; BURN-BRAE PRIVATE HOSPITAL, PHILADELPHIA, PA.; PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM, COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO.

This paper is a protest against the current surgical theory and practice that all cases of appendicitis must be split open. This protest is based on twenty-seven years' experience as physician and surgeon, including services in three hospitals, one Western fort, five years in mining surgery, five years in railroad surgery, twelve years in general practice on the central western plateau of Minnesota, and four years in this great city, which—unique in the speed of its rise, unique in the snap of its people, unique in vast tributary territory and population—is decreed by the fates to be the hub of the earth in the near-by future.

My experience is that appendicitis and all other bellyaches for which men now operate are promptly amenable to proper medical treatment. I can recall one hundred cases treated with symptoms of this malady—or of typhlitis or perityphlitis, as it was formerly called—but I have never yet met a case of it in which I felt it was my duty to cut or which terminated fatally. Influenced by the prevailing craze to cut, time and again in coming to new cases of this kind I have thought: "Now, sir, your time has come; in this case you must cut." But, presto! simple medical treatment again availed. Later on I shall cite other unimpeachable practitioners who share my views that medical treatment avails in this malady, one showing forty-nine out of fifty-one cases successfully treated—being more than ninety-six per cent.

My treatment for appendicitis is free calomel-and-soda purgation, supplemented by hot applications, to be followed by a saline if action is too slow. Fæcal impaction of the colon is present in some instances; here the bowel must first be unloaded by suitable enemata. This unloading the bowel is in some instances a slow and difficult task. I recall a case in Shenandoah, Pa., some ten years ago, in which the colon was so severely impacted in a male student, aged twenty years, that, despite the almost continuous use of all kinds of enemata, six days elapsed before the bowel was completely evacuated. The persistent use of ox gall and olive oil finally effected it. Dr. Straub, now of Bethlehem, Pa., was my colleague in this case (it was his case), and the good doctor, if he reads this article, will remember how strenuously he advocated operation after the first few days had elapsed. This patient is now principal of schools in Cranston, R. I.

If symptoms continue after the enemata have done their work, then the calomel-and-soda purgation follows. In all cases light, hot applications, as of cloths dipped in boiling water and slightly cooled, are important adjuncts to treatment. But the main factor in treatment in the vast majority of cases is the calomel-and-soda purgation, and here is the mode of administration.

According to the age of the patient, a few powders, each containing from two and one-half to ten grains each of calomel and bicarbonate of sodium, are ordered. One powder is given every hour until the few powders are taken. That is all there is to the calomel-and-soda treatment, except that when its action is too slow a saline purge is given. Free purgation follows, and all symptoms cease. Is anything simpler? Could anything be cheaper? Certainly nothing could be more effective. The least price charged by druggists for filling a prescription is twenty-five cents, and this sum is the exact charge for these powders, so that the caption of this paper is literally correct.

Calomel, like many a good man, has suffered much for the sins of others. Through no fault of its own, but simply because some of our predecessors abused it, it had fallen under a chronic ban. But, far from needing apology, its record, rightly used, is all eulogy. It is a, or rather the, protean remedy. It fills the greatest number of indications of any remedy in the entire materia medica. "The man who still sits in the seat of the scornful" as to the virtues of this agent, but shows his own profound ignorance. I would almost say of calomel what Beecher said of "cheek"—that a thorough knowledge of its virtues is to the practitioner equal to a cash capital of $50,000. I recall one little formula alone, taken from Vogel, on "Diseases of Children," twenty-eight years ago, which certainly has been well worth from $5,000 to $10,000 cash to me. It is for the summer troubles of infants and children, and is as follows:

℞ Hydrarg. submur ..... gr. i.
Sodii bicarb ..... gr. vi
M. Div. in cht. No. vi. S. One every hour. A teaspoonful of castor oil after all are taken.

For older children the dose can be increased.

As one druggist who filled a three five-grain powder prescription for me afterward asked me if that dosage was not pretty large (his book stated the full dose to be two grains), I will now make a few brief quotations from the article on "Calomel" in the latest edition of the "United States Dispensatory":

"It is the most valuable of the mercurial preparations. . . . In the case of children it is peculiarly valuable, from the facility of its administration. . . . For children larger doses are generally required in proportion than for adults. Not less than from two to three grains should be given as a purge to a child two or three years old. . . . When given alone, it should be followed if it does not operate in six or seven hours by castor oil or some other cathartic. . . . As a purgative, from five to fifteen grains or more may be exhibited. . . . Enormous quantities may be given with impunity. . . . With a view to salivation, the dose is from half a grain to a grain three or four times a day, to be increased considerably in urgent cases. . . . In very large doses calomel is supposed by some to act directly as a sedative, and with this view has been given in yellow and malignant bilious fevers, violent dysentery, malignant cholera, etc. The quantities which have been administered in such affections with asserted impunity and even advantage are almost incredible. A common dose is one or two scruples repeated every half-hour or hour."

The protean quality of this remedy is proven by the fact that it is laxative, purgative, sedative, secernent, alterative, resolvent, tonic, anti-emetic, antiplastic, antiphlogistic, antisyphilitic, antiseptic, and, by removing the cause of pain, anodyne, as illustrated by the

class of cases under discussion in this paper. A meeting of the British Medical Society, held at Belfast some ten years ago, was a continuous eulogy of this remedy. Those who wish to know the facts should procure that report.

A few illustrative cases:

I was called in consultation with Dr. W. C. Bedford, now of Salt Lake City, to Mrs. Charles B——, aged thirty-five, six months pregnant, with urgent symptoms of this malady. On retiring to consult, I asked the doctor if he had given any calomel, to which he replied: "Yes; six grains." I asked him if he thought that was enough. He said: "Yes." "Well," I replied, "we will let it go at that for to-day." Next morning early I was called to the case again. I first went to the doctor's office, and told him I would not accompany him to the case except I be allowed something to say in the treatment. He agreed that I should. We found the patient in a most serious condition. I prescribed four powders, each containing ten grains of calomel and ten grains of bicarbonate of sodium, one to be taken every hour until free purgation occurred. Soon after two or three of the powders had been administered all symptoms subsided.

One evening, while I was driving rapidly home from a call on the borders of Dakota, a young farmer, living three miles from town, called me in to see his son, who had all the urgent symptoms of this ailment. I have already stated that time and again I have been called to cases in which I felt myself that "very likely I must operate in this case." I distinctly recall that in this instance, after dealing out four calomel-and-soda powders and directing this father how to administer them, I added: "I will be back in the morning, Jim, and if this treatment don't do, I may have to do something else." Next morning the boy was well, no trouble whatever remaining.

On the 29th of September (five weeks ago) I was called post haste to a barber shop here, to see a burly young man, aged eighteen—Gus Weber—who had been taken suddenly ill in the Piano Manufacturing Company's Works. He was so seriously ill that he could not be removed six or eight blocks to his home, but was dropped in at a relative's in this barber shop. He was suffering extreme pain, so that he could scarcely speak, and when I asked him where his trouble was he simply planted his hand over his right groin. Some of the shop hands who accompanied him asked if it was not appendicitis, and my own *alter ego*, like *Gobbo* and *Bottom* and the rest of Shakespeare's witty fools, kept whispering to me: "Stuck, at last; go home and get your cutting-machines." But I did nothing of the sort. I ordered folded towels dipped in boiling water to be applied to the seat of the pain, and three powders, five grains each of calomel and soda, given one every hour. I made five hourly calls that evening, and at six o'clock next morning this patient opened the barber-shop door to let me in. He was all right.

At 9 P.M., October 12th, I was called to see a boy, aged thirteen. The young man who called me stated that he was a medical student past eighteen months and was the son of a physician. He said this boy was very ill, either with typhoid fever or appendicitis—he could not make out which—and begged me to do my very best for him. The boy had high fever, rapid pulse, and severe pain, extending from the liver down to the right groin. I ordered two powders, each containing two and one-half grains each of calomel and soda, one to be given at once, the other an hour later, and that a report of his condition be sent me next morning. At 8:45 next morning the boy himself called on me, to know if he could go to school that day.

My neighbor, Mr. Gilmore, states that his son had appendicitis, and consulted separately Drs. S—— and H——. Each stated emphatically that he must be operated on, and each went so far as to state the fee—$100. The young man, however, did not take the advice of these surgeons, but consulted Dr. N. S. Davis, Jr., whose treatment cured him without operation. Why should not medical treatment cure inflammation of this organ as well as that of any other organ? Do we remove all inflamed organs? If not, why this one?

Let me quote, from the *Medical Times*, Dr. Terry's medical treatment for appendicitis: "Dr. M. O. Terry, surgeon-general of the national guard of New York, advocates the use of oleaginous cathartics for the treatment of appendicitis, declaring that of fifty-one cases under his personal supervision forty-nine were successfully handled without operation. This treatment is as follows: At first cathartics of castor oil and sweet oil followed by hot water are given, until the bowels are thoroughly cleaned out. This treatment is followed by enemas of glycerin and sweet oil. Flaxseed poultices soaked in sweet oil are kept on the abdomen. The diet is restricted to very light, easily digested foods. The oil treatment, Dr. Terry says, removes the friction of the inflamed tissues and relaxes them during resolution. In this way, he says, he has cured cases of chronic recurrent appendicitis. To prevent a return of the trouble, after the original treatment he prescribes a tablespoonful of sweet oil followed by a glass of hot water before each meal for several weeks."

Evidently Dr. T. J. Happel, vice-president of the American Medical Association, is also like-minded with me on this question. I quote from his article, entitled "Fuss, Feathers, and Foolishness," which appears in *Leonard's Illustrated Medical Journal* for October, 1898: "At the outset I would disclaim any personalities or intention to ruffle in the least the feelings of any one, but offer the paper with the hope that it may serve as a balance wheel for a machine that for the last few years has been going, as I believe, at a breakneck speed. . . . The operation for appendicitis still has its headquarters in ——. Any case of colic or bellyache occurring in a pauper, if picked up in the streets, is at once transferred to the —— Hospital, and as soon as the patient can be boiled and cleaned with bichloride he is placed upon the operating-table and the useless appendage removed. If he recovers, all right—a record is being made; if he dies, there is one pauper less in the city and the operation is not counted. The favorable record must not be broken by counting this one fatal case."

And again: "The pell-mell rush into the field of specialism by half of the college students of the day accounts to me in a satisfactory way for much of the present state of affairs. Many . . . desire to enter upon the field of surgery . . . forgetting and ignoring the fact that a knowledge of general medicine is necessary to and must precede the successful prosecution of specialties. . . . The specialists in abdominal surgery, more than in any other line, have been looking more to making records than to the pathological condition of the cases brought before them; and too many [patients] have been subjected to the cold argument of a sharp knife, more than can be justified by any course of ratiocination."

Acute Urethritis in the Male.—From a specially conducted experience with potassium-permanganate irrigations I would conclude that while the duration of the discharge is thereby limited, and the evidences of the inflammation are rapidly reduced, the ultimate recovery of the mucous membrane is not only not hastened, but its course is not spared the usual disappointing relapse.—JAMES PEDERSEN.

ELECTRICITY IN DEAFNESS AND STRICTURES OF THE EUSTACHIAN TUBE.[1]

By ROBERT NEWMAN, M.D.,

NEW YORK,

CONSULTING SURGEON, HOME IN YONKERS, HACKENSACK HOSPITAL; EX-PRESIDENT, AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION, ETC.

If specialists had a sure cure for chronic middle-ear diseases with deafness, this paper would not have been written. The usual routine of aurists keeps some patients deaf who would be benefited, perhaps cured, if electricity had been employed.

In the month of April, 1868, I had a patient, Mrs. M. C——, widow, who had been deaf for eight years. Several aurists of the highest standing found deafness due to cartilaginous growth over the left tympanum, etc. The routine treatment did not improve her condition. The writer was then induced by Dr. Neftel to give galvanism, which improved the hearing considerably, so that the patient could hear all noises and music in the street and conversation carried on only a little louder than normal. While she never was cured, yet she was made entirely comfortable, and on bright, clear days could hear very well.

In February, 1874, she had a pain at the lower part of the humerus, in the bone and muscles.

March 27th. At the dinner table, without anybody touching her, she felt a snap on the arm, and a distinct loud sound was heard by everybody at the table. One hour later the writer saw the patient and found a complete fracture of the humerus, which diagnosis was verified by authorities. Union and recovery took place in due time. She has had several ailments during several years, and could hear pretty well.

About 1890 the deafness increased, and as she had not had treatment it grew worse, so that in 1896 she was almost as deaf as years ago.

In 1897 she grieved about the death of her daughter.

In April, 1898, she came again for treatment for aneurism of the brachial artery, with distinct calcification and atheroma. External galvanic applications, particularly over the calcifications, absorbed the latter and improved the circulation. She has not come regularly for treatment, but is materially benefited; she is not cured, and never will be. Galvanism has ameliorated her deafness, so that for over twenty years she was comfortable, but at the present time she is very deaf again.

Deafness Improved by Galvanism.—Many years ago the writer used galvanism in different stages of deafness, and always on patients who were not benefited by specialists; in fact, they were told that they were incurable. In some instances such patients told the specialist that the writer treated them with electricity, and received generally the answer that electricity probably would not hurt them; they might be amused by it. Those specialists were my friends! Patients were always benefited by the galvanic applications, and some very much improved. As all the patients were under treatment for other ailments, and the deafness was treated only as an intercurrent malady, no regularly detailed notes were kept; but it is certain the electricity benefited, though given in an experimental manner. All these cases were treated during the period of 1868 to 1874, and are mentioned here only to show that electricity is a therapeutic measure which should be cultivated by specialists. Progress has been made gradually, and many benefits in the treatment of deafness have been originated by the efforts of members of this society.

Dr. Edward C. Mann has reported the treatment of blindness and deafness resulting from cerebro-spinal meningitis,[1] a disease generally considered incurable. He believes that in the constant current we have a means more powerful than any other of modifying the nutritive conditions of parts that are deeply situated. I believe that the results of our investigation in this direction will lead us to be able to class blindness and deafness resulting from cerebro-spinal meningitis among the curable forms of diseases of the nervous system.

From Vienna I hear from Dr. H. L. Morse that electricity is used there for the relief of tinnitus. A weak current of galvanism is used, sometimes followed by the faradic induced current. The results vary. Urbantschitsch uses electricity for otalgia.

Hysterical Deafness.—This form has been cured by electricity. Cases have been published by M. Ouspenceky, of Moscow,[2] in the *Annales des Maladies de l'Oreille*. The electrical examination and diagnosis of the ear have been treated by our fellow, Dr. W. F. Robinson, in section B, page 56, in the "International System of Electro-Therapeutics." Cataphoresis in labyrinthine deafness has been used by Dr. Gagney of London,[3] and reported November 7, 1889, at the Harveian Society. He used Lugol's solution. Nervous deafness has been successfully treated by Erb, Brenner, and De Watteville, by excitations of the auditory nerve by galvanism with interruptions.[4] Automatic instruments of electricity have also come into existence. Dr. Henry C. Houghton, of New York, has constructed one, and has described it in a paper, "A Phono-Faradic Massage Battery for the Treatment of Aural Cases."[5] Mechanical massage by electricity is indicated in thickening of the drum, partial paralysis of the nerve, or ankylosis of the ossicles, etc. A weak faradic current will help to break up the adhesions between the ossicles in subacute catarrhal otitis media, a disease very difficult of treatment.

Deafness from Strictures of the Eustachian Tube.—As strictures of the Eustachian tube are formed in a manner similar to that producing stricture of the urethra, it is very plausible that they should be cured by electrolysis, like other strictures formed after chronic inflammations. Others have argued to the same effect and made cures accordingly. In a paper read in Brooklyn at the first meeting of the fifth district branch of the New York State Medical Association, October 13, 1885,[6] the writer mentioned cases of M. Mercier and M. Garricon-Desarines.[7] Their operation consists in passing a fine silver sound into the Eustachian tube and a small olive-shaped electrode into the external auditory meatus. A feeble current is then passed, the sound is gradually pushed on, and the stricture disappears.

In 1890, while I was in London, Dr. W. E. Steavenson communicated to me his treatment of Eustachian obstructions at St. Bartholomew's Hospital. This he conducted in collaboration with the aural surgeon, Mr. Cumberbatch. The first seven cases were reported[8] in Steavenson's "Electrolysis in Surgery," and the writer has mentioned these cases in his section M, page 46, "International System of Electro-Therapeutics." The operation had then been performed a large number of times without any unpleasant experience; nor had the treatment anything more than very temporary discomfort for the patients. In those cases in which the deafness has been due to a simple obstruction of the Eustachian tube, the results have been most encouraging.

Other electro-therapeutists have followed, and it is pleasant to state that some specialists use now with success electrolysis in stricture of the Eustachian tubes. Among the latter is particularly Dr. Arthur B. Duel, of New York, whose report has been mentioned in several journals. It may be of general interest to quote from an article in the *Journal of Electro-Therapeutics* of March, 1898.

"Dr. Arthur B. Duel says that one of the chief causes of deafness and tinnitus aurium is the narrowing of the lumen of the Eustachian tube by hypertrophy of the submucous tissues surrounding it, thereby preventing the maintenance of the normal air pressure behind the tympanic membrane. He recommends the following method: For the purpose of conducting the current he has had four copper bougies, varying from No. 3 to No. 6 (French scale), mounted on No. 5 piano wire. These are passed through small, insulated, pure silver catheters, and drawn back until the bulging portion of the bougie fits tightly in the mouth of the catheter. The other end of the wire is fastened an inch and a half from the funnel-shaped end of the catheter to the handle, which connects it with the negative pole of the battery. The positive pole is connected with the patient's hand by means of an ordinary contact electrode. The battery should be supplied with a perfect rheostat and milliampere meter. The bougie is passed through the tube in the usual manner, the tip being pushed forward until it is felt to be obstructed by the stricture. The current is then slowly turned on until from two to five milliamperes are used. It is never necessary to use more than this, and probably the best results are obtained by a longer contact with a small amperage than *vice versa*. After a contact of from two to five minutes, the bougie is felt to pass on through the softened stricture with a slight pressure. The bougie is then slowly withdrawn and the current gradually turned off before the catheter is removed. The current should never be opened or closed suddenly."

The whole procedure of Dr. Duel's is very sensible, arranged according to the rules of aural surgery and the laws of electro-therapeutics, and meets fully the writer's rules for the application of electrolysis in the treatment of strictures. Reports say that Dr. Edward B. Dench, aural surgeon of the New York Eye and Ear Infirmary, also uses electrolysis with success in strictures of the Eustachian tube. Statistics could not be procured directly, as the doctor was in Europe when this paper was written. Sometimes patients have been sent to the writer for the treatment of Eustachian obstructions by electrolysis, who have had professional care by the best specialists in the country, without success. Knowing how difficult such cases are to handle, and not being a specialist for ear diseases, in some cases I have had the assistance of Dr. Edward S. Peck, of New York, who has taken part in these operations and helped to devise a new instrument. We have had considerable success, and the details of a few cases will be given here for illustration.

Case I.—December 30, 1894. Mr. J. E——, aged thirty-five years, was sent to me from Chicago by Dr. Nieswanger. He was almost deaf; had been suffering from catarrh for a long time. Five years ago he began to feel that hearing was a little impaired, first on the right side. An excellent specialist of St. Louis examined him and made the prognosis that the hearing would grow gradually worse. He had a musical education, and could distinguish discords in singing or on musical instruments. Hearing became gradually worse, and unpleasant noises in the ears troubled him. One year ago an authority in New York had found on examination that the anatomical relation of the ears were normal, but hearing nevertheless was much impaired; no treatment would cure or improve him. He had been treated in Hot Springs and other localities in various ways. Operation on the turbinated bones improved breathing; galvano-cautery and inflation by Politzer's method, however, did not help at all. He still had catarrhal discharges and his hearing was much impaired. The left nasal canal is smaller than the right; partial deafness is greater on the right side.

December 31st, Dr. E. S. Peck made a careful examination in consultation with me. We found the relations of the ears normal; the passages, however, were full of catarrhal secretions, and there were strictures in both Eustachian tubes.

January 2, 1895. Electrolysis in right Eustachian tube. The catheter was introduced till arrested by the stricture and then connected with the negative pole of a galvanic battery. An electrode pad in the hand was used as the positive pole. The current, from two and one-half to three and one-half milliamperes, was used for five minutes, during which time the movable point of the catheter advanced four-tenths of an inch in the stricture. No unpleasant symptom was experienced.

January 4, 1895. Patient considered his hearing improved. Electrolysis was used in the right ear in the same manner as before.

January 6th. Electrolysis repeated. Right ear, five milliamperes for six minutes; the movable electrode advanced three-tenths of an inch. Left ear, four milliamperes for three and one-half minutes; electrode advanced four-tenths of an inch. Patient felt better and had no unpleasant symptoms. After two more *séances* the patient felt so much improved that on account of urgent business in Chicago he left for home. The time allowed was too short to expect an entire cure, but he felt content with the improvement, and all that could be learned afterward was favorable.

For future use we constructed an improved electrode, which may be described as follows: The instrument consists of a hard-rubber Eustachian catheter, shortened one inch. Of course the hard rubber is an insulator. Through the hollow tube is inserted a metal electrode, the end emerging from the open catheter as a small egg-shaped bulb or olive, like the bulb in the writer's electrodes for the urethra. From the exterior end of the catheter emerges a conical cylinder, which is divided into ten equal rings, each representing one-tenth of an inch. On the outer side is a binding screw, for the attachment of the rheophore to the negative pole of the battery. The rod can be pushed forward by one-tenth of an inch at a time to one full inch, so that when the rod is pushed inside the catheter the whole instrument is just as long as any Eustachian catheter; the one-inch conical piece making up for the one inch taken off the catheter. The *modus operandi* is similar to the treatment of an urethral stricture. The catheter is introduced into the Eustachian tube with great care, till the stricture arrests its progress. When it is attached to the negative pole of the galvanic battery the patient takes in his hand as a positive pole a moistened pad or handle. The current is from zero very slowly increased, according to the toleration of the patient, but as a rule should not be stronger than five milliamperes. The operator very gently guides the inner tube as the electrode, and pushes it forward only when the electrolytic current has absorbed the obstructions, and must never do too much in one *séance*. Undue force must never be used; the electrolysis must do the work of absorption. The milliampere meter is a necessity. The current must be steady, slowly increased, and before removal of the catheter slowly decreased to zero. Otherwise all rules should be observed which the writer has given for the treatment of urethral strictures by electrolysis. Another case will demonstrate the details and progress of the treatment.

Case II.—Twelve years' aural catarrh, two years'

deafness. November 9, 1897. Mrs. J. M——, aged forty years, married, has had catarrh for twelve years, for which she has been treated off and on. Hearing has been affected, but the real deafness is two years old. She has been treated in the South, in St. Louis, and in New York by very competent authorities, in the regular routine manner. She complained of much trouble from dyspepsia, meteorism, poor appetite, and getting tired easily. The bowels were somewhat constipated; the tongue was clear.

Consultation with Dr. E. S. Peck, who examined and treated the patient together with me. A.D., watch heard feebly in all regions; A.S., watch heard much better in all regions. Slightly loud-spoken voice at six feet and for right ear the same at three feet.

November 19th. Electrolysis. Eustachian catheter inserted as negative pole; positive electrode, pad in hand. Five milliamperes for five minutes, during which time the electrolysis advanced the catheter four-tenths of an inch.

November 21st. Electrolysis by Eustachian catheter as negative pole; positive in hand. Five milliamperes for five minutes; advanced six-tenths. Electrolysis to left side of Eustachian tube. Positive pad behind mastoid. Three milliamperes for four minutes; catheter advanced four-tenths. A.D., voice slightly raised at two and one-half feet. Cutaneous surface very sensitive to the electric current.

November 23d. A.D., Eustachian catheter, five milliamperes for five minutes; six-tenths. A.S., Eustachian catheter, six milliamperes for five minutes; two-tenths.

November 25th. General galvanization. Positive in hand; negative behind ear and over mastoid; five milliamperes. Skin very sensitive. Five milliamperes reddened skin, caused a metallic taste, and only a fraction of a milliampere caused dizziness.

November 26th. Electrolysis with Eustachian catheter as before. A.D., six milliamperes for six minutes; seven-tenths. A.S., six milliamperes for four minutes; two-tenths.

November 28th. A.D., electrolysis, Eustachian catheter. Eight-tenths in five minutes; five milliamperes. A.S., electrolysis, Eustachian catheter. Three-tenths in four minutes; five milliamperes.

November 30th. A.D., electrolysis, Eustachian catheter. Nine-tenths in five minutes; five milliamperes. A.S., electrolysis, Eustachian catheter. Three-tenths in four minutes; five milliamperes.

December 3d. A.D., electrolysis, Eustachian catheter. Ten-tenths in five minutes. A.S., electrolysis, Eustachian catheter. Seven-tenths in five minutes.

December 5th. A.D., electrolysis, Eustachian catheter. Ten-tenths in five minutes; six milliamperes. A.S., electrolysis, Eustachian catheter. Seven-tenths in five minutes; five milliamperes.

December 7th. A.S., electrolysis, Eustachian catheter. Eight-tenths in five minutes; five milliamperes.

December 15th. A.D., electrolysis, Eustachian catheter. Ten-tenths in five minutes; five milliamperes. A.S., electrolysis, Eustachian catheter. Seven-tenths in five minutes; five milliamperes.

December 19th. A.D., electrolysis, Eustachian catheter. Ten-tenths in six minutes; six milliamperes. A.S., electrolysis, Eustachian catheter. Eight-tenths in six minutes, five milliamperes.

December 24th. Electrolysis, Eustachian tube advanced on both sides to its full length. Ten-tenths in six minutes; with six milliamperes.

December 29th. Electrolysis as before; on both sides full length. Ten-tenths of catheter.

During January, 1898, the same treatment was continued and eight *séances* were held. When the patient went home she was very much improved. The strictures of the Eustachian tubes have been cured by electrolysis, but the patient suffers from other ailments in the auditory anatomy, which specialists have not removed.

The object of this paper was: 1. To show that electrolysis can cure strictures of the Eustachian tube. 2. To induce the profession, and particularly the aurist, to add electro-therapeutic measures to the treatment of the ear in deafness, and particularly when other means will not cure.

A CASE OF PRIMARY TUBERCULOSIS OF THE CERVIX UTERI.

By FRANK S. MATTHEWS, M.D.,

NEW YORK.

Since the publication of the work of Williams[1] and of Penrose and Bryen,[2] much work has been done and many articles have been written to show the frequency of tuberculosis of the female genital tract. Williams' investigations showed eight per cent. of all tubes removed for inflammatory disease to be tuberculous. Penrose and Bryen, in a routine examination of all tubes removed by them for inflammatory disease, found nine cases of tuberculosis of the tubes in fifty-two cases, or seventeen per cent. A fact to which they call special attention is that in a large percentage of their cases neither from the clinical history nor from macroscopical appearances could a diagnosis of tuberculosis be made.

Tuberculosis of the endometrium is also encountered in a considerable number of cases. In most of them the process has extended to the endometrium from the tubes. In a small number of cases the tuberculosis is primary, so far as the genital organs are concerned, in the endometrium. But whether the uterine mucosa be involved primarily or secondarily, the cervix uteri very often escapes the infection. It has been suggested that the solutions of continuity occurring with menstruation and labor render the body of the uterus more prone to tuberculous infection than the cervix. A number of cases, however, have been reported, in which the cervix uteri was primarily infected. J. D. Williams[3] reports two cases. Emanuel[4] and E. Frankel[5] each report a case. In all of these cases there were extensive tuberculous lesions in distant organs.

Brief reviews of these cases may be found in the volume on "Tuberculosis of the Genito-Urinary Organs," by Nicholas Senn.

More recently a case has been reported, in which the lesion in the cervix was the sole tuberculous one. The following review of the case is taken from the *Centralblatt für allgemeine Pathologie u. pathologische Anatomie*, October, 1898.

"E. Kaufmann:[6] Autopsy on a woman, aged seventy-nine. The cervix was eroded, showing infiltrated growth with necrosis of tissue and formation of polyps.

"Microscopical examination showed epithelioid and giant cells, with granulation tissue and cheesy degeneration. Tubercle bacilli were demonstrated. The autopsy showed this to be a case of primary isolated tuberculosis of the cervix uteri. The uterine body was small. The tubes, ovaries, and lymph nodes were normal."

We add the following case of tuberculosis of the cervix, with, so far as could be clinically determined, no other tuberculous foci. In spite, however, of absent clinical evidence, the probabilities would be strong of the existence of other foci.

E. H——, negress, single, aged twenty-two years. The patient was admitted to Roosevelt Hospital, service of Dr. George M. Tuttle, April 18, 1897. She menstruated first at fifteen, at first irregularly; later every three weeks. The duration of flow was one day, and it was scant. There was considerable dysmenorrhœa. She was never pregnant.

Present illness: Dysmenorrhœa has been increasing for the past three years, and during the same time she has suffered from colicky hypogastric pains. She has a profuse muco-purulent and blood-stained discharge. She now suffers from headache, backache, and lack of energy. The bowels are costive. Temperature, 99.6° F.; pulse, 90. Urine, acid; specific gravity, 1.023; contains a faint trace of albumin.

Examination: The cervix is large, worm-eaten, and its cavity is excavated. It bleeds easily. The growth has extended to the vagina and involved it, especially on the anterior wall. The left tube and ovary are easily felt and appear normal. The right appendages are slightly enlarged. The broad ligament is thickened. The fundus is enlarged and movement restricted.

On April 26th, under ether anæsthesia, the ovaries, tubes, and uterus, together with the diseased portion of the vaginal wall, were removed by vaginal hysterectomy. Previous to the hysterectomy the cervical cavity was curetted and packed with gauze. The broad ligament was ligated with catgut. Adhesions were found between the appendages and intestines. The pelvic cavity was packed after Mickulicz's method.

Convalescence was retarded by a severe secondary hemorrhage on the following day.

May 2d, the wound was free from infection.

May 6th, the sinus was two inches deep.

May 20th, the patient was allowed up.

May 31st, a granulating spot appeared at the vaginal vault.

June 14th, the patient was discharged healed.

Pathological report: The broad ligaments are thickened; ovaries, small and adherent; the right tube is distended to above the size of a lead pencil; left tube of normal size. The uterine body is not enlarged. Its cavity contains a dark bloody material. The cervix is enlarged to at least twice its normal size, and contains a cavity as large as a hickory nut—the result of curetting as a preliminary step to the hysterectomy. The mucous membrane of the vagina adjacent to the cervix and removed with it is deeply ulcerated.

Microscopical examination shows the interior of the cervix to be the seat of a diffuse tuberculous inflammation. There are tubercle tissue, cheesy degeneration, and giant cells. Deep in the muscular wall of the cervix there are discrete miliary tubercles. The broad ligament shows œdema and moderate exudative inflammation, but no tubercle. The body of the uterus has a slightly enlarged cavity distended with blood and débris. Its mucous membrane is thinner than normal and almost entirely destitute of glands. The epithelial lining is fairly well preserved, and there are no evidences of tubercle above the internal os. The right tube shows a similar condition—a cavity distended with blood and débris, a mucous membrane whose folds have disappeared at its inner end and whose lining epithelium is well preserved. The right tube and ovary contained no tuberculous lesions. The left tube, which was not preserved for microscopical examination, was said not to have been enlarged and distended, as was the right.

77 West Fiftieth Street.

Amyl Nitrite in Diabetes Insipidus.—Dr. Ernest F. Clowes, house physician of the Royal County Hospital, Winchester, reports the successful treatment of diabetes insipidus with this drug. There was a gain of ten pounds in weight.

PRELIMINARY COMMUNICATION ON THE BIO-CHEMISTRY OF THE BACILLUS TUBERCULOSIS.[1]

By PHOEBUS A. LEVENE, M.D.,

Associate in Physiological Chemistry, Pathological Institute of the New York State Hospital.

After the certain specific microbes for different diseases were found, the question arose, How do they produce the disease? And the chemical theory was to become the prevailing one. The microbes are not simple parasites that are robbing an organism of its nourishment; they are attacking by means of poisons —toxins. What is the nature of those toxins? Where do they originate? were the next questions of pathologists.

The products of metabolism of the micro-organisms were the first to attract attention of students, and a number of toxic substances of different chemical natures were soon discovered among them.

Soon, however, facts were established which showed that the body substance of micro-organisms is toxic *per se*. Thus Wissokowitz found that the substance of anthrax bacillus produced abscesses. Buchner saw the same effect of the pneumo-bacillus. But most interesting and striking were the observations of Professor Prudden and Dr. Hodenpyl, that the dead tubercle bacilli are able to produce in the organism of animals formations very similiar to those in ordinary tuberculosis. The same experiments were then repeated by Straus and Gamaleia and by a good many investigators in Germany, and the main conclusions were corroborated by all the authorities.

This fact being established, the next question was, what chemical part of the micro-organism was it that was toxic? Buchner was first to answer the question *a priori*, naming the proteid matter of the micro-organism as the cause of their toxic effect. But if so, why do only these proteid bodies, in distinction from all other proteids, possess such a peculiar action? Are they different in their chemical nature? Nencki and his students were the first to investigate the question, and they found some substances of proteid nature that differed considerably from all other proteids, and which they called mycoproteids. But the methods they employed were such as would change the true nature of any proteid, and their conclusions leave enough room for objections. The opinions of later workers were contradictory to those of Nencki. Of all of them, however, only very few succeeded in obtaining true genuine proteids from the body substance of bacteria. Hellmich, in Franz Hoffmeister's laboratory, was the first to obtain a coagulable proteid from a water bacillus, and later Hoffman precipitated by means of alcohol a proteid from the water extract of tubercle bacilli.

Nishimura in Rubner's laboratory was investigating the nature of the nucleins of microbes, but failed to extract the nuclein itself and had to limit his work to the products of their decomposition, the nucleobases. This work was important, in so far as thereby to establish the fact that by the nature of their nucleins the bacteria do not differ from any other living cells. Finally Gileo-Galeotti succeeded in extracting from different bacteria, by means of weak alkali, a nucleo-proteid with one per cent. of phosphorus and twelve per cent. of nitrogen.

It was our task to examine the chemical and toxicological nature of the proteids of tubercle bacilli, and this work, the result of which I intend to report briefly, was carried out during the past summer in the Saranac laboratory of Dr. Trudeau, in collaboration with Dr. E. R. Baldwin. Our first aim was to use

[1] Read before a meeting of the New York Pathological Society, on November 9, 1898.

such methods in our work as to attack the original nature of the body substance as little as possible. Further, in order to be certain that the proteids that we were to obtain were not contaminated with those of the media, we used mineral media, taking for the necessary supply of nitrogen to the bacilli asparagin, and for the carbon supply mannite and glycerin. The growths were transferred directly from the flasks on a suction funnel, the culture media filtered off and the residue was washed several times with very small quantities of water. It was then dried in vacuo over sulphuric acid, to dryness. The dry bacilli were then weighed and placed in a porcelain mill and left there to be ground for two or three days. The object of grinding the bacilli was the same as Koch's, namely, to crush as much as possible the membrane of the micro-organism and thus facilitate extraction. We must, however, remark that, even after prolonged grinding, we never succeeded in total disintegration of the bacilli, and we could always find in the test specimens numbers of tubercle bacilli taking their usual stain. The very fine powder obtained after grinding was extracted with eight per cent. of ammonium chloride solution for about two days. To avoid contamination as much as possible, the flask was always kept sealed with chloroform. The extraction was then repeated several times, and the extracts were analyzed.

It proved to contain three different proteid substances of the coagulation points: 50–64° C.; 72–75° C.; 94–95° C.

These proteids differ further in their relations to neutral salts.

1. Thus, fifty per cent. of magnesium sulphate will precipitate only the first one, and eighty-five per cent. of the same salts will complete the precipitation of the first proteid. Magnesium sulphate to saturation precipitates the second proteid, but does not precipitate the third.

2. Sodium chloride to saturation precipitates only the first one, leaving in solution the other two.

3. Ammonium sulphate precipitates all the three.

Their relations to acids seems also to be somewhat different, inasmuch as it requires less acid to precipitate the first proteid than the last; but on addition of hydrochloric acid diluted to 0.2 per cent. all the three proteids are precipitated.

In order to obtain each proteid in purity the following method would be advisable: Saturate the ammonium chloride extract with magnesium sulphate. The precipitate will contain the first and second proteids, the filtrate the third (Solution A). Wash the precipitate with fifty per cent. of magnesium sulphate; the first proteid will remain insoluble, the second in solution (Solution B). Saturate this solution (Solution B) again with magnesium sulphate and wash repeatedly with eighty-five per cent. of magnesium sulphate = proteid 2. Saturate the first filtrate with ammonium sulphate = proteid 3. Dialyze out the salts of each of the proteids and they will be obtained in purity.

The largest quantity we had for analysis was twenty drachms of dry material.

The magnesium sulphate precipitate was too small to separate the first two proteids one from another. The entire magnesium sulphate precipitate was then purified and tested for phosphorus with positive result.

The third proteid was obtained by means of coagulation, and proved to be much richer in phosphorus than the first two. Another point of difference between them was in the color reactions; the first two gave a positive Biuret's, while the second gave a negative one.

The residue of the ammonium chloride extract was freed of the greatest part of salt by repeated washing with water and then digested in pepsin with hydrochloric acid; the residue was filtered, washed, and extracted with 0.5 per cent. of aqua ammonia and the extract treated with diluted hydrochloric acid of about 0.1 to 0.2 per cent. A precipitate was formed. This precipitate gave xanthoprotein and Biuret's reactions. Part of it was treated for determination of bases, but the quantity was not large enough to separate the individual bases.

To sum up our results, we can say that the body substance of tubercle bacilli does not contain any proteids of the albumin nature; that as the nucleus of cells it consists mostly of nucleoproteids; that one of the nucleoproteids differs from all the other nucleoproteids inasmuch as it is not precipitated by magnesium sulphate (and in this point resembles nucleohiston), and does not give the Biuret's test; that it contains nuclein or nucleins as such.

Another point worth noticing and further investigating is the coincidence of the coagulation point of the first proteid and of the sterilization point of the tubercle bacilli; both are about 70° C. It would be very interesting to investigate other bacteria in the same direction.

I wish also to remark here that I tested the sample of tuberculo-plasmin prepared by Drs. E. L. Trudeau and E. R. Baldwin, after Buchner's method. The sample proved to contain only the first proteid.

The toxic effect of the different proteids we are not as yet ready to communicate. This part of the work is being studied at present by Dr. E. R. Baldwin.

We hope to be able to continue during the coming winter our studies on the chemical side, so as to be able to work up the quantitative composition of the different substances.

In conclusion I wish to express my sincere gratitude to Dr. E. L. Trudeau, who took great interest in the work. His private scholarship enabled me to carry out this very expensive investigation. Dr. E. R. Baldwin very kindly collaborated in the entire work, and I desire to express my thanks and indebtedness to him.

A CASE OF HODGKIN'S DISEASE TERMINATING WITH LEUCOCYTOSIS.

By HARLOW BROOKS, M.D.,

NEW YORK.

INSTRUCTOR IN HISTOLOGY IN THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; ASSOCIATE IN BACTERIOLOGY, NEW YORK STATE PATHOLOGICAL INSTITUTE; ASSISTANT CURATOR TO BELLEVUE HOSPITAL; PATHOLOGIST TO THE HARLEM CITY HOSPITAL.

The patient was A. F——, female, aged thirty-one years. She was born in Hungary, of Jewish parentage. She entered Bellevue Hospital on September 27, 1898, during the service of Dr. Nammack, to whom I am indebted for the following notes.

The condition of the patient was such that no previous history could be obtained from her, and the relatives were able to state only that the patient had been sick for a long time and that she had been treated at various city dispensaries.

"Physical Examination.—Patient was very poorly nourished. There was extreme subjective and objective dyspnœa. The expression was anxious; the lips were blue. There was great restlessness; skin cold and clammy; abdomen somewhat enlarged. The legs

were œdematous, and the inguinal and cervical glands enlarged.

"Lungs: Auscultation was difficult on account of loud fluid râles over the entire pulmonic area. The breathing and voice are broncho-vesicular behind, and the same but less in degree anteriorly. There is dulness on percussion over the posterior region.

"Heart: The apex beat is hardly visible, but on auscultation it is found in the fifth space, nipple line. There is a faint systolic murmur heard at the apex area. The pulse is rapid, soft, and weak. Considerable arterial change is evident.

"The liver dulness is increased, extending down to near the umbilicus. The inferior border is palpable and is found to be smooth and sharp. The area of splenic dulness is enormously enlarged, and extends down to the left iliac crest. Palpation shows the tumor to be smooth and regular in contour.

"The temperature was 101.2° F.; pulse, 88; respiration, 34.

"The urine was amber colored, cloudy; specific gravity, 1.023. There were granular casts and non-characteristic epithelial cells. There were no albumin and no sugar.

"The patient's distress and dyspnœa were controlled by means of morphine. The temperature varied from 100.5° to 102.7° F. She became very restless and noisy, and finally died on September 30th."

Some time after the death of the patient I found that, previous to her admission to Bellevue, she had been under treatment at one of the dispensaries, where several examinations of her blood had been made, and the two following blood counts were furnished me through the kindness of Dr. William Berkeley:

May 10, 1898: Leucocytes—polynuclear neutrophiles, 32.5; large lymphocytes, 41.5; small lymphocytes, 24.8; eosinophiles, 1.2.

May 12, 1898: Red blood cells, 2,900,000; leucocytes, 6,700.

The autopsy was made October 1, 1898.

The body is poorly formed, and it is more of the masculine than feminine type. The feet and ankles are œdematous. The thorax is bell-shaped. The abdomen is slightly distended. Emaciation is marked. The pupils are equally dilated. The skin, which is apparently very thin, is of a peculiar whitish-blue color. The mucous membranes are anæmic. Rigor mortis is absent.

Section.—The amount of panniculus adiposus is small, and it is of a grayish-yellow color. The marrow of ribs is light in color, but presents no particular gross abnormality. The lymph nodes along the course of the internal mammary arteries are enlarged somewhat. There are dense old adhesions of both pleural cavities. The pericardium shows thickened patches, especially over the right auricle and ventricle. The heart is enlarged. The left ventricle contains a small amount of post-mortem clot. The right auricle and ventricle are distended with a cast of ante-mortem clot. Both of the right chambers show evidences of considerable long-standing dilatation. The heart muscle is fairly firm, but it is somewhat elastic and of a light-brown color. The aortic segments are slightly thickened; otherwise the valves of the heart are in a very normal condition, save that the orifices are in general distended. The coronary arteries show a moderate thickening of the intima. Otherwise the examination of the heart is negative. Weight of heart, thirteen ounces.

The lungs are enormously congested posteriorly, while the anterior portions are emphysematous. The connective tissue is greatly increased throughout the entire lung structure, especially in the lower lobes. The right middle lobe shows complete atelectasis, apparently entirely due to the enormous increase of its connective-tissue elements. There is a calcareous nodule, one centimetre in diameter, situated in the left apex; it is surrounded by a dense capsule of connective tissue, and is the only lesion which could be taken as of tuberculous origin in either lung. Certainly, then, the extensive fibroid changes are due to some other cause than a chronic or residual pulmonary tuberculosis.

The mucous membranes of the trachea and bronchi are congested, and the lumen of the tubes contains a considerable quantity of muco-purulent secretion. The thyroid gland is small, and its tissues show nothing abnormal. There are no abnormalities in the configuration or structure of the tongue, epiglottis, or larynx.

The lymph glands of the cervical chains, especially those located just at the root of the lungs, are greatly enlarged, sufficiently so to interfere to some slight degree with the normal lumen of the trachea and the larger bronchi; the peribronchial lymph nodes following into the substance of the lungs are also more or less enlarged. On section these enlarged nodes are found to be generally of a reddish-gray color, though some of the larger ones are more of a purplish hue, being moderately congested; still others show a quite extensive anthracotic pigmentation. The tissue of the nodes shows a very considerable interstitial increase, so that the cut surface of the gland is firm, and the substance is scraped off with difficulty. The nodes contain no necrotic or tuberculous areas, and the enlargement is plainly not of an acute inflammatory nature.

The capillaries of the peritoneum are congested, but the surface of the membrane is glossy and there are no evidences of acute inflammatory changes. The omentum is thickened and retracted. The mesenteric lymph nodes are enlarged, some to a considerable degree. Their structure presents the same characteristics as those already noted in the peritracheal nodes.

The liver is enlarged. It weighs six pounds six ounces. The capsule is thickened and opalescent; it has the appearance of being under tension, and when it is incised the liver tissue rolls out from the line of section. The liver tissue itself is firm and solid. The lobules are plainly marked, being of a yellowish-gray color, while the interlobular substance is congested and deep purple in its color. The paths of connective-tissue stroma are apparently considerably thickened.

The gall bladder contains about two hundred cubic centimetres of slimy, burnt-umber-colored bile. The duct is patent.

The spleen is greatly enlarged. It measures thirty centimetres in length, twenty centimetres in breadth, and has an average thickness of eight centimetres. The capsule is thickened and is under considerable tension. The tissue is very firm and is dark brown in color. The Malphigian tufts are not evident. The blood-vessels are very much congested, but the cut surface does not drip blood or serum. The splenic tissue is not easily removed on scraping the cut surface. Apparently the increase in size is mostly, at least, dependent on the great hyperplasia of the connective-tissue elements of the organ. The weight is four pounds ten ounces.

The pancreas is small and its tissue presents no evident pathological lesion, save that the lymph nodes along the course of the main artery are enlarged.

The adrenal bodies are small. They are deeply pigmented and the medulla is soft.

The kidneys are somewhat enlarged. The capsules are generally adherent. The cortex is thin and irregular. The medullary portions show a quite marked congestion, and the general color of the tissue is a purplish-gray, but in the cortical portions numerous

yellowish blotches are seen. The consistence is firm. The main branches of the renal arteries show a quite marked degree of arterio-sclerosis, and the smaller vessels show a marked proliferation of the surrounding connective tissue. United weight of the kidneys, ten ounces.

The ureters are natural.

The bladder is contracted, but contains a few cubic centimetres of purulent turbid urine. The cystic mucous membrane is greatly congested, and shows in places a loss of substance.

The stomach is dilated. It contains a small amount of fluid. The mucous membrane is greatly congested and in places atrophic.

The small intestine contains a soft fecal material. Its mucous membrane is generally congested, and the solitary follicles and Peyer's patches are enlarged, but not inflamed.

The caput coli shows no abnormality. The vermiform appendix is about of the usual size; it has a complete mesentery and presents no lesion. The large intestine is collapsed, and contains but a small amount of soft, normal fecal matter.

The ovaries are small and atrophic. Their gross structure shows no variation from the usual; recent ruptured follicles are not to be seen. The tubes and the pampiniform plexuses are normal. The uterus is small, measuring but six centimetres from fundus to cervix. The cervix presents the scars of an old stellate laceration. The arbor vitæ of the cervical canal is indistinct. The mucous membrane of the uterine cavity is anæmic and atrophic. The vagina shows nothing aside from ordinary atrophic changes.

The intima of the large arterial trunks of the abdominal and pelvic cavities shows a quite extensive arterio-sclerosis.

The retroperitoneal lymph glands are enlarged, and show the same changes already noted. The nodes situated about the saphenous opening are also enlarged to a considerable degree, but below this point the lymphatic enlargement appears to be very slight.

Anatomical Diagnosis.—Interstitial pneumonitis; hypertrophic nephritis; hypertrophic hepatitis; chronic lymphangitis and acute cardiac dilatation, the last named being probably the direct cause of death. The possible diagnosis of Hodgkin's disease was made, but was not substantiated until the microscopic examination had been made.

Microscopic Examination.—Lymph nodes: Sections of the enlarged lymph nodes show the enlargement to be due to a vast increase of the cellular elements of the tissue. The arrangement into cortex and medulla, seen in normal lymph glands, is obliterated, and compact masses of lymph cells are found filling the entire section. Mingled with the small mononuclear cells are found a good many cells, spherical in shape, about four or five times the diameter of lymphocytes, and containing a small round nucleus. The protoplasm of these cells is frequently loaded with coarse brown pigment granules. Vessels are very numerous in the sections, and they are, as a rule, packed with blood cells. In some, but not all, of the sections extravasations of red blood cells are found. All the sections show a very marked increase in the connective-tissue elements of the nodes.

Spleen: The sections of the spleen show the spaces normally found between the Malphigian tufts to be so infiltrated with lymph cells as to render the detection of the tufts almost impossible. The sections also show a considerable congestion of the blood-vessels and spaces. There are a great many young connective-tissue fibres seen everywhere throughout the sections.

Lungs: The sections show an enormous increase in the connective tissue, which has resulted in the complete obliteration of the pulmonic structure in large areas. In some places air vesicles are still to be seen, but with greatly thickened walls and filled by an exudate of cells, the cytoplasm of some of which is filled with pigment substance. Areas of lymph-cell infiltration are quite numerous, and are found in every part of the section. The numerous large blood-vessels which are included in the section are for the greater part filled with blood cells, among which it is seen that the white blood cells are in large proportion, and that of these the small mononuclears make up over fifty per cent.

Heart: The connective tissue of the heart is increased. The muscle cells are atrophied and their nuclei are irregular in shape and show occasional mitotic figures. The striation is quite evident in most of the cells, but the protoplasm in many contains a large amount of coarse brown pigment substance, which is found for the greater part in the immediate region of the nucleus. There are a few small areas of lymphatic infiltration, mostly located in close proximity to the blood-vessels. The vessels included in the heart sections show the same preponderance of the lymphocytes.

Liver: The liver shows an increase in its connective-tissue elements, though not of great degree, excepting in the immediate region of the interlobular structures, where the proliferation is much more marked. The liver cells are in general atrophied, and the cytoplasm of nearly all shows a parenchymatous and fatty degeneration. The nuclei of most of the cells are intact. Scattered throughout the sections, sometimes in the neighborhood of vessels and sometimes not, are found small groups or patches of lymph cells. These nodes are not surrounded by any evidences of acute inflammation, though the connective tissue in such areas is usually more increased than elsewhere, and is frequently seen to have a somewhat capsular arrangement. The blood-vessels found in these sections show a great proportionate increase of the leucocytes, with the lymphocytes in by far the greatest preponderance.

Pancreas: The stroma of the pancreas is moderately increased, and a few patches of lymphoid infiltration are found in it; otherwise the structure appears to be normal.

Kidney: The kidney sections show an extensive parenchymatous degeneration of the cells of the convoluted tubules. In many places this is combined with a fatty degeneration of considerable degree, and the cells of a good many of the tubules are almost completely destroyed, the lumen of such tubules being filled with cell débris. There are a few small patches of lymphoid infiltration in the neighborhood of the columns of Bertini, but they are neither numerous nor particularly characteristic. The perivascular connective tissue shows a moderate hyperplasia. The blood-vessels here show the same picture as those already described in the other viscera.

The extent of the post-mortem investigation was somewhat restricted by the demands of relatives, and as the autopsy was not obtained until twenty-four hours after death, when post-mortem infection might have become extensive, no bacteriological examination was made; hence the case is of no importance, in so far as tending to prove or disprove the very probable infective theory of the causation of Hodgkin's disease.

The case represents a fairly typical one of the disease, though the involvement of the viscera by the lymphatic infiltration is of rather less degree than I have seen before in cases presenting so marked an anæmia, and so extreme symptomatic manifestations of the disease as did this case.

The symptoms present just before death, and the mode of death, together with the general pathological

findings, seem to be those commonly present in the condition.

The chief point of interest presented by this case is the fact that the diagnosis of Hodgkin's disease was made on May 12th, when the glandular enlargement was already quite pronounced, on the sole differential point between Hodgkin's disease and leukæmia, that the number of leucocytes present in the blood at this time was not above the normal, and that the relative proportions of the leucocytes one to another was practically normal. Yet in the arteries examined after death it was found that a considerable lymphatic leucocytosis was present, which must have developed between the date of the last blood examination and the time of death. It is to be very much regretted that no blood examination was made when the patient first entered our wards at Bellevue, but circumstances were such at the time as to preclude this, and as death took place before it was expected this important link in the history was lost; nevertheless the pictures presented in the sectioned blood-vessels seem to render the presence of a small, mononuclear leucocytosis beyond question.

Cases of Hodgkin's disease terminating with leucocytosis are not so very uncommon; instances are reported by Troje, Cohnheim, and many others, who then conclude that since leucocytosis is sometimes or even often found as a symptom of Hodgkin's disease, it is hardly logical to consider Hodgkin's and lymphatic leucocytosis as distinct conditions.

The general symptomatic and pathological manifestations of the two diseases are the same, and an absolute differentiation on the single and variable symptoms of leucocytosis which may be present or absent in either, or present at one time and absent at another, is far from logical.

Lympho-sarcoma is now quite commonly thought to be but a more active and virulent form of the same general disease of which we consider Hodgkin's to be a type; indeed, it seems very proper that Hodgkin's disease, lympho-sarcoma, and lymphatic leukæmia should all be classed as one disease, differing one from another only in the prominence given to some symptoms or set of symptoms. Accepting the unity of these processes, as many do, it would seem well to apply to the general conditions the name—first, I think, used by Trousseau—of "adenie."

THE ETIOLOGY OF GENERAL PARESIS.[1]

By WILLIAM STEINACH, M.D.,
ASSISTANT PHYSICIAN, WILLARD STATE HOSPITAL.

The name general paresis, or paralytic dementia, is given to a disease of the brain characterized by progressive dementia, with periods of exaltation or depression coupled with a gradually progressing weakness and a muscular inco-ordination.

The disease has often been regarded as of comparatively recent origin. However, indistinct descriptions of the disease appear in the writings of Willis as far back as 1672, and subsequent authors, as Haslem in the beginning of the present century, as well as Pinel, Esquirol, and Georget, described the disease with more or less distinctness. To Bayle, who in 1822 clearly described the condition, however, belongs the honor of having discovered the disease, if such a term may be applied to a recognition of a condition as a clinical entity which previously had been shrouded in obscurity. Parachappe in 1838 went so far as to regard the condition as a distinct form of insanity. Previous observers, while recognizing the clinical features of the disease, regarded the motor symptoms and dementia as complications arising in the course of any of the types of insanity; hence the name general paralysis of the insane, which it bears even to this day.

Forty years ago a case of general paresis was regarded as more or less of a rarity, while to-day it is one of the commoner diseases appearing in a hospital for the insane. The frequency of the disease varies considerably, according as statistics are taken from the cities or from the rural districts. It is estimated that from five to twenty per cent. of all admissions to hospitals for the insane are of paretics. Thus among 39,097 cases of insanity admitted to all of the State hospitals in New York, for the period from October 1, 1888, to September 30, 1896, there were 2,469 cases of general paresis, or about six per cent. of all admissions. This is, however, very much smaller than the actual percentage of paretics, because during the above period the county houses were cleared of insane; their population was mostly made up of terminal dements which had accumulated there for a number of years. Thus during the year ending September 30, 1896, there were admitted to all State hospitals of New York 5,563 patients, of whom 399 suffered from general paresis, or about seven per cent. of the cases. During the previous period of eight years there were admitted to the Manhattan State Hospital 12,596 patients, of whom 1,229 were paretics, or about nine per cent. In our own hospital at Willard during about the same period there were admitted 3,175 patients, of whom 87 were paretics, or only about two per cent., thus showing an overwhelming preponderance of cases in the city asylums as against those drawing their population largely from the rural districts.

That the disease is increasing as years go on is so self-evident that statistics are unnecessary. Where one paretic was admitted a number of years ago, a goodly proportion are now paretics. In the Charité at Berlin in 1891–92, Kraepelin reports that no less than 45.6 per cent. of all the men patients were paretics.

The sexes are very unequally liable to the disease, and it appears among men anywhere from three to five times as often as in women. During the period from October 1, 1890, to October 1, 1898, there were admitted to the Willard State Hospital 3,580 insane patients, of whom 1,753 were women and 1,827 were men. In this group there were 114 cases of general paresis, or 3.2 per cent. of all the cases. Of these there were 95 men, or 5.2 per cent., and 19 women, or 1.08 per cent., showing that in this neighborhood the disease appears to be about five times as frequent among men as among women.

The pathology underlying the disease, as will be brought out at length by a succeeding paper this evening, is a degeneration of the cerebral cortical cells, together with a new growth of connective tissue in the cerebral cortex and meninges, as well as more or less marked changes in the arterial walls. Bearing these facts in mind, we can sum up the causes of general paresis in any conditions which cause continued hyperæmia of the cortex, together with excessive and prolonged fatigue of the cortical cells. This condition of hyperæmia and exhaustion of the cerebral-cortex cells, when kept up for a long while, is very apt to give rise to the disease. In fact, all the causes which are credited to paresis have the above features in common. Of the 114 cases above enumerated, admitted to the Willard State Hospital, intemperance was assigned as a cause 29 times; syphilis, 14; insolation, 4; overwork, 3; worry, 3; trouble, 5; apoplexy, 2; and traumatism, 2. A variety of other causes were given in one or two cases, but were always conditions which cause great exhaustion of the system, as typhoid fever, imprisonment, gunshot wounds, etc. Regarding the occupations of those

[1] Read before the Willard Medical Society, Wednesday evening, October 12, 1898.

affected with general paresis we find that it generally affects those in the higher walks of life; all those whose occupation is such as to cause great worry or mental strain. Thus we find that those affected with the disease are mostly clerks, railroad engineers, merchants, brokers, lawyers, physicians, and others in the higher and better classes of society. It does, however, occur in the lower walks of life, but with these it is almost invariably associated with alcoholic or sexual excesses. We find that a goodly number of our patients affected with general paresis are locomotive engineers, and it is quite natural, as these are subject to great strain for long periods, without proper recuperation of the nerve cells.

Among 89 men affected with the disease, admitted to this hospital, 64 were married, 17 single, 6 widowed, and 2 divorced, thus showing that the disease is about five times as frequent among married men as among single ones. This is not to be wondered at, for there are about twice as many married men in the world between the ages of thirty and fifty, when paresis mostly occurs. And then, too, the conditions and stress of life fall more heavily upon married men than upon single ones. All of our women were married. In some places the statistics are different regarding the civil condition, and Kraepelin says that single persons are more often affected. Mickle, however, says that there is an overwhelming majority of married general paretics, and in 54,642 admissions 3.6 per cent. of the single and 12.1 per cent. of the married insane population were affected with general paresis.

Most cases of general paresis occur between the ages of thirty and fifty-five. It occasionally occurs in earlier life, and then especially around the period of puberty, and is apt to be in cases with strong hereditary taint, whereas in ordinary cases heredity plays but a very subordinate part. It has been observed quite young in life. Dr. Köhler, quoted by Mickle, says that he saw it in a girl, six years of age; Krafft-Ebing's and Régis' youngest subjects were twelve years of age. Kraepelin has occasionally seen it between the ages of nine and eleven, and Clouston's youngest subject was sixteen. Mickle's youngest was twenty-one years of age. Among women it occurs later in life and is apt to be of longer duration.

Of the relation of syphilis to general paresis the views of different writers are very discordant, some saying that seventy-seven per cent. of all paretics have syphilis, while others maintain that only eleven per cent. have it. In our own cases in the country, where syphilis is comparatively infrequent, we have it given as a cause in fourteen out of one hundred and fourteen cases, or in about thirteen per cent. Kraepelin found it in his experience in about thirty-four per cent. of the cases. Rieger maintains that a person infected with syphilis is sixteen or seventeen times more liable to the disease than are ordinary individuals. In this connection it may be stated that the majority of French alienists believe that syphilis is very infrequently the cause of general paresis. Régis, however, takes the side of the minority in France, and says that in his experience it occurred in from sixty to ninety per cent. of the cases.

Kraepelin regards general paresis as a disease of infective metabolism and the expression of a species of intoxication, and classifies it with disorders of metabolism. He says: "We have to do with a poison, which, from its extensive action, must circulate in the blood." From faulty metabolism and improper methods of life by-products are produced, which are poisonous and affect equally the ganglion cells with the muscularis of the arterial wall, which still further augments the mischief by causing irregular blood supply to the brain.

The vessels are very frequently found atheromatous, and also the kidneys, liver, and heart appear diseased in general paresis. It is after all but another expression of the same gouty or connective-tissue diathesis which appears in the brain and gives rise to cirrhosis of the liver, or kidney, or fibrous degeneration of the heart. All are due to the same kind of causes, and general paresis is no exception; and it is, indeed, found in the same class of cases. Looked at from this view, which appears very logical, it is simply a cirrhosis of the cerebral cortex.

With reference to its toxic nature, some little experimentation has been done. Abundo, an Italian alienist, in 1892 injected the blood of paretics into rabbits and found it to poison them. Kraepelin regards the disease as being of the same nature as myxœdema and diabetes, and likens the convulsions of paretics to the uræmic convulsions in kidney disease. Everything points to a strong similarity between general paresis and the intoxication brought about by the various poisons. While this may be a new idea, it certainly appears quite logical, and whether it is sufficiently founded on fact time alone can tell.

Progress of Medical Science.

A Case of Primary Purulent Inflammation of Both Suprarenals.—The patient, twenty-five years of age, married, was admitted to the hospital March 3d. She had had small-pox, typhus, and scarlatina in childhood. Her present illness began thirteen weeks previously with an attack of severe chills, reappearing at intervals for several days, and severe pain at the lower half of the right chest. The pain soon became constant, and extended to the right half of the posterior and lateral surface of the chest and to the upper extremity. There were also vomiting and loss of appetite. Present condition: A middle-sized, well-nourished woman, pregnant seven months. The sclerotics are slightly icteric. The skin also shows a yellowish discoloration. The pulse is small and accelerated. The respiration is accelerated and superficial. The skin of the right half of the chest is œdematous and so painful that the patient cannot lie on that side. The diagnosis was made of right-sided purulent inflammation of the pericellular tissue of the kidney. Operation showed the presence of pus in the region of the upper part of the right kidney, between the adipose and fibrous capsules. The patient aborted just after the operation and died within an hour. The post-mortem showed changes only in the suprarenals. Of these only the capsules remained. They were filled with very foul-smelling yellowish-green pus. Small portions of the suprarenals in the form of black masses were distributed throughout the pus. The kidneys were normal, with the exception of the above-stated accumulation of pus between the capsules. The writer considers the purulent degeneration of the suprarenals, primary in origin, a condition very rarely met with.—Janowski, M.D., *Gazeta Lekarska*, 14.

The Modern Cystoscope; Its Use in Bladder, Urethral and Kidney Lesions.—Dr. B. O. Coates (*Medical Times*, November), in an article on the above subject, makes the following statements: That the diagnostic range of the modern cystoscope is not confined to diseases of the bladder, but extends in many cases to those of the kidney with considerable exactness, is an established fact. Not only are we able with its help often to localize the seat of the trouble—"negative vesical evidence giving a positive diagnosis of renal disease"—but also to distinguish whether there be two "working kidneys," or whether

one or both be affected. It may be said that the cystoscope fails under certain conditions. To some extent this is true, but by keeping in mind three essential points necessary for its employment we may overcome difficulties to a great extent which would otherwise appear to obstruct its use. (1) It can rarely be passed without undue violence in patients with irregularly enlarged prostates and when the prostatic canal is very devious, as blood becomes smeared on the windows and mixed with the urine in the bladder. An ordinary enlarged prostate offers but little resistance. (2) In stricture of the urethra. This should be dilated or cut. If the meatus is too small to admit of a No. 22 French gauge sound, incise under cocaine with a blunt-pointed bistoury. (3) If blood or pus is sufficient in quantity to render the urine non-transparent, this may be removed by washing out the bladder with distilled water, or, better, a boracic solution, and refilling with distilled water. (4) In contracted bladders, or in those in which the capacity has been diminished by pressure from without. (5) With spasmodic contraction of the bladder, more especially in tuberculosis and other ulcerations. A two-per-cent. cocaine solution usually overcomes this. (6) In certain deformities, such as ankylosed hip, a rickety pelvis, or a kyphotic spine. A little adjustment of the head is needed in these cases to obtain a good view.

Angeio-Neurotic Œdema of the Larynx.—Dr. Samuel G. Dabney (*Medical Times*, November) reports the following case: The patient, a lady, aged forty-two years, was seen in consultation. She had been having some cough, and for several days had been coughing up blood, and this occurred just at the time of her menstrual period. She had lost her voice also. There was no pain in the larynx or elsewhere, but a little difficulty in breathing from obstruction. An examination showed that there was considerable swelling of the larynx above the vocal cords, in what are called the false vocal cords; also considerable redness there. From the appearance of the mucous membrane of the larynx it seemed that vicarious menstruation had occurred from this structure. The case is also interesting from another standpoint. She gave the history of repeated attacks, with great shortness of breath and impairment of voice, coming on quickly, accompanied always by great nervous excitement. It would last several hours, and was usually attended by some hoarseness. In my judgment this is a rather rare trouble, angeio-neurotic œdema of the larynx, and at the time I saw the case it was attended by vicarious menstruation. A diagnosis of this affection is said to depend on the presence of lesions in the skin, attended with an irritable nervous system and often gastric disturbance. In this case, however, I believe I am warranted in the diagnosis from the suddenly occurring laryngeal œdema, attended with symptoms of nervous irritation. It is important to state that the kidneys and the heart were carefully examined with a negative result. All the symptoms subsided in a few days. As to the pathology of angeio-neurotic œdema, it is thought to be due to a disturbance of the vasomotor nerve centre, possibly due to peripheral irritation, more frequently occurring from the stomach than elsewhere. Such cases are apt to be attended by some systemic disturbances.

Clinical Chips.—In mumps during pregnancy, pyæmia or polyneuritis may supervene. . .In intubation the removal and reintroduction of the tube will sometimes save life which would have been lost by allowing the tube to remain or by failing to replace it. . . . A bridle has been invented for the control of mouth-breathing. . . .Infectious endocarditis may be due to the gonococcus without any other microbic involvement. . . .Hartmann and Reymond have collected and published fourteen cases of torsion of the Fallopian tube. . . .Tuberculosis of the skin, keloid growths, and warts have been successfully treated by compression with a rubber band. . . .Klein treats vomiting of pregnancy by an exclusive liquid diet, with no alcohol, tea, or coffee, and the patient is put to bed and kept there, in isolation, until at least three days after the vomiting has ceased. . . .Retinal hyperæsthesia may result from irritation as well as from inflammation of the uterus and the ovaries. . . .Rüdel reports a case of athetosis cured by the expulsion of a tapeworm.—*The Clinique*, October.

Formalhyde Douche.—Dr. Wallace A. Briggs, of Sacramento (*American Gynæcological and Obstetrical Journal*), advises vaginal douches (1:500) in puerperal sepsis without uterine infection. When the uterus is infected he uses intra-uterine douches of the same strength every twelve hours, followed by hydrogen peroxide applied with a piston syringe. He then fills the uterus with antiseptic glycerin, *i.e.*, formaldehyde 1, alcohol 100, glycerin 400. He then leaves the patient in the exaggerated Sims position for at least an hour, so that the glycerin will remain in the uterus. After the fourth injection he substitutes a two-per-cent. lysol solution.

Medical Hemorrhage.—Dr. Frederick J. Smith includes under this title all intracranial hemorrhages not due to violence; those from the mouth or nose, from spongy gums or pharyngeal varicose veins; aneurism of the aorta; from the lungs in bronchitis, pneumonia, phthisis, emphysema, malignant disease, etc.; from the stomach or duodenum; from the anus either as blood or melæna, or in typhoid fever and other forms of ulceration, *e.g.*, tuberculous or dysenteric; gastric hemorrhage if not vomited; hemorrhage from piles, internal and external; from the urethra, bladder, or kidney; from the vagina, and subcutaneous hemorrhage, as in purpura and scurvy. A mixed class is due to serious disease—leucocythæmia, acute yellow atrophy of liver, some other forms of blood poisoning, and hæmophilia. Ergot is condemned in all arterial bleeding. The following propositions are made: (1) Most cases of medical hemorrhage cease spontaneously and are essentially not dangerous to life from loss of blood. (2) Active treatment by ice-bags and ergot frequently defeats its own purpose; if the bleeding ceases it does so in spite of treatment. (3) Where experience of morbid anatomy or the profuseness of the blood loss makes an arterial source certain ergot is distinctly contraindicated. (4) Complete rest, opium, and iodide of potassium are our most powerful and most trustworthy agents for the emergency, except in certain special cases, *e.g.*, from the stomach, where additional treatment by astringents should be applied. —*Lancet.*

Twin Bearing and Prolificacy.—Dr. J. W. Ballantyne recently read before the Edinburgh Obstetrical Society a paper on "The Causation of Twins as Illustrated by some Clinical Histories." After giving the history of several cases he mentioned that of a woman who was one of a family of seventeen, no twins; one of her sisters had had triplets and another twins; she herself had had twenty-two children in eighteen confinements, viz., four times twins and fourteen single births. In all the cases referred to there was good evidence to show that the twins were of the binovular or dichorionic kind. He mentioned the association of twin-bearing and prolificacy, and deduced that the daughters of a woman who has borne twins are usually highly prolific, and conversely the mothers of twins are usually the daughters of specially prolific women. He mentioned the theory that the ovaries of the twin-

bearer resemble those of the fœtus in the great number of Graafian follicles they contain. Plural pregnancies result from the simultaneous rupture of several ovisacs, and this is a consequence of the existence of a relatively or absolutely large number of ova in the ovaries. Dr. Haig Ferguson mentioned at the same meeting the case of a woman who had seven children in three years, twice twins and once triplets. Dr. James Ritchie referred to a mother who had borne thirty-two children. The fact had been mentioned in an application for life insurance and he had verified the statement.—*Journal of the American Medical Association.*

A Further Account of the Treatment of Aneurism by the Conjoint Use of Galvanism through Introduced Coiled Wire.—In an original article under the above title, Dr. D. D. Stewart (*Philadelphia Medical Journal*, November 12) briefly outlines the newer method, which he regards as a most decided advance over the older plans of treatment of aneurism by the mere introduction of filiform material. It consists in the introduction into the sac, under the strictest antiseptic precautions, of fine coiled wire, previously so drawn that it may be readily passed through a thoroughly insulated needle of somewhat larger calibre than the wire, and which will, after introduction, assume snarled spiral coils. With a moderate amount of wire the entire calibre of the sac will be occupied, unless the cavity be already filled with coagula or the sac be of unusual size. The wire must not be too great either in amount or in calibre, nor too bulky nor too highly drawn, in order that the results desired be not interfered with; nor should the wire be of such brittle material as steel, nor of hard drawn iron, lest fracture occur in the process of contracture of the sac, with danger of rupture. For a globular sac of approximately three inches in diameter the writer regards from three to five feet as sufficient; for a sac of from four to five inches eight to ten feet are required. The anode or positive pole should invariably be the active electrode. This is connected with the wire, and the negative rheophore, a large clay plate or an absorbent cotton pad of equal dimensions, made after the method of Massey, is placed upon the abdomen or the back. The current is slowly brought into circuit, and its strength is noted by an accurate milliampere meter. The increase is gradual for a few moments until the maximum strength supposed to be required is reached. It is maintained at this until the approach of the end of the session and then gradually diminished to zero, after which the wire is separated from the battery, the needle carefully withdrawn by rotation and counter-pressure, and the released external portion of the wire gently pulled upon and cut close to the skin, the cut end being then pushed beneath the surface. The strength of the current must be high—from forty to eighty milliamperes—and the session long—from three-quarters of an hour to one and a half hours—resulting in consolidation by virtue of clot formation. The consolidation is rapid and is generally manifest before the end of the electrical session, through changes apparent to the eye and hand in the pulsation and the degree of consistence of the sac-wall. These changes become more marked in the course of a few days, until after a time, in the most favorable cases, a hard nodule, with a communicated pulsation, replaces the previous expansible tumor. The writer also emphasizes the fact that through portions of the coils of wire, which must in small sections lie in direct contact with the sac-wall, an electrolytic effect is, under the current's influence, produced on the endothelial lining of the sac, such as Macewen has demonstrated is highly favorable to the subsequent deposition of leucocytes derived from the vessel-wall and by segregation from the blood stream, resulting in the formation of organizable white thrombi, from which vascularized fibrous tissue readily springs. From these wall-thrombi, which in a fair number of cases, if not in all treated by this method, are likely to result, organization may rapidly extend to the red thrombi formed directly about the centrally disposed wire, and thus solidification and organization of the sac promptly occur.

Extra-Uterine Pregnancy; Extirpation by Abdominal Section of the Fœtus, which had been Dead Four Years.—An unmarried woman, aged thirty-four years, when admitted to the hospital, showed upon examination the presence of a tumor in the left side of the abdomen. The patient, either through ignorance or deceit, did not give any previous history. The tumor was considered fibromatous in origin and connected with the uterus. Laparotomy was performed, and extra-uterine pregnancy was discovered. The sac was made up of the uterine appendage and the broad ligament. The fœtus was forty-six centimetres long and weighed two and a half kilograms. It was found to be very dry. The patient, when cured and discharged, admitted that she knew she carried the fœtus in her abdomen. She had become pregnant five years previously. Pains had appeared at the proper time and lasted three days. After the discharge of a fleshy mass, with profuse hemorrhage, the pains as well as the fœtal movements disappeared. She had resumed and continued at her work until a fall resulted in severe pains and caused her to seek relief.—Dr. Bastian, *Rev. Méd. de la Suisse Romande*, August.

The Iodides in Chronic Parenchymatous and Creosote in Suppurative Nephritis.—Dr. Leonard Weber (*The Post-Graduate*, October), concludes as follows: After sufficient clinical observations of the good influence of small doses of the iodides in certain forms of chronic nephritis during the last eighteen years, and the value of creosote in the medical treatment of inoperable surgical kidney in the past six years, I believe I am justified in drawing the following conclusions: (1) The iodides given in relatively small doses, three or four times daily, and continued for many months and even years, have the power to retard, modify, and improve subacute and chronic inflammatory processes concerning the connective tissue of parenchymatous organs like the kidneys, the liver, the lungs, and particularly so the sclerotic disease of the arterial vessels. (2) It appears that this salutary effect is brought about by direct inhibition of the proliferation of the connective tissue, as well as by subsequent induction of disintegration and fatty metamorphosis of infiltrated corpuscular elements and the removal of the same. (3) It is reasonable to hold that the drug manifests and develops its activity through the lymph channels and spaces of the affected organs by direct action upon the irritating substances, by stimulating the vasomotor nerves and increasing the functional activity of the parts. (4) The favorable influence of the iodides can be clinically demonstrated, and is more decided in arterial sclerosis than in similar disease of parenchymatous organs, and will show itself frequently, whether the underlying cause is gout, alcoholism, or syphilis. In cases with a syphilitic history, however, it is well to give larger doses of the iodides for a while, *i.e.*, from ten to fifteen grains, t.i.d. (5) Creosote in doses from two to four to six grains, t.i.d., steadily administered, I can recommend as a safe and trustworthy remedy in suppurative disease of the urinary organs. Guaiacol-carbonate in similar doses will do as well, and may be used when creosote is not borne by the stomach. I have found them to reduce suppuration and fever considerably, improve nutrition, and help the patient greatly in cases which had passed the limits of surgical interference.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, December 17, 1898.

THE NAVY MEDICAL DEPARTMENT AND THE LATE WAR.

THE work placed upon the shoulders of the naval medical department before and during the late war cannot, of course, be compared with the strain to which the army medical department at the same period was subjected, and under which to a certain extent it broke down. But, although the naval authorities had not the difficulties to contend with which it was the somewhat unlucky fate of their brothers in arms to meet, yet their way cannot be said to have been all plain sailing. The report of the surgeon-general of the navy, which has just been given to the public, discloses in the clearest manner one conspicuous fact—that the preparations made to meet any possible contingency were distinguished not only by the promptness with which they were carried out, but also by their thoroughness. Nothing was left to chance. Almost as soon as the mournful news of the blowing up of the *Maine* was flashed across from Havana, and when it had become apparent to every reasoning person that war would certainly follow that deplorable incident, those at the head of naval affairs made it their duty to see that the commencement of hostilities should find them ready at every point. In the words of the report itself: "The naval hospitals were equipped to their full capacity; plans were prepared for building pavilion wards on the hospital grounds, to give accommodation to any number of sick and wounded that the bureau might be called upon to care for. The director of the naval laboratory prepared to furnish medical and surgical supplies in any quantity, at any place, and immediately. No additional expense was incurred until war seemed imminent; then the vessels that were likely to be engaged were supplied with a full outfit of supplies for war. In anticipation of a large number of additional vessels being taken for service, medical and surgical outfits of a kind suitable for the various classes of vessels were bought, assembled, and boxed, ready to be shipped anywhere as soon as called for. There has not been an instance during the war of any vessel having had to wait for her medical stores."

But the crowning triumph of the war just over—that is, so far as the medical department is concerned—has been the successful solution of the long-considered problem as to the best means of transporting the sick and wounded. Many points relating to naval warfare, which it was thought would have been elucidated in the late sea fights, still remain obscure; but at least the great value and efficiency of the ambulance ship have been amply demonstrated. The inception and consummation of the idea and the work done by the ships have already been so fully described in the pages of the MEDICAL RECORD, within the past few months, that further lengthy comments on the subject would be superfluous. Suffice it to say that our navy has in this respect shown the way to the rest of the world. Foreign nations have already followed the lead given them by America, and it may be taken for granted that in future the hospital ship will be regarded as an absolutely necessary complement to a naval squadron, in time of war at all events. The duties pertaining to the regular medical officers of the navy, though in the nature of things not so arduous as might have been expected, were fulfilled in a most satisfactory manner, and the medical officers of the naval reserves who were transferred to the service with the reserves from their States ably supplemented these efforts. The ten women who volunteered their services as nurses were assigned to duty at the naval hospitals at Brooklyn and at Norfolk, Va., and gave the fullest satisfaction. In short, there has been ground for little or no adverse criticism of the management of the naval medical department throughout the war. This happy state of affairs was doubtless partly owing to the fact that no excessive pressure was at any time placed on the department. This, however, should detract in no way from the merit of anticipatory performance. Its members did all that was required of them, and, judging from the manner in which their duties were discharged, there would seem to be no reason to doubt that they would have been equal to any emergency. The general health of the navy during the war was exceptionally good. Yellow fever broke out at Key West, and, owing to the unsatisfactory condition of that station, gave rise to some uneasiness on the part of the department. Thanks, however, to the prompt measures adopted by the medical officers in isolating the sick, in disinfecting their quarters, and in removing those who were well to a place beyond danger of infection, the disease was most successfully localized. History may be ransacked in vain to find a parallel in sea warfare to the Spanish-American conflict, both as regards its successful issue and the small loss of life.

A PARASITIC TRIUMVIRATE.

MANY institutions in the social sphere are characterized by their great complexity, and in the realm of disease a like intricate nexus of causes and events is often appreciable. In many of the so-called organic diseases this complicated interwoven mass of causes defies ultimate analysis, and it is with a feeling of relief that the scientific mind contemplates the germ theory as a definite factor in the production of a number of ills. In these an appreciable entity is known and grappled with. But even this light has commenced to

grow less distinct and has lost its former clear-cut outlines, since it is becoming manifest that other classes of organisms than bacteria might be causative of disease, and, on the plant side, bacteria, yeasts, and moulds are seen seeking to live on the lord of the universe. The lowly animal, man's ancient, very ancient progenitor, the amœba, in several forms, takes refuge in his descendants' intestinal tract; and a score of others are recognized in the war with man's life and happiness. And now we are brought face to face with the fact that the pestiferous fly and the gnat and the buzzing mosquito, in addition to their other undesirable qualities in general, may be the means of the transmission of typhoid fever or of malaria. Perhaps the latest, up-to-date, *fin-de-siècle* movement on the part of the enemies of human kind in their own struggle for existence, is the coalition of the rat and the flea and the microbe in the propagation of the bubonic plague. That all of these enter into the matter is the conclusion drawn by Dr. P. L. Simond, *Annales de l'Institut Pasteur*, vol. xii., 1898, p. 625, "La Propagation de la Peste." Here the author has given an extended geographical study of the results of the spread of the plague, and a series of experimental researches, all of which point to the following general conclusions:

1. He shows that the plague was spread by two main agencies, the rat and man. For long distances man is the chief contributor to this transmission, while for short distances, from place to place in the near vicinity, the rat is the main agent, and from the practical point of view this animal is more to be feared.

2. The introduction of infected rats into any healthy district is generally followed after a brief delay by epidemic cases in man. The importation of an infected man into a healthy community is not followed by indigenous epidemic cases; indeed, it seems necessary for a certain time to elapse, long enough for rats to become infected, before the disease commences to appear in man in epidemic form.

3. The gravity of an epidemic among human kind is in proportion to the gravity of the epidemic among rats. Its progression in a village follows the paths chosen by the emigrating rats.

4. The influence of the seasons seems to be but little marked in the development of the plague. In India the epidemics have appeared at all seasons; otherwise, however, the epidemics have always been at their height in the warm season.

5. A second epidemic usually manifests itself in general within twelve months after the appearance of the first, from which it is separated by a period varying in length. The reason for this periodicity has not been determined; it probably is related to the life history of the rat, which, in the course of time, again "repeoples" a community.

6. Control experiments made upon the rat, the monkey, and other animals, whereby they were fed with infected food material, showed that it was not probable that these animals were infected by this channel; and experience would go to show that man is not infected by means of external communication nor through excoriations on the skin.

7. The chemical study of the plague teaches that in a certain number of human cases the point of entrance of the organism is marked by a local reaction, and is always situated in these cases in a region where the skin is delicate and sound. Metchnikoff's work on inflammation and the chemical facts of infection by other pathogenic organisms tend to support the view that, in the cases where the local reaction or the regional reaction (bubonic) are missing, their absence is due rather to a variation in the virulence of the organism than to a difference in the method of penetration.

8. The idea of transmission by means of a parasite, which would seem to be the conclusion drawn from clinical experience, is in accordance with the invasion of sick rats by fleas, which several hours after death abandon the cadavers to attack other animals and man. This is confirmed (1) by the presence of the specific microbe in the intestinal contents of the flea; (2) by other certain peculiarities of transmission from rat to man, and from man to man, in which latter case it is possible that other parasites, more particularly the bedbug, may intervene; (3) by the possibility of the transmission of the plague to a healthy rat by his cohabitation with an infected rat with fleas, when such cohabitation of healthy rat and flealess infected rat is uniformly innocuous.

9. The mechanism of the propagation of the plague includes the transport of the virus by the rat and by man, its transmission from rat to rat, from man to man, from man to rat, and from rat to man, by the parasites. Prophylactic measures should take into account all three of the agents—man, rat, and the flea.

THE HAND AS AN INDICATOR OF DISEASE.

The study of the physiognomy and of the hand is curiously interesting. It is now generally admitted that a person's character can be gauged with a very considerable degree of accuracy by a visual analysis of the features, and the same remark applies, with less force perhaps, to a study of the hand. The professors of palmistry indeed claim that they are able by a careful perusal of the lines of the hand not only to tell of the past actions of an individual, but even to peer into and raise the veil from the mysterious future and to predict with certainty as to the coming events in his or her life,—when death or misfortune may be expected to occur, and whether marriage or celibacy is to be the lot of the seeker after forbidden knowledge. However, it must be confessed that the prognostications of these would-be prophets should be regarded with the same scepticism as was accorded to the prophecies of the Delphine oracle in days far back by the less superstitious members of the community, and we think that any person who is sufficiently misguided to pay good money, in the hope of thus learning his fate, is deserving of no sympathy. But the study of the face and hand for indications of disease is manifestly a great aid to a correct diagnosis. The fact that in certain diseases the expression of the face and the appear-

ance of the hands are fairly reliable indices of the nature and progress of the disease, is too well known to require further emphasis. For instance, a skilled physician can in the majority of cases decide if a patient is a sufferer from Bright's disease by the expression of his countenance, and can also by the color, contour, and texture of the hand, by the shape and tint of the fingers and nails, diagnose more than one complaint. For very many years clubbing of the finger ends has been held to be one of the most important signs of consumption, and the condition also appears in several other diseases. Recently Dr. Edward Blake, of London, has written a work on the study of the hand for indications of local and general disease, in which many instructive and peculiar points in connection with the subject are well brought out. In the introduction to the book Dr. Blake makes mention of the fact that on those rare occasions when the aid of the European physician is sought for a female member of any Mohammedan family of distinction, the only part of the patient which the doctor is permitted to see is the hand, which is thrust for that purpose through a small opening in a curtain. The object of Dr. Blake's paper, then, is to answer to the best of his ability the question as to whether it is possible that a fairly respectable diagnosis might be based upon a sight of the hand alone. In the first place it is shown that the hand is often dry in cancer and in paralytic dementia. If the hand is dry and claw-like, the possibility of diabetes enters the mind; if hot, dry, and emaciated, the hectic of advanced tuberculosis is suggested. When one hand is persistently hot and the other cold, the case may be one of subclavian aneurism, but it is much more likely to be gout or else lead poisoning. If the palm is not only hot but also clammy, the causes may be excitement, recent exertion, or hyperidrosis. A cold and dry hand may mean starvation, anæmia, or one of the innumerable forms of vasomotor ataxia. The hand is cold, harsh, and swollen in myxœdema. If cold, clammy, and tremulous, then hysteria, dyspepsia, certain depressing emotions of the mind, and the action of some nerve poisons, as alcohol, tea, and tobacco, present themselves to us. With regard to the nails the author points out that paludal fever causes in them a typical change of tint; that the nails are pale in hectic and in anasarca, gray in serious internal disease, yellow in jaundice, white in convalescence, chalky in some forms of paralysis, acutely livid in ague, and chronically purple in cyanosis. With the assertion that brittle nails accompany diabetes mellitus, Dr. Blake does not entirely agree, but says that as a matter of fact the subjects of glycosuria are prone to neuritis; and any form of peripheral neuritis, from gout to beri-beri, may be followed by fragility of the nails. Attention has already been drawn to the long-held belief that clubbing of the finger ends is an important sign of consumption. Patrick Manson has seen it as a sequel to the evacuation of hepatic abscess by way of the respiratory passages. It has been described as a result of congenital heart disease. It is seen after nerve injury, pneumonia, and spinal caries. And the paper written by Dr. Vivian Poore on "Nervous Affections of the Hand" is quoted by Dr. Blake as noticing the fact that clubbing is absent in patients whose legs are swollen with tortuous veins; nor is it always present in bronchiectasis with emphysema, where there is considerable venous stasis; to which the writer adds that clubbing forms no part of the phenomena of Raynaud's disease, and that all the cases of Marie's disease that have been recorded up to the present time have occurred in men. The question of eruptions and invasions of the skin is entered into at some length, and instructive and somewhat curious information is given with regard to the diagnostic value of a study of the form of the hand in many diseases. In fact, it would certainly appear to be more than likely that the study of the hand is deserving of closer attention than is usually bestowed on the subject by medical men in general practice.

News of the Week.

Harold Frederic on Doctors. — The late Harold Frederic, whose Christian-science slayers were recently discharged from custody, was perhaps led to his doom through dislike for the medical profession. He was known to entertain a very unflattering opinion of physicians, and in his last novel, "Gloria Mundi," gave vent to his contempt in the following passage: "He drifted into an attack upon doctors as a class. He denounced them, root and branch, as impostors and parasites who darkened and embittered human life by fostering all the mean cowardices of small-brained people in order that they might secure a dishonest livelihood by pretending to dispel the horrors their own low tricks had conjured up."

A Convalescent Hospital at Manila.—It has been decided to establish a convalescent hospital on Corregidor Island. Two companies of the Tenth Pennsylvania Regiment have been sent there to erect the hospital and to act as guard. Major Owen will have charge of the hospital, which will contain one hundred beds. There will be fifty nurses to attend to the patients. The chief surgeon contemplates the enlargement of the hospital as soon as possible. The sick report of the garrison at Manila during the first week in September was as follows: Typhoid fever, 114; malarial fever, 573; dysentery, 105; diarrhœa, 186; all other intestinal troubles, 38; gastric fever, 22; wounds and other injuries, 73; heat, 3; small-pox, 20; all other diseases, 836. There were nine deaths during the week.

Progress.—General Greene has recently caused several of the streets in Havana to be cleaned, and that his efforts have begun to be appreciated is shown by the following warning which has been placarded at the corners of these recently cleaned streets: "I, the Marquis Esteban, Mayor of Havana, do hereby make known that this street has been cleaned and disinfected at the expense of the United States of America. All persons who throw or deposit dirt or refuse of any kind here will be prosecuted to the full extent of the law."

Wholesale Poisoning.—Fifty-two persons were recently taken ill with symptoms of irritant poisoning at the Cleveland orphan asylum near Versailles, Ky. The sufferers included the matron, her daughter, a music teacher, and forty-nine of the orphans. They were affected shortly after supper, but the offending substance has not been discovered.

To Guard against Future Visitations of Yellow Fever.—A circular addressed to the physicians of the city has recently been issued by the New Orleans board of health, calling attention to the urgent need of educating the people to adopt measures to prevent a recurrence of the fever epidemic next year. Among other suggestions in the circular, the *New Orleans Medical and Surgical Journal* quotes the following: "It is a well-known fact that sunlight and oxygen destroy germs of disease. In the case of yellow fever, cold is a potent factor in such destruction. Let us then give Nature a chance, during the present winter, to destroy with her own inexpensive agents any possible remaining vestige of infection left over from the summer. Let our houses be thrown open on every cold and clear day as much as is practicable, more especially the bedrooms. Let the clothes and bedding, curtains and all woollen, linen, and cotton materials be frequently aired and sunned. And most particularly let the clothes worn during the past summer be frequently subjected to the disinfecting influences of cold, fresh air and sunlight. Trunks, chests, armoires, closets, and bureau drawers should be opened and emptied of their contents during cold and clear weather; and fresh, cold air should be permitted to circulate in the remotest corners of the house among articles which cannot be moved to the sunlight."

A Milk Epidemic of Typhoid Fever.—A limited epidemic of typhoid fever broke out recently in the northern part of the city. There were seventeen cases within a small area, and of these thirteen were traced to infected milk sold by a grocer in the neighborhood. It was not charged that the milk was diluted, but it was believed that the cans were washed in polluted water.

Shorter Hours for Drug Clerks.—The executive committee of the Druggists' League for Shorter Hours has decided to introduce in the next legislature its ten-hour bill for drug clerks in amended form. The bill passed at the last session was vetoed by the mayor. The new bill provides that no clerk engaged in the compounding of prescriptions in any drug store shall be required or permitted to work more than ten hours on any week day other than Saturday, more than twelve hours on Saturdays, and more than six hours on Sundays and holidays. There is also a section forbidding any clerk to sleep in a drug store or in any store-room or laboratory connected with it. He may, however, sleep in any other room adjoining the pharmacy, provided that such room is properly ventilated and complies in all other respects with the sanitary regulations of the board of health.

Winter Hospitals for the Army.—In his testimony before the War Investigating Commission on December 5th, Colonel Martin of the quartermaster-general's office explained what preparations were being made for the construction of permanent winter hospitals for the sick of the army. Large contracts have been made for lumber to be shipped to Cuba for use there by the medical department. This was in anticipation of the needs of the medical department and with a view to the construction of a large number of pavilions to be used for the sick. In this country the preparations were on a large scale. A one-thousand-bed hospital was to be erected at Fort Monroe, a one-thousand-bed hospital at Savannah, a five-hundred-bed hospital at San Francisco, and at other places pavilions were to be built to accommodate from one hundred to five hundred patients. At Fort Myer, near Washington, the riding hall had already been converted into a hospital, and other buildings were to be constructed for that purpose. The hospital capacity of the government, exclusive of the colonies, would, when completed, take care of between five thousand and six thousand soldiers.—*The Sun.*

Explosion on a Hospital Ship.—An explosion of the ice machine on board the hospital ship *Bay State*, lying at a wharf in Brooklyn, on December 6th, killed one man, seriously injured another, and twelve others were more or less overcome by the fumes of ammonia which spread to all parts of the ship.

The Alumni of the College of Physicians and Surgeons met at the annual dinner at Sherry's last week, over two hundred members of the association being present. Dr. John G. Curtis, president of the Alumni Association, presided. Mr. Seth Low, president of Columbia University, delivered an address in which he said that 1898 had been a notable year in the history of the college, and spoke of the twenty-two Columbia students who had enlisted during the war with Spain. One of the first men to fall on the American side during the conflict, he said, was Dr. John Blair Gibbs, an alumnus of the college, who was killed at Guantanamo. Another graduate of the school was Dr. Lindheim, who had brought fourteen carloads of fever-stricken soldiers from the South without losing a man, but, while saving them, sickened and died himself.

The Army Medical Supply Depot in New York will be moved next week to a new building at the southeast corner of Washington and Hubert streets. The depot, which is in charge of Lieut.-Col. J. Morris Brown, has heretofore been located in the Army Building. The new building, besides being suited to the storage needs of the depot, will afford ample office room.

Small-pox at Bedford, Pa.—According to a despatch to the New York *Times*, the citizens of Bedford, Pa., are up in arms against Dr. William B. Atkinson of the State board of health, who is said to have reported that there are over two hundred cases of small-pox there, and that victims of the disease are walking unrestrained about the streets. A town meeting was held, and a committee of citizens, health authorities, and councilmen drew up resolutions denouncing Dr.

Atkinson's statements as untrue. Dr. Atkinson is said to adhere to his declarations, and the board of health will accordingly take active measures in the matter without delay.

The Prince of Wales on His Feet Again.—A circular note published in the English medical journals announces that the Prince of Wales has now made a complete recovery from his accident last July, whereby he suffered a rupture of the insertion of the left quadriceps extensor muscle, which tore away with it at the same time the upper portion of the patella. The fragments of bone were separated by a considerable interval which gradually became reduced, and the gap is now completely filled with strong fibrous material which shows no sign of stretching. The knee readily bends to considerably more than a right angle, and the power of active extension at the joint is very good. The Prince can readily go up and down stairs, and can walk with a scarcely perceptible limp due to the slight interference with joint movement caused by the splint which he is still wearing.

A New Whooping-Cough Bacillus.—An Italian investigator, Dr. Vincenzi, at Sassari, claims to have discovered the specific pertussis microbe. He found it in the sputa of children suffering with whooping-cough, being present in some cases in very large quantity, while it was absent in other diseases. Dr. Vincenzi ascertained by a series of researches the peculiar qualities of the micro-organism, but he did not succeed in causing the same disease by inoculation in animals. It is, however, well known that whooping-cough never occurs in animals.

A World's Temperance Congress.—The Archbishop of Canterbury, as president of the British National Temperance League, has issued invitations to the national and international temperance organizations throughout the world for a "World's Temperance Congress" to be held in London during the year 1900.

A Benefactor of McGill Honored.—It is announced in Montreal that Queen Victoria will confer the honor of knighthood on Mr. W. C. McDonald on the occasion of the opening of the new chemistry and mining building of the McGill University on the 20th instant. This building and its equipments are Mr. McDonald's latest gifts to the university, and make the total of his donations amount to more than one and a half millions.

Reports on Red Cross Work.—A meeting of the National Red Cross relief committee was held last week to hear the reports of the work of the committee. Bishop Potter presided, and reports were made by ex-Major Schieran of the central Cuban relief committee; Dr. A. M. Lesser, E. C. Smith, and Horace Barnes, Red Cross agents at Chickamauga; Howard Townsend, who directed the relief work at Camp Wikoff, and Cleveland H. Dodge of the supply committee. Resolutions were adopted thanking Miss Barton for her part in the work.

Prize for an Essay on Epilepsy.—A prize of one hundred dollars is offered by the board of managers of Craig Colony for the best original essay bearing upon the pathology and treatment of epilepsy. The essay must be written in English, but competition is open to the world. The award will be made upon the recommendation of a committee composed of three members of the New York Neurological Society, at the annual meeting of the board of managers of Craig Colony on October 10, 1899. The successful essay becomes the property of the Craig Colony, for publication in its annual medical report. Papers submitted for the competition should be sent to Dr. Frederick Peterson, 4 West Fiftieth Street, New York City, on or before September 1, 1899.

Foot-and-Mouth Disease in Belgium.—According to reports from United States consuls in Belgium, a very extensive epidemic of foot-and-mouth disease prevails in that country at the present time. Horses are chiefly affected. One hundred and fifty-two stables in fifty-two communes are said to be affected, and the outbreak is considered so serious that the governor of the province has peremptorily prohibited the holding of the usual cattle markets in the affected districts. No permit will be issued by the department of agriculture for the importation of animals from Belgium while the epidemic lasts.

Communicability of Leprosy.—The British Colonial Office has requested the Royal College of Physicians to report to it on the communicability of leprosy, and the question has been referred to a committee consisting of members to confer with others not belonging to the college.

The Monument to Charcot, which has been erected in front of the Salpêtrière, was unveiled on Sunday, December 4th, at 10 A.M. M. Leygues, Minister of Public Instruction, presided at the ceremony.

The Eastern Medical Society of the City of New York.—At the annual meeting of the Eastern Medical Society, held Friday evening, December 9th, the following officers were elected for the ensuing year: *President*, Dr. William S. Gottheil; *First* and *Second Vice-Presidents*, Drs. A. E. Isaacs and E. K. Browd, respectively; *Secretary*, Dr. R. Abrahams; *Treasurer*, Dr. I. Barsky; *Chairman of Ways and Means Committee*, Dr. Louis Fischer; *Trustees*, Drs. Abram Brothers, Henry J. Garrigues, and M. Cisin.

Virchow's Political Triumph.—At the general election of deputies in Prussia on November 3d, Professor Virchow was returned by the third electoral district of Berlin, receiving 1,358 votes against 782 polled for his opponent. Virchow received nearly 200 more votes than at the election of 1893. In politics he is a liberal.

The Massachusetts Hospital Ship "Bay State" has been purchased by the United States government for the sum of $100,000. The vessel will retain the name of *Bay State* and will be used as a transport to carry soldiers and supplies to and from Cuba and Porto Rico.

A Large Sick Rate.—The official statistics compiled under the direction of the Commissioners of Pensions show that the total number of deaths on the

American side due to the war was 2,906 up to October 1st. As only 348 men were killed in battle or died from their wounds, the large death rate from sickness becomes apparent, giving a mortality from disease of 2,558.

River Pollution in Connecticut.—A correspondent of the *Evening Post* says that the city of New Britain will probably apply to the next legislature for power to build a sewer for a distance of about ten miles, emptying into the Connecticut River a short distance above the city of Middletown. The sewers of the latter city empty into the river, but its residents object strenuously to the New Britain plan, on the ground that it would contaminate the waters at a place dangerous to public health. A contest between the two cities over the question is expected at the next legislative session. The sewerage commission has been making an exhaustive study of the matter of discharging sewage into running waters, and will probably report against permitting sewers to empty into streams.

The Bucks County (Pa.) Medical Society celebrated its semi-centennial at Doylestown on November 2d. Reviews of the progress of medicine in its different departments during the past fifty years were presented by Drs. W. R. Cooper, Joseph Thomas, Frank B. Swartzlander, and G. M. Grim. The following officers were elected for the ensuing year: *President*, Dr. O. H. Fretz, of Quakertown; *Vice-Presidents*, Dr. R. C. Foulke, of New Hope; Dr. A. S. Wilson, of Bristol; *Secretary*, Dr. A. F. Myers, of Blooming Glen; *Treasurer*, Dr. Frank Swartzlander, of Doylestown.

Dr. Sanger Brown, of Chicago, has resigned from the faculty of Rush Medical College.

Dr. E. B. Smith, of Detroit, has assumed editorial management of *The National Hospital and Sanitarium Record*, a monthly journal published in the interests of hospitals, trained nurses, and everything connected with the medical side of institutional work.

A Hospital for Consumptives.—The medical direction of the new Hospital for Consumptives, at Dunning, Ill., has been placed in the hands of Drs. W. A. Evans, J. B. Murphy, Homer M. Thomas, Harold N. Moyer, Robert H. Babcock, Florence W. Hunt, William J. Butler, and Frank Billings.

The Spanish Red Cross Society.—A Washington despatch states that the French Embassy has submitted to the State Department a request from the Spanish Red Cross Society for illustrations and explanations of all the surgical, medical, and humane devices used by the American Red Cross and the Army and Navy medical departments to alleviate the horrors of war. A request similar to this has been made of all other governments, the purpose being to publish a volume showing the advances made the world over in caring for the sick and wounded, and in meeting the many distressing situations arising from a condition of war. A full set of illustrations is desired of the American field hospitals, ambulance trains, stretchers, surgeons' outfits, and the manifold requirements and conveniences of the military and naval surgeons' bureaus.

The Jefferson Medical College.—Ex-Senator George F. Edmunds was recently elected a member of both board of trustees of Jefferson Medical College in Philadelphia, to succeed Lewis A. Biddle, resigned.

Health of the German Empress.—The health of the German Empress, not to speak of that of the Crown Prince, occupies a great deal of the attention of the European quidnuncs just now. The extraordinary interest which the Emperor displayed in Dr. Koch and his phthisis cure some years ago is connected with the persistent rumor that the Empress' lungs are affected, and the fact that the Crown Prince is in garrison in South Germany is brought forward as a proof that his parents wish to spare him the rigors of a Potsdam winter. The fact that we have heard very little of late of the Emperor's ear trouble must not be taken as indicating that it has ceased to give anxiety, and the circumstances of his father's death are not forgotten. So that, taken all together, the "family history," as insurance experts call it, is not a very favorable one, and there is much whispering and shaking of heads accordingly.—*Saturday Review.*

Diphtheria Antitoxin in Chicago.—Whether there has really been an increase in the number of cases of diphtheria in Chicago or not, the demand for this new agent is increasing. Every morning a line of applicants is reported at the health office in that city, and during the first two weeks in September five hundred vials have been distributed. As each of them contains material enough to treat several sick victims, it can readily be seen that much suspicion at least has been aroused. Dr. Reynolds is reported as saying that there is no epidemic of the disease, that physicians are steadily taking advantage of the facilities offered by the city laboratory for microscopic tests, that every day twenty to thirty cultures are brought in for examination, that more antitoxin is being used than ever before by physicians, and that the intelligent use of the remedy has robbed the disease to a certain extent of its terrors.—*Peoria Medical Journal.*

Hydrotherapy in Cleveland.—It has been proposed to establish a hydriatric hospital in Cleveland where patients can be sent while remaining under the care of their own physician, the medicinal treatment being supplemented by any form of hydrotherapeutic applications.

The Insane in the State of Wisconsin are cared for in a manner quite different from that adopted by most other commonwealths. Instead of two or three large asylums to provide for the 3,000 insane charges, there is what is called the "county system," there being twenty-five asylums in as many counties, some being larger than others, but altogether providing comfortably for the total of 3,000 patients. The advantages claimed for this system are principally that the expense is much less, that the patients are nearer to their friends and relatives, that it approaches the

separation-and-isolation plan, and that it admits of no small amount of out-of-door occupation, which is so beneficial and which does not obtain in the large insane hospitals, where one and two thousand patients are gathered under one management.—*Clinical Review.*

Medical Teaching in Chicago.—It is asserted in the *Clinical Review* that, owing to the increased registration for the present session, Chicago now has not only the largest aggregate number of medical students of any city in this country, but as well has, in point of numbers of matriculants, the largest individual undergraduate medical school in the world. It is announced that very close to eight hundred students are enrolled at one college. If quality keeps pace with quantity Cook County may eventually become a medical centre.

Muscle and Meat.—The six-days' bicycle contest of last week demonstrated that some men may undergo severe physical and a certain amount of mental strain, without sustaining any appreciable immediate ill effects. One contestant declared at the finish that he was prepared to start on another journey on the following day, and physical examination, it is said, failed to find any reason to the contrary. The victor, after his two-thousand-mile ride, was found to be in comparatively good condition, and it is a matter of interest that during the week he partook of no meat but lived entirely on liquids, cereals, fruits, and eggs. Professor Atwater, of Wesleyan College, made a study, to be incorporated in a report he intends soon to make, of the foods consumed in their relation to energy expended during the contest. According to the notes of his trainer, the following food was taken by the champion: Three pounds of rice, one pound of barley, four pounds of Scotch oats, four dozen pint bottles of prepared milk, one pound rice pudding with raisins, four one-pound bottles of beef extract, six raw eggs (in milk and lime water), ten quarts of milk, one-half gallon of lime water, three pounds of grapes (on Saturday only), three dozen apples, one dozen oranges, one-half gallon of coffee. No stimulants were taken, and the total sleep during the race was nine and one-quarter hours.

May Yet be Tried.—The authorities in London have not yet decided whether to press the charge of manslaughter against the "peculiar people" who were considered responsible for the death of the American newspaper correspondent, Harold Frederic, or accept the coroner's verdict of not guilty.

A New Hospital at Allegheny.—It is purposed by the United Presbyterian Women's Association of Allegheny, Pa., to erect a memorial hospital in that city at an estimated cost of forty thousand dollars. The building will be of four stories, seventy-four feet front by one hundred and sixty-two feet in depth.

A Huge Hospital Abuse.—A writer in the *Medical Times and Hospital Gazette* says that, taking a leaf out of the book of the vendors of foreign stamps and other commodities which boys delight in, the promoters of the Prince of Wales' Hospital Fund have made a raid on the larger of our public schools with a view to get the bigger boys to spend their scanty pocket-money in what is neither flesh, fowl, nor good red-herring, to wit, those precious hospital stamps which are hawked about at prices ranging from one shilling to ten, according to color, and are intrinsically not worth the paper they are printed on. Agents are being sent to the public schools all over the country, delivering lectures illustrated by lantern views of the scenes to be met with in the daily work of a London hospital. After the sympathy of the boys is excited the hospital stamps and albums are introduced to their notice, and they are urged to purchase. Every English boy worships the Prince of Wales, and many are led to get the stamps through their admiration.

Consolidation of Medical Societies.—It has been proposed to establish an academy of medicine in Toronto and to abolish all the other medical societies, the present members of which will become fellows of the academy. The work of the academy will probably be performed in three sections—of medicine, surgery, and gynæcology—each of which, as well as the entire body, will hold one meeting each month.

Obituary.

SIR WILLIAM JENNER.

Sir William Jenner, Bart., G.C.B., F.R.C.P., F.R.S., Physician-in-Ordinary to the Queen and Prince of Wales, died at his residence at Bishops Waltham, Hampshire, on December 11th, at the age of eighty-three years. He was born in Chatham and was educated at University College, London. He was made a fellow of the Royal College of Physicians in 1852. He began professional life as a general practitioner, and was first connected with the Royal Maternity Charity and then with the London Fever Hospital and the Hospital for Sick Children. Much of the work which made him famous was done at the Fever Hospital. In 1861 he was appointed physician-extraordinary to the Queen, and in the following year he was gazetted physician-in-ordinary to her Majesty. In 1863 he became physician-in-ordinary to the Prince of Wales. He was one of the physicians who attended the Prince Consort in his fatal illness.

He was created a baronet in 1868 and a Knight Commander of the Bath in 1872. In 1881 he was elected president of the Royal College of Physicians and held the office for seven years. He severed his connection with the London Fever Hospital in 1861, and with the Hospital for Sick Children in 1862. In 1889 he retired from practice, being then seventy-four years old. In 1894 the Royal College of Physicians awarded him the Moxon medal, a medal voted every three years to some one who is judged to have rendered distinguished services in the field of clinical medicine.

GOUVERNEUR MATHER SMITH, M.D.,

NEW YORK.

In the death of Dr. Gouverneur M. Smith, which took place on December 8th at his home in this city, the medical profession of New York loses one of the best known and most beloved of its members.

Dr. Smith was born in New York City, his father being Dr. Joseph Mather Smith. He was graduated in arts from the New York University in 1852, and in medicine from the College of Physicians and Surgeons in 1855. At the outbreak of the Civil War he entered the army as an acting assistant surgeon, and served until the close of the war. In 1864 he was appointed executive officer in charge of the United States Army General Hospital. On the death of his father, Dr. Joseph Mather Smith, in 1866, he succeeded him as an attending physician at the New York Hospital, and in 1879 was made consulting physician. He was vice-president of the Academy of Medicine for several terms, and was also for a number of years a member of the board of trustees. He was a member of the Metropolitan Club and the Century Association, the Sons of the Revolution, and the Society of Colonial Wars, the Society of the War of 1812, and the St. Nicholas Society, as well as of the Academy of Medicine, the Medical Society of the County of New York, and the Society for the Relief of the Widows and Orphans of Medical Men. The cause of his death was cardiac disease.

He was in a marked degree a typically courteous, dignified, and sympathetic gentleman, ethical in all his doings; thoroughly considerate of the rights of others and earnest in all his many and varied purposes of elevating the tone of the profession, increasing its influence, and adding to its resources. His numerous and varied contributions to medical and general literature earned for him a reputation as a careful observer, a clear thinker, and a polished scholar.

The Late Dr. R. C. M. Page.—The Northwestern Medical and Surgical Society of the City of New York has adopted the following resolutions concerning the death of Dr. Richard Channing Moore Page:

"*Resolved*, That by his death the Northwestern Medical and Surgical Society loses one of its best-esteemed and beloved members. A member of our Society for over sixteen years, his great medical and literary ability, combined with an indescribable charm of manner, endeared him to all who knew him.

"*Resolved*, That in his death the Society has suffered an irreparable loss.

"*Resolved*, That these resolutions be engrossed in the archives of the Northwestern Medical and Surgical Society, and that a copy be transmitted to the widow, and to the weekly medical journals for publication."

PALMER C. COLE, EDWARD S. PECK, HENRY FRUITNIGHT, *Committee.*

The Death of Dr. Salmon P. Cahen.—At an emergent joint meeting of the medical board of the West-Side German Dispensary, and the corps of professors of the New York School of Clinical Medicine, held at the Dispensary and School building, the following resolutions were adopted:

"*Whereas*, We have learned with great pain of the death of our friend and colleague, Salmon P. Cahen, M.D., Secretary of the Medical Board of the West-Side German Dispensary and Associate Professor of Practice at the New York School of Clinical Medicine; and

"*Whereas*, Professor Cahen, by his nobility of character, scientific attainments, and devotion to the sick poor, endeared himself to us as a man and a physician; and

"*Whereas*, His death is to us an irreparable loss; be it therefore

"*Resolved*, That in manifestation of our deep grief, we ask that the Dispensary and School be closed on Friday, the 9th instant, until 1 P.M., that all connected with these institutions may attend the services in a body; and furthermore be it

"*Resolved*, That four copies hereof be engrossed, one to be given to the widow of our friend and colleague, another to his brother, James P. Cahen, Esq., president of the board of trustees, another to Julius P. Cahen, Esq., secretary of the board of trustees, and another to be placed in the assembly-room of this Dispensary and School; and further be it

"*Resolved*, That a copy of these resolutions be spread upon the minutes of the Medical Board of the West-Side German Dispensary, and upon the minutes of the corps of professors of the New York School of Clinical Medicine; and be it further

"*Resolved*, That copies hereof be furnished the medical journals of New York for publication."

FERD. C. VALENTINE, M.D., *President Medical Board of West-Side German Dispensary.* LOUIS FISCHER, M.D., *Secretary New York School of Clinical Medicine.*

Obituary Notes.—DR. SAMUEL DECKER, of Griffin Corners, N. Y., died of typhoid fever on December 3d, aged fifty-nine years. He was born at Livingstonville, N. Y., July 21, 1839, and graduated from the College of Physicians and Surgeons, New York City, in the class of 1867, and had been engaged in active practice since at Livingstonville.—DR. L. CHAPMAN SMITH died on December 10th at his home in Brooklyn. He was born forty-five years ago in Smithtown, L. I. He studied dentistry, receiving his degree in 1876, and then began the study of medicine at the New York University, graduating in 1878. He afterward took up the study of pharmacy and received his diploma from the board of pharmacy.—DR. SALMON P. CAHEN died at his home in this city on December 6th, of pneumonia. He was born in Germany in 1845, and came to this city in 1860. In 1864 he returned to Germany, and was graduated there as a mining engineer. Later he attended medical colleges at Leipsic, Strasburg, and Berlin, and obtained the degree of M.D. from the University of Leipsic in 1876.—DR. GEORGE W. BAKER, of Brooklyn, died of pneumonia on December 5th. He was born sixty-two years ago, and was graduated from the College of Physicians and Surgeons, New York, in 1864. He had practised in Brooklyn ever since his graduation.—DR. EDWARDS HALL, one of the oldest physicians of this city, died on December 11th. He was born in Middle Granville, N. Y., in 1818, and was graduated in arts from Hamilton College in 1840. His medical education was obtained at the Albany Medical College, where he was graduated in the class of 1844. He served three years on the resident staff of the Children's Hospital, Blackwell's Island, and in 1849 went to California. Returning in 1851, he began practice in New York and had lived here ever since.—DR. ALBIN J. FULDA, of this city, died on December 9th. He served during the Civil War as surgeon to the Forty-fifth Regiment of Volunteers, and after the war began practice in New York. He had been in poor health for several years.—DR. JAMES LAWRENCE TYSON died on December 11th at Penllyn, Pa., in his eighty-sixth year. He was born in Philadelphia, November 19, 1813, and was graduated from the medical department of the University of Pennsylvania in the class of 1838. In 1854 he was elected professor of medicine and therapeutics in the Philadelphia College of Medicine. For several years he was physician to the Wills Eye Hospital. He was one of the founders of the Howard Hospital, and for many years was one of its physicians.—DR. THOMAS H. HUZZA, of Atlanta, Ga., died a few days ago in the New York Hospital after an operation for appendicitis. He was born thirty-four years ago in Missouri, and was a graduate of the Jefferson Medical College, Philadelphia, 1887.

Reviews and Notices.

TRANSACTIONS OF THE OHIO STATE MEDICAL SOCIETY.

In compact and handy form there are here presented the papers and discussions at the last meeting of State Medical Society of Ohio. To the members of this society these pages will be full of interest, and to the outside reader there are some papers which may be of profit.

DIPHTHERIE UND DIPHTHERITISCHE CROUP. By PROF. DR. ADOLF BAGINSKY, Director of Kaiser und Kaiserin Friedrich Children's Hospital in Berlin; Professor of Pædiatrics in the Berlin University.

In his preface, Professor Baginsky states that this work is the result of his personal experience, gained by the immense amount of clinical material at his disposal, and that the pathologic-anatomical portion is the result of personal control, aided by his trained assistants, whose zeal he recognizes. These illustrations are reproduced from specimens prepared from his own material in the hospital. The author makes a distinction between the local manifestations of the disease, which he describes as diphtheritis "und diphtheritisch," and between the general infection, so-called constitutional manifestation, which he describes as diphtherie "und diphtherisch."

He defines diphtheria to be a contagious, usually febrile disease, and continuous with fever, producing more often in the upper air passages a grayish or a dirty yellow membrane, which is firmly adherent. It is caused by the invasion of a specific, well-characterized bacterium, discovered by Klebs and Loeffler, and which is usually accompanied by streptococci and staphylococci.

In the history of diphtheria is a vast amount of literature from all over the globe. In this chapter he quotes one hundred and forty-eight different articles and references.

The chapter on etiology and pathogenesis treats of the climatic and geographical conditions. The author cannot see that this disease is really influenced by the effects of climate, for it is met with in tropical countries as well as in northern climates; cases are reported from Egypt, Syria, Spain, as well as from Norway. Nor does the season of the year influence its development. The author gives the details of his experience, and finds in a review of six years a series of 1,344 cases treated from October until the end of March, and 1,017 cases from April until September. Other authors quoted do not regard this disease as being influenced by seasonable changes, as are cholera and dysentery.

Cleanliness is a valuable factor in the prevention of this disease. It can by no means be laid down that a distinct cause of this disease is filthiness, for we frequently find this disease among the cleanly. The author refers to the fact that this disease is frequently met with in the royal households and among the well-to-do families. Interesting facts pointing to the probable etiological factor between damp dwellings and the disease, especially unsanitary apartments, are herein described.

The author does not believe that sewer gas *per se* can cause this disease, but he agrees that people living in apartments in which sewer gas escapes, can, by inhaling the gas, attain a distinct subnormal condition, and then be more susceptible to the infection of any disease The author does not believe that anybody can question that sewer gas should cause diphtheria in one, pneumonia in another, and typhoid in a third.

The spread of the disease he believes to be purely a question of the dissemination of the seed on a proper soil. The disease is contagious, and therefore can be carried from person to person.

In the chapter on the diphtheria bacillus, pages 63–91, the minutest details are given as to the morphological character of the Klebs-Loeffler bacillus, the manner of taking a culture, the recipes for the various culture media and for the staining, etc., with several beautiful illustrations of the Loeffler bacillus stained with Neisser's stain and of unstained specimens. On page 86 is given the formula for a good stain for these Klebs-Loeffler bacilli.

The next chapter deals with the pathological anatomy of the pharynx, respiratory organs, the heart, gastro-intestinal canal, spleen, liver, pancreas and mesenteric glands, urogenital apparatus, central nervous system, and organs of sense. This is profusely illustrated, containing no less than twenty different pathological (stained) and also bacteriological cultures and specimens. Especially good are the illustrations showing hemorrhagic nephritis, and the fatty and degenerative changes in the nerves and spinal cord.

Localized diphtheria angina is next detailed, and the chapter illustrated by numerous fever curves. Following this, the author describes constitutional diphtheria, or, as the author terms it, a diphtheritic general infection, in which the whole body participates. Every symptom is given especial weight, and all the secretions and excretions of the body are given the prominence that they deserve.

In the next chapter, the author describes septicæmic diphtheria, which he regards as the most virulent form of this disease. This is also profusely illustrated with charts (temperature), etc. The lesions of the skin and of the lymph glands, of the joints, of the respiratory organs, of the circulatory apparatus (pulse tracings), arrhythmic heart action, tachycardia, and every form of pulse variation are chronicled and illustrated. Next follow the participation of the digestive apparatus, the urinary organs, the nervous system, and lastly, the complications and the sequelæ.

A chapter deals with the various forms of post-diphtheritic paralysis and also hemiplegic paralysis.

Next we come to diphtheritic nephritis, then to the chapter on diphtheritic rhinitis.

Diphtheritic laryngo-tracheo-bronchitis and diphtheritic croup, are the subjects of the next chapter. This chapter is truly a masterpiece, and is the stronghold of this monograph, for every detail is herein carefully outlined.

Diphtheritic vulvo-vaginitis, diphtheritic ophthalmia, diphtheritic otitis, the combination of diphtheria with measles, scarlet fever, and pertussis receive due consideration. Diphtheria and varicella, diphtheria and ileo-typhus, are the subjects given due prominence.

The chapters on the diagnosis and prognosis are followed by the most vital one, which is that on therapeutics. The author describes all the remedies which have been used and recommended, for both the local and constitutional treatment of this disease. He lays careful stress on the amount of antitoxin to be used in a mild and in a severe form of this disease, and the dose to be given in cases in which there is a croupy manifestation of laryngeal stenosis. It is interesting to learn, for instance, that this distinguished pædiatrician recommends the beginning dose to be three thousand units in malignant cases. The author advises coolness and a careful study of the severe symptoms following this latter injection; and if there is no amelioration of the symptoms, then he advises a second injection of the same dose. The statistics correspond with those given in the discussion of the paper on the treatment of diphtheria, read before the section on pædiatrics of the New York Academy of Medicine, December 10, 1896, by Louis Fischer, M.D., of New York, published in the MEDICAL RECORD, December 26, 1896.

"Medication and Stimulation" and "Treatment of Collapse" are given proper weight, and here we note that on page 331 the author opposes the use of strychnine injections. The next chapter deals with the treatment of laryngeal croup. This contains fifteen illustrations (instrumental and anatomical), detailing all the methods pursued in the intubation and extubation of the larynx, much of which is to us certainly not new, but adds greatly to the completeness of the work. Dr. Edwin Rosenthal, in a paper read before the State Society of Pennsylvania, May 21, 1896, has given an immense amount of study to the same details described by Professor Baginsky, and his statistics of recoveries are virtually the same.

The book ends with the description of tracheotomy, inferior and superior; the method of introducing the cannula, and the after-treatment.

To one desiring a complete insight into the subject of all forms of diphtheria, we can certainly recommend this book. There is nothing in the English language so complete as this work. Based as it is on Professor Baginsky's personal experience, and he being really the first man thoroughly to educate the profession of the world to the true status of the antitoxin question, this book completes to date all that can be said on this subject. Nothing has been omitted; the anatomical, bacteriological, pathological, and instrumental (mechanical) illustrations are so perfect that no praise that we can bestow on this book can be too much. The book deserves a translation and a very prominent place in the library of every up-to-date physician.

Society Reports.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 9, 1898.

T. MITCHELL PRUDDEN, M.D., PRESIDENT.

A Case of Primary Tuberculosis of the Colon in a Child.—DR. ROLAND G. FREEMAN presented this report, together with the specimens. The patient had been passing bloody-looking urine for a long time prior to being admitted to St. Mary's Hospital on September 28th. One week before it had been kicked in the abdomen. The child was poorly nourished. No specimen of urine could be obtained, because of incontinence. All over the right side of the abdomen there were tenderness and bogginess, and the abdomen was slightly retracted. The child had a convulsion shortly after admission, another later in the night, and three more the following day. Death occurred on the second day after admission. At the autopsy the examination of the heart, lungs, and liver was negative. The spleen was smaller than usual, and its capsule was shrivelled. The bladder was distended, so that it reached to one inch and a half below the umbilicus. Connecting the bladder with each kidney was a large, tortuous ureter, about the size of the colon. Pressure on the bladder distended both kidneys and ureters and caused the urine to be discharged from the urethral orifice. The lymph nodes adjacent to the caput coli were enlarged and, on section, were found to be cheesy and to contain creamy fluid. The caput coli contained a large tuberculous ulcer. Examination of the brain was negative. The interesting features of the case were the dilatation of the bladder with hydronephrosis, the acute nephritis, and the tuberculosis of the caput coli and adjacent lymph nodes. The frequency of the occurrence of tuberculosis of intestinal origin, Dr. Freeman said, was a disputed point, men of wide experience holding radically different opinions. Sims Woodhead [1] states that he has seen a lage number of cases in which the infection seemed to be from the intestine, and Cohnheim, Aufrecht, and Peterson [2] hold the same view. Schmidt [3] states that out of a series of three hundred and thirty-six autopsies at Freiburg there were six cases of primary infection of the mesenteric lymph nodes, while Eisenhardt, of Munich (quoted by Schmidt), in a seris of one thousand autopsies found only one such case. There had been very few such cases reported in New York. Dr. Hodenpyl [4] had reported one in an adult in 1895 to this society, and Dr. Northrup [5] had reported one in an infant, and he had himself reported previously two such cases—one with the late Dr. J. Lewis Smith to the Pediatric Section of the Academy of Medicine,[6] and the other to this society in 1896.[7] In Dr. Hodenpyl's case there was no involvement of the lung. In Dr. Northrup's case there was a generalized tuberculosis with but slight involvement of the lung, the origin of which had evidently been in the intestine. In the case presented by the speaker to the Pediatric Section of the Academy of Medicine no lesion was found in the lungs. One bronchial lymph node at the bifurcation of the trachea contained tuberculous nodules, but no fluid contents. The mesenteric lymph nodes adjacent to the caput coli were markedly enlarged, and some of them contained broken-down cheesy material. In his second case there was an ulcer of the caput coli, and beneath it was a large tuberculous lymph node. However, as there were tuberculous lesions disseminated through the mesentery, the mediastinal and bronchial lymph nodes, and lung, the exact origin of the disease was somewhat a matter of conjecture.

A Case of Hodgkin's Disease Terminating with Leucocytosis.—DR. HARLOW BROOKS reported this case. (See page 874.)

Three Cases of Lympho-Sarcoma or Hodgkin's Disease.—DR. F. C. WOOD reported these cases. He said that the first patient was a large, well-nourished man, who had entered the hospital with a complete paraplegia, loss of power of both sphincters, and with a very vague history. The autopsy showed that the bronchial lymph nodes were enormously enlarged, and that the disease had involved the bodies of the vertebræ, the vertebral canal, and the spinal cord. There was one small nodule in the liver. The retroperitoneal glands were not enlarged, and the glands in the neck, axilla, and groin were not affected. The involvement of the tissue around the lymph nodes made it seem proper to call the case one of lympho-sarcoma. In the second case, the specimens had been removed by operation from a poorly nourished child of five years, under the supposition that the glands were tuberculous. Microscopical examination showed that the nodes were simply hyperplastic. In two or three weeks there was a recurrence, and all the superficial glands rapidly enlarged. The blood showed a marked diminution in the hæmoglobin. The specimens presented from the third case were lymph nodes of the neck which had been removed from a colored woman who had been in St. Luke's Hospital for about two months. About four months before admission she had noticed a swelling of the right side of the neck. This had increased in size, and she had lost flesh and strength rapidly. The enlarged glands extended from the zygoma to the clavicle. Microscopical examination of the blood showed nothing but an extreme anæmia. There was marked œdema of the lower extremities. The autopsy revealed only enlargement of the glands of the right side of the neck. These glands could be rolled around in the loose connective tissue, and, on section, were opaque and firm and had no cheesy centres. The retroperitoneal glands in some places were calcareous. The spleen in this case was quite small. There were a few small nodules in the lung, apparently sarcomatous. There was also a small, firm, whitish nodule in the liver. The kidneys were normal. On section of the lymph nodes their centres were seen to be the seat of a necrosis. Around this was a small ring of lymph cells, and within this were a few giant cells and tubercle bacilli. There were nodules in the lungs showing tuberculous change. The speaker said that the enlargement was too rapid for an ordinary tuberculosis, and the process in the lung was so old that the nodules were calcareous. The question then arose as to whether the case was one of tuberculosis or of Hodgkin's disease with an accidental infection. A number of cases had been described under the name of Hodgkin's disease in which there had been a rapidly fatal termination, associated with enlargement of the glands in certain regions, and in which tubercle bacilli could be demonstrated. In these cases there was no tendency to general tuberculous infection.

DR. LEWIS A. CONNER said that he hoped an explanation would be forthcoming which would enable a proper classification to be made of these puzzling tumors. At the New York Hospital there had been

[1] Woodhead: Medical Press and Circular, 1888, xiv., p. 265.
[2] Wurzburg: Therapeutische Monatshefte, 1891, p. 18.
[3] Schmidt: Inaugural Dissertation. "Ueber die Häufigkeit der Tuberculose," etc. Freiburg, 1897.
[4] Hodenpyl: MEDICAL RECORD, 1895, i., p. 313.
[5] Northrup: Proceedings of New York Pathological Society, 1890, p. 42.
[6] Smith and Freeman: American Medic. Surgical Bulletin, 1895, p. 1,461.
[7] Freeman: Proceedings of New York Pathological Society, 1896, p. 105

two cases in the past year, neither of which had corresponded with the classical description of Hodgkin's disease, and in neither had there been any of the usual gross or microscopic appearances of tuberculosis. The glands had been individually enlarged and, on section, had presented a waxy, translucent appearance and had been of fair consistency. In both instances the disease had lasted a considerable time. In one there were immense masses of glands in the neck only, but each was distinctly outlined. Under the microscope there had been found lymphoid cells with distinct stroma between them.

Dr. Wood said that he had seen one similar case in which the glands had been removed by operation, and, on section, there had been nothing found but a hyperplasia. However, on inoculating a guinea-pig with some of the gland, the animal had died of tuberculosis. The enlargement of the glands had occurred too rapidly—within about three weeks—so that it seemed probable that the infection had been rapid and the glands had been removed before the occurrence of characteristic tuberculous changes.

Dr. Harlow Brooks said that he had noticed, in a recent report of an English bacteriologist concerning observations on the glands in Hodgkin's disease, that this observer had found a great many germs in the glands, most of them being either streptococci or members of the colon group. The opinion of this investigator seemed to be that these were either post-mortem or terminal infections. The tubercle bacillus had been found in a good many of the reported cases, but these had not been included under the classification of Hodgkin's disease. When the autopsy had been made fairly early no growth had been observed.

Perforating Ulcer of the Stomach with Hour-Glass Contraction of the Stomach.—Dr. Leon U. Le Wald reported this case. The patient was a woman of forty-three years who had been admitted to hospital with evident signs of general peritonitis. A very indefinite history only could be obtained, but it was stated that she had suffered from indigestion and pain in the region of the stomach for about three years. At the autopsy the abdominal cavity was found to contain a large quantity of purulent fluid. In the anterior wall of the stomach, just slightly anterior to the lesser curvature and about the middle of the stomach, was a perforating ulcer. It measured four millimetres in diameter, had very sharply cut edges, and felt somewhat indurated. The stomach was divided into two nearly equal portions by a constriction situated to the pyloric side of the ulcer. There were adhesions between the posterior wall of the stomach and the pancreas and between the stomach and liver and transverse mesocolon. On opening the stomach, there was an aperture discovered between the two portions which just admitted the tip of the finger and measured thirteen millimetres in diameter. Coming off from the cardiac side of this constriction was a small pouch which led to the perforation on the anterior wall of the stomach. The area surrounding this was indurated, but microscopical examination of this portion revealed only a chronic inflammatory process. From the presence of the surrounding adhesions and from the general appearance it did not seem probable that the hour-glass contraction of the organ was congenital; it was more probable that a former ulcer in the process of healing had caused a drawing up of the stomach wall.

An Unusual Lesion of the Intestine in Typhoid Fever.—Dr. Le Wald also reported this case—that of a male, twenty-eight years of age, who was supposed to have died in the third week of a typhoid fever that had been contracted at the Montauk Point camp. The clinical record was that of a severe typhoid fever. The blood gave the Widal reaction. At the autopsy very typical lesions were found in the small intestine. There were also ulcers with elevated edges extending throughout the large intestine, even down to the anus. The mesenteric glands were enlarged, and some of them were suppurating. The unusual lesion in the case, however, was the extensive involvement of the vermiform appendix. The organ was enlarged to the size of one's index finger. It was of usual length, but measured two inches in circumference toward its base. On opening it, the lumen was found nearly obliterated, due to the marked infiltration and swelling of the mucous membrane. The infiltration also extended into the mucosa and muscular layers. A number of small superficial ulcerations of the mucous membrane were present, particularly toward the base. The lesion was considered important as an explanation of the occasional cases of typhoid fever which give abdominal symptoms so closely simulating ordinary appendicitis. Only recently a patient had been operated on at Bellevue Hospital for appendicitis, when the incision revealed the presence of typhoid fever with an involvement of the appendix similar to the present case.

Dr. E. K. Dunham said that he had examined microscopically some of the lesions in the intestine and other organs in this case, because it had seemed to be such a typical example of typhoid fever. His attention had been called to the observations of Dr. Mallory in typhoid fever. This investigator had studied the lesions in a number of cases, notably one in which death had occurred before ulceration had taken place, and had arrived at the conclusion that the lesions in typhoid fever were essentially proliferative; that the endothelioid cells, as he called them, of the lymph nodes in the intestine and elsewhere, and the endothelium of the veins and lymphatic vessels proliferated during the course of the disease; and that as a result of this proliferation phagocytic cells of large size were produced, which wandered into the lymphatics and blood-vessels and destroyed the ordinary leucocytes and red blood cells. In this way it seemed possible that they might clog some of the vessels and cause local necrosis. Dr. Dunham said that he had seen some of the specimens prepared by Dr. Mallory, and they were very suggestive and instructive. Certainly some of the phagocytes were crowded with red blood corpuscles, and others with leucocytes and lymphocytes. Although the specimens received from the case now under discussion had been very much altered, it had seemed to him that in the sections which he was about to exhibit to the society there were similar appearances. Dr. Mallory, in his publication of last April, had likened typhoid fever to tuberculosis, claiming that in tuberculosis the proliferation was focal, while in typhoid fever it was general. This difference was explained by the fact that the poisons produced in typhoid fever were diffusible and absorbable, whereas in tuberculosis they were more nearly confined to the region in which the bacillus is found. Dr. Dunham then exhibited under the microscope a series of six sections illustrating the points already alluded to.

Dr. Hodenpyl said, regarding the swelling and ulceration of the lymphatic nodules in the appendix in typhoid fever, that he had seen this condition twice, but without any symptoms which could be regarded as those of appendicitis. Looking over the literature some time ago, he had found that there had been a number of such cases reported, but in none of them apparently had there been any symptoms of appendicitis. The same held true of tuberculous ulcers of the appendix which are observed from time to time.

Dr. Brooks said that a member of General Lee's staff had made many autopsies on typhoid-fever patients dying in the camp near Jacksonville. This

gentleman, Dr. Bolling Lee, had stated to him that one of the patients had presented the symptoms and physical signs of an acute appendicitis, but the surgeon had refused to operate. At the autopsy the appendix was found to have been perforated by an ulcer which appeared to be typhoid. He had also found in these patients very commonly large ulcerated areas in the intestine, which were thought to be due, not to the typhoid fever, but to a phagedenic condition associated with malnutrition.

A Case of Primary Tuberculosis of the Cervix Uteri.—Dr. F. S. Matthews reported this cases (see page 872).

Duodenal Ulcer.—Dr. Lewis A. Conner presented an ulcer of the duodenum removed from a man twenty years of age, who had entered the Hudson Street Hospital with the history of having been severely ill for less than twenty-four hours. There were evidences of peritonitis, and, suspecting appendicitis, the abdomen was opened over that organ, but the appendix was found to be normal. There was a general peritonitis with gas in the peritoneal cavity, but the condition of the man was so bad that no further search was admissible. He died a few hours later. The post-mortem showed a perforation in the anterior wall of the duodenum, immediately below the pylorus, and in the most favorable situation for operative interference. Within the last four years there had been at that hospital five cases of duodenal perforation, as well as one perforation of a gastric ulcer and another from an ulcer in the upper part of the jejunum. In four of the cases the ulcer had been on the anterior wall and in the remainder on the posterior wall. In one case there was an ulcer in the stomach as well as in the duodenum. In most of the cases the ulcers were very close to the pyloric ring.

Chronic Ulcer of the Stomach.—Dr. E. Hodenpyl presented two such cases. The first of these was a man thirty-five years of age, who had been a very heavy drinker except during the last year, when he had been more temperate. Seven days before death, and without any warning, he had a very profuse hemorrhage from the stomach, which almost exsanguinated him. There was a well-marked nephritis present on admission to the hospital, and he died seven days later in a uræmic attack. At the autopsy, aside from the chronic diffuse nephritis and marked œdema of the meninges of the brain, the only noteworthy feature was a circular ulcer, with sharply cut edges, on the upper curvature of the stomach about one inch from the pylorus. On the base of this ulcer were two rather large arteries with open mouths. The second case was that of a woman, fifty-one years of age, who had been well up to two months before death. She complained of increasing weakness and occasional attacks of vomiting. On admission to hospital, there was some tenderness over the epigastrium, and her temperature was 99.5° F. The autopsy revealed an intense general peritonitis, with fully two quarts of the stomach contents in the abdominal cavity. There were numerous pockets of pus all over the abdominal cavity, shut in by firm adhesions, most of which were fibrinous, but some were distinctly organized, indicating that the peritonitis had existed for a considerable time. The cause of this subacute peritonitis was a very large perforation in the anterior wall of the stomach, and two inches from the pyloric opening and near the lesser curvature. The perforation was through the base of an ulcer having sharply cut edges, one inch in diameter, which had apparently occurred some time previously.

Dr. James Ewing said he was reminded of the case of a woman who had entered the Roosevelt Hospital with symptoms of perforation of a gastric ulcer. She remained in a critical condition for one month, with symptoms of peritonitis. At the autopsy it was found that the first perforation had caused a peritonitis, involving the surface of the stomach and the greater omentum; that the peritonitis has been limited by the limits of the omentum; and that an abscess cavity had formed, which had been shut off from the rest of the abdominal cavity.

Intra-Nasal Growths.—Dr. Robert C. Myles presented two growths from the nose. The first, which seemed macroscopically to be a papilloma, had been removed from the inferior turbinate of a man. According to recent investigation, Dr. Myles said, these growths were claimed to be simple hypertrophies. The other growth, from a girl of twelve years, was three inches in length. It grew from the under surface of the middle turbinate and from the ethmoid bone, and, following the channel of the middle meatus, passed into the rhino-pharynx. The tumor was hidden from view in the nose, the only part visible being that in the throat. It presented a peculiar chain-like appearance, apparently myxomatous.

Ulceration of Both Stomach and Duodenum with Perforation of the Splenic Artery.—Dr. Le Wald presented specimens from a case in which there was ulceration of both the stomach and duodenum. They had been removed from a girl of twenty-two years. Two years ago she had had an attack of pain in the stomach and had vomited blood. She had been recently admitted to the hospital because of indigestion. The stools were noticed to be tarry, and she vomited blood in considerable quantity until death occurred, about six hours after entering the hospital. At the autopsy it was found that the stomach and intestines were filled with blood, and there was an ulcer, one inch in diameter, on the posterior wall of the stomach, having characteristically clear-cut edges, which were adherent to the pancreas. At the bottom of this ulcer was an opening into the splenic artery, and this had been the source of the fatal hemorrhage. There was also an ulcer in the duodenum, just below the pylorus, which had healed, and which exhibited a certain degree of contraction of the walls of the duodenum, thus illustrating the method of production of the hour-glass contraction of the stomach in the case presented earlier in the meeting.

Dr. Harlow Brooks presented a fresh specimen of ulcer of the stomach.

A Preliminary Communication on the Bio-Chemistry of the Bacillus Tuberculosis.—Dr. P. A. Levene presented this paper (see page 873).

Dr. E. K. Dunham said that some years ago when tuberculin was first being used in Germany there had been a death after the tuberculin treatment. On autopsy there had been observed what appeared to be submiliary tubercules scattered through the lungs and several of the other viscera, but a search made by Professor Orth and various assistants, including himself, had failed utterly to show any evidence of the presence of tubercle bacilli. The observation seemed to be very interesting because there were already present, as far as the morphology was concerned, the beginnings of tuberculous formation, an apparent proliferation due to toxic substances. The process had not gone far enough to cause degeneration.

The society then went into executive session.

Coryza in Infants.—

℞ Cocainæ hydrochlorat..... 2 parts.
Aq. dest..... 50 "
Glycerini..... 50 "
M. S. One drop instilled into each nostril three or four times a day.

—Naegeli-Akerblom.

Therapeutic Hints.

Car Sickness. — When a person who contemplates a journey details a history of car sickness, I advise a dose of calomel at night and Epsom salts before breakfast the day of starting, since during the journey and often for a day or two after the trip the bowels are constipated. Light, digestible food is allowed. In an emergency case my usual treatment is to lay the patient down in as comfortable a position as possible, apply a bandage to the eyes with cold water, and give a tablet consisting of acetanilid, gr. iiiss.; sodium bicarbonate, gr. i.; sodium bromide, gr. $\frac{1}{10}$; citrate of caffeine, gr. ss.; and, if the heart's action seems weak, trinitrin, gr. $\frac{1}{100}$.—W. M. Bemus.

Treatment of Hemorrhagic Infarction of the Lungs. —The treatment is purely symptomatic. Hemorrhage is rarely so profuse as to require the use of hæmostatics. Absolute rest in bed and regulation of the heart's action, in case of disease of that organ, may be necessary. For this purpose digitalis may be employed when the heart is acting weakly. If signs of collapse develop, such as cold extremities, etc., alcoholic stimulation and the application of sinapisms to the body and extremities are indicated. Extensive dry cupping will relieve the dyspnœa better than anything else. For the dyspnœa and the cough, as well as for the enfeebled and irregular cardiac action, five to ten minims of Magendie's solution of morphine may be given hypodermically with good effect. Pleurisy and pneumonia, should they occur, must be treated independently of the infarction.—R. C. M. Page.

Hypodermic Injections of Alcohol and Tincture of Belladonna in the Treatment of Apparent Death in the Newborn.—According to the *Semaine Médicale*, Dr. Brown, to the classical means of combating apparent death in the newborn, has added a new remedy. He is accustomed to inject under each arm of the child five drops of whiskey, to which has been added a drop of tincture of belladonna. Soon after the child opens its eyes and utters a cry, which is indicative of the beginning of respiratory function. In case alcohol and belladonna do not resuscitate the child immediately, the author gives a hypodermic injection of from four to eight grams of hot sterilized water, and introduces into the stomach the same quantity of this liquid, to which has been added a drop of aromatic spirits of ammonia.

Acute Conjunctivitis.—Protargol, in two to ten-per-cent. solutions, dropped into the eyes, three, six, or twelve times a day. In the chronic forms of conjunctivitis with hyperplasia, the results are not so satisfactory.—Pergens, *Klin. Monats. f. Augenh.*, April.

Opium in Diarrhœas of Young Children.—It is contraindicated: (1) In the first stage of acute diarrhœa, before the intestinal canal has been freed from decomposing matter; (2) when the passages are infrequent and of bad odor; (3) when there is a high temperature or cerebral symptoms are present; (4) when its use is followed by elevation of temperature or the passages become more offensive. It is indicated: (1) When the passages are frequent, with pain; (2) when the passages are large and watery; (3) in dysenteric diarrhœa, together with castor oil or a saline; (4) in late stages, with small, frequent, nagging passages; (5) when the passages consist largely of undigested food and the bowels act as soon as food is taken into the stomach.—Crandall.

Pernicious Vomiting of Pregnancy.—Dr. G. W. Harris (*The Medical Age*, August 25th) concludes a paper on this subject by stating that there are certain methods of procedure which the experience of this and similar cases he has met with lead him to accept as safeguards in future emergencies. (1) In cases of uncontrollable vomiting of pregnancy, when the woman's health begins to fail and emaciation becomes marked, he counsels insistence on terminating the pregnancy, and, failing to gain the consent of the patient and her friends, withdrawal from the case at once. (2) When active interference is decided upon in cases that come under treatment in the so-called third stage, he deprecates wasting time by the slower methods, and urges rapid dilatation and the emptying of the uterus at once. (3) After emptying the uterus by this or any other method, the patient should always be left in charge of a competent nurse or a physician, at least during the twenty-four hours immediately following.

Diuretic in Ascites and Œdema from Bright's Disease.—

— *Westminster Hospital.*

Biliary Lithiasis.—Ox bile is used internally in biliary colic by Gautier (*Rev. Méd. de la Suisse Rom.*, June 20th). The bile is decolorized to get rid of the toxic coloring matter (especially bilirubin), and then sterilized at 104° to 105° C.; one hundred grams of bile produce ten grams of the extract. Of this latter he gives ten to twenty centigrams in pill or capsules twice a day after meals. This treatment cannot be regarded as a certain preventive of colic, since, if the gall bladder is full of stones, it does not cause them to disappear, though its effect will be evident later. This treatment is also to be recommended after operations for the evacuation of calculi, to prevent relapses.

Conservatism in the Use of the Stomach Tube.—Dr. A. L. Benedict (*American Medico-Surgical Bulletin*, June 25th) concludes an article on this subject in the following manner: "(1) Don't use the stomach tube simply because you want to be considered scientific and up to date. (2) Don't withdraw stomach contents for examination unless you are prepared to examine them. (3) Don't discard external means of physical diagnosis because you have a stomach tube. (4) Don't expect too much from diaphanes, electric buzzers, buckets, complicated tubes, etc. All of these have their uses, but are available in very rare cases. (5) Don't pass the tube without first examining the mouth and throat, and also the heart and arteries, and at least inquiring as to pregnancy, piles, and other possible complications. (6) Don't pass the tube as a means of treatment unless you know precisely what you wish to accomplish with it. (7) Don't introduce a weight and bulk of water which you would consider injurious if swallowed. As a rule, don't introduce more than a pint at once and never more than a quart. Don't be deceived by the ball-valve action of a particle of food or any other cause which may allow water to remain in the stomach. Make sure that you withdraw as much as you introduce, except that you may allow a little for leakage through the pylorus, or possibly for absorption. Remember that the more a stomach can hold the less it ought to. (8) Don't imagine that the gastric douche will cure all the diseases of the stomach; you would laugh at a gynæcologist who held such a view about the vaginal douche. (9) Don't imagine that a stomach is doing well until it can digest plain but varied diet without mechanical interference. Don't speak of a patient as cured until he can indulge in all the ordinary food without medical aid

and without injury. (10) Don't let the patient learn to pass the tube himself. This rule holds for his benefit as well as yours. (11) Don't fail to use the tube or to have it used when the indications outweigh the contraindications."

Gouty Neuritis and Allied Affections.—

℞ Colchicine ..... gr. $\frac{1}{60}$
Sulphate of quinine ..... gr. i.
Extract of colocynth ..... gr. i.
M. et ft. pil. S. One three times a day.

Correspondence.

OUR LONDON LETTER.

GENERAL MEDICAL COUNCIL—SURGEONS' GOWNS OF THEIR COLLEGE—SARCOMA—LONDON WATER SUPPLY —ROENTGEN SOCIETY'S CONVERSAZIONE.

London, November 25, 1898.

The autumn session of the General Medical Council began on Tuesday. The president followed the bad custom of delivering an opening address, but he was commendably brief on this occasion. Sir W. Turner is a strong man and may yet abandon a plan which only wastes time—and time is a very expensive item, though the Council seems scarcely to realize its cost. To repeat what every one knows is a dreary proceeding. To go over the items of an agenda paper, or even to set forth what might well be included in such a paper, is an unworthy task for the president of such a body. The councillors are not novices in public work and should set to work with business-like alacrity.

The afternoon of Tuesday was frittered away in consequence of the objections of some councillors to others being allowed to inspect the documents of the council. I told you how at the former session this question arose. Mr. Victor Horsley had been denied access to such documents by direction of the president. He appealed to the council against this high-handed proceeding, and a standing order was made as to the way in which the documents could be consulted by members. Strong man as he is, and with plenty of common sense, Sir W. Turner evidently blundered, and now that the obstruction of the standing order is manifest to all he should move that it be rescinded. To consume half a day in moving separately for the production of documents in each case is to reduce the proceedings to the level of a farce.

It was satisfactory to find most of the weighty councillors were in favor of the contention that every member has a right to examine all papers belonging to the council. It will strike you as ridiculous that documents in the hands of office clerks are not to be perused by their employers, or that the president or a committee may commit the council to legal proceedings and refuse their colleagues leave to see the evidence or the lawyer's bill. Now that another half-day has been wasted, we may hope all objections will be withdrawn. The subject was renewed on Wednesday, but leave was given in all the cases requested, and opposition only wasted time.

The rest of the day and Thursday were devoted to penal cases. The council also considered several applications to be restored to the register on the part of persons whose names had been removed. Among other subjects the tables supplied by the army and navy departments gave rise to some conversation, as they seemed to show that persons holding the diplomas of the conjoint board had been specially successful at the competitive examinations for commissions. Some jealousy among the corporations was evinced, which will scarcely interest you, but it illustrates the unfairness of denying London students the opportunity of becoming M.D.'s.

The question of preventing graduates from using degrees who had been expelled from the register was left for the president to represent to government last session, and Sir William stated what he had done. The universities seem now to have come to the conclusion that they should have power to deal with their black sheep. If they consent to legislation in this sense, there is hope for a bill indorsed by all the licensing bodies.

The annual meeting at the Royal College of Surgeons has afforded plenty of material for jesting at professional gatherings. The claim of members to representation was brought forward in a mild resolution moved by Mr. Joseph Smith; but little is expected to come of it, though Surgeon-General Ince, who is nothing if not amusing, urged the council to give members a vote on the ground that, like the baby in the soap advertisement, they will not be happy till they get it, and when they do they cannot use it. Several speakers pointed out that members lost all interest in the college from the consciousness that they were cold-shouldered by its governing body.

The council scored by its declaration that the question of a gown for members had been referred to a committee. So the question of clothes is to take precedence of rights. Dr. Alderson seemed quite unconscious of the humor of the situation when he gravely recommended a white gown with a purple border like a toga to be worn at operations and social functions. It borders on broad farce for the annual meeting to be thus occupied, but it has added to the fun at social functions since.

A less reverent member says, "Why not utilize the dissecting-dress?" another suggests a night-gown. I asked a fellow what right the council had to institute a gown. He said: "None at all; but every man has the right to dress as he likes, provided he observes decency." And for his part he thought tar and feathers would do very well for both fellows and members.

Sarcoma has lately received a good deal of attention at the societies. Thus, besides the discussion at the Medico-Chirurgical Society noticed in my last, it came up at the Pathological as well as at the Clinical Society. At the former Mr. T. D. Lister showed a specimen of sarcoma of the right auricle of the heart associated with the same disease in the right kidney, taken from a child aged four years. The growth was round-celled with considerable extravasation of blood. Death occurred within a month of the first complaint of abdominal pain. Mr. Lister thought the primary growth was in the heart.

Mr. Carwardine communicated a brief account of a tumor of the rectum, which clinically appeared to be epithelioma, but the sections showed it to be a spindle-celled sarcoma with some large round cells and giant cells. Very few such cases have been recorded and their authenticity has often been doubted, but Mr. Carwardine thinks his specimen proves their reality. Mr. Barker mentioned a case of primary sarcoma of the colon, and Mr. Boyd one of the rectum. Mr. Targett looked upon such cases as rare except as secondary to lympho-sarcoma. The type generally was spindle-celled. Dr. Hunter mentioned a case of round-celled sarcoma of the cæcum with disseminated growths in various parts. Dr. Rolleston did not consider round-celled sarcoma rare in the digestive tract, nor did Dr. Voelcker, who told of a case of spindle-celled sarcoma of the ileo-cæcal valve and one of melanotic sarcoma of the rectum.

The subject was introduced at the Clinical Society by Mr. Howard Marsh relating a case of primary sarcoma of the synovial membrane of the knee-joint. The patient, a man, twenty-one years of age, was admitted in September, 1892, with a swelling of fourteen months' duration which was thought at first might be due to tuberculous disease. When cut into, it was found to be entirely in subsynovial tissue and of the nature of new-growth. It was removed with a zone of surrounding tissue and found to be a mixed spindle- and round-celled sarcoma. Recurrences took place in March and December, 1895, August, 1896, October and lastly December, 1897. The new growths on the four former occasions were removed, but on the last amputation was performed. On examining the joint, a growth the size of a bantam's egg was found spring-

ing from the synovial membrane at the back of the joint, and there was a smaller mass extending forward into the joint between the condyles.

Mr. Marsh said he had not met with another case of primary sarcoma of synovial membrane. The history extends over six years, the disease remaining local, and the patient is now well.

Mr. Hutchinson, Jr., referred to a case of a boy, aged ten, who had a fibro-sarcoma growing from the posterior ligament of the knee, in which, after several recurrences, he had amputated at the hip with a fatal result. He thought there were cases of regional sarcoma, and mentioned a case affecting the abdominal wall recurring until the wall was covered with scars and new growths. He asked if Mr. Marsh's case was fibro-sarcoma, and was answered that it might fairly be so described. These growths are probably such as Sir James Paget has called recurrent fibroids. Mr. Marsh now has under his care in the hospital a man with a similar growth of the cheek which has been excised so many times that it is thought no further operation is feasible. The president (Mr. Langton) recalled a case recorded by Sir J. Paget affecting the foot. Twelve or more recurrences were operated on with ultimate recovery.

At last the East London Water Company has begun to extend the hours during which some of its customers can have a supply. I say *some*, because only a part of its district at present receives the increase, and it will not be general until next Monday or Tuesday. By then it is expected the water will be on for eight hours out of the twenty-four. For above a quarter of a year there has been a shortage, part of the time to a most distressing extent; but the company still considers itself entitled to the quarter's payment. In fact, to one of the customers who objected to an extra charge for a bath during that time on the ground that he had never had enough for other uses, the company replied that it had incurred great expense through the drought and could not afford to make a reduction!

The other companies have taken steps to promote bills in Parliament. They will join to obtain authority for making intercommunication beween the pipes. Some of them ask to be allowed when necessary to take more water from the Thames. All ask for this whenever the local government board may consider it necessary. Meantime the Royal Commission on the supply has resumed its sittings after a long interval, and we shall have to wait for its report. The county council is promoting bills enabling it to buy out the companies and to obtain a further supply from Wales.

Mr. Mansell-Moullin, as the new president of the Roentgen Society, entertained the members on Tuesday evening at a conversazione, when demonstrations were given illustrating the uses of the *x*-rays, and the ex-president, Professor Sylvanus Thompson, showed experiments with the Tesla oscillator. This juvenile society is growing satisfactorily.

Situation of Pain in Intra-Abdominal Conditions.—The small intestines are abundantly supplied by and intimately associated with the great sympathetic ganglia. The fickle-minded sympathetic nerves have no geographic sense; hence a pain coming from an obstruction in any part of the small intestine is expressed in the solar plexus of the sympathetic or superior mesenteric ganglia. This holds true with other intra-abdominal conditions. In a large percentage of cases of appendicitis a careful review of the history of the pain will show that it was first expressed above the umbilicus in the region of the superior mesenteric ganglion.—Eastman, *Denver Medical Times.*

THE ORIGIN OF THE PLAGUE IN VIENNA.

To the Editor of the Medical Record.

Sir: In an editorial of the Medical Record of October 29, 1898, and in an article under "News of the Week" entitled "The Plague in Vienna," the first plague victim is referred to as "Dr. Nothnagel's assistant" and as "an assistant in the laboratory." Herr Barisch was not an assistant, but was the laboratory "Diener," or janitor. In the European laboratories these "diener" are generally men of no particular culture or training, who are employed in a bacteriological laboratory, for example, to care for the animals, to clean and sterilize Petri dishes, prepare culture media, etc. They acquire a certain amount of skill and knowledge, and likewise the contempt bred of ignorant familiarity. One report from Vienna stated that this "Diener" was suspected of smoking in the laboratory, and another report that he had the habit of biting his nails—both naturally dangerous habits in the company of bacilli. Dr. Müller, Nothnagel's assistant, and the sister of charity were infected from Barisch before it was known that he was sick with the plague.

The unfortunate affair cannot be considered as a proof that scientific investigation in scientific hands is a source of danger to the health of communities, but rather as a striking example of the criminality of allowing persons who lack the proper training and intelligence to expose themselves in any way whatsoever to the invisible executors of nature's sanitary laws.

J. Edwin Sweet, M.D.

Giessen, November 19, 1898.

"HAWAII FROM A HEALTH POINT OF VIEW."

To the Editor of the Medical Record.

Sir: In your last week's issue, I observe a communication from Dr. F. R. Day, member of the Hawaiian board of health, criticising your editorial, "Hawaii from a Health Point of View," of October 15, 1898. In it the writer impugns the correctness of certain statements made by me in a communication to the Medical Record of April 27, 1889, to which reference is made in the editorial, and makes the following complimentary allusion to myself: "If Dr. Prince A. Morrow is the best-informed person on the subject, then I am sorry to say that he knows very little about the conditions as they exist here to-day. He describes them as they were in the first half of the present century, and we are led to infer that the same conditions prevail at the present time."

It is evident that Dr. Day has not read my article to which reference is made, or he would not have fallen into such an error. The article in question was written years before the advantages or disadvantages of "Hawaii from a health point of view" had any practical interest to the people of this country. It was entitled "Causes of the Depopulation of these Islands, the Demographic Effects of Introduced Diseases," etc., and was devoted to a study of the causes which have led to the rapid decay and death of a population which in a little more than a century had dwindled down from four hundred thousand to less than forty thousand. Prominent among these causes I placed the introduction in a virgin soil of diseases peculiar to civilization, favored by certain conditions which I considered in detail, but will not occupy your space by quoting here.

As examples, I instanced the extraordinary mortality of syphilis, introduced by Captain Cook's men; of measles, introduced in 1849; of small-pox, introduced in 1853, etc. I stated that "the rapid spread

and excessive mortality of the acute infectious diseases were attributed to the intimate social relations of the natives, their disregard of precautions, and their free use of cold water upon the first accession of febrile symptoms." I also called attention to the remarkable influence of hereditary immunity already exhibited in the production of a milder type of disease and diminished mortality. I am glad to see that Dr. Day, however unintentionally, has confirmed these statements in every particular. He says: "It is true that in the early part of this century contagious diseases wrought sad ravages among the native population. It is true that measles and whooping cough had a terrible mortality in 1849, because the natives in their ignorance persisted in bathing in the sea and the cool mountain streams to allay the accompanying fever. It is true that small-pox slew thousands in 1853 for similar reasons, and because they had not the protection of vaccination."

He also confirms my testimony in regard to the modification in the type of disease seen at the present day: "During the past five months quite a general epidemic of measles has prevailed, brought here by the United States troops; only two persons have died of the disease—one in August and one in October; and yet Dr. Morrow says 'The mortality was excessive, almost every case terminating fatally.'"

In regard to this manifest perversion, I can only say that it is hardly ingenuous, or even honest, on the part of Dr. Day to quote a statement of mine which distinctly referred to an epidemic of measles in 1849, of acknowledged virulence, and apply it to a mild epidemic in 1898, and which occurred nearly ten years after the article containing the statement had been published.

There is another question raised in Dr. Day's criticism of your editorial, which, in view of the recent annexation of the Hawaiian Islands by the United States, has a special interest for the people of this country. He says: "In regard to leprosy, your quotations are equally misleading. The idea that ten per cent. of the native population is afflicted with leprosy is simply preposterous." He does not believe that there are three hundred lepers at large in the whole group.

In estimating the value of Dr. Day's testimony, we must appreciate his possible official bias as a member of the Hawaiian board of health, whose policy has always been to minimize the extent and danger of the national evil. In looking over the biennial reports of this board, we find the same optimistic opinion—"Leprosy is decreasing"; "There are few lepers at large"—expressed for twenty years past, only to be contradicted by the never-ending procession of lepers to Molokai. The number consigned to the settlement each year is a varying quantity, depending upon the more or less vigorous policy of the board of health and the activity of the agents of the board in identifying and apprehending the lepers. In the report of the board of health, March 31, 1890, we read (page 13): "According to the best information obtainable, there are at date of this report about one hundred persons supposed to be affected by the disease still at large, who have not been before the examining board." And yet the statistics of the leper settlement show that in 1890 there were 202 admissions; 1891, 143; 1892, 109; 1893, 211; 1894, 128; 1895, 106; 1896, 146; 1897, 124—nearly 1,200 altogether; or to take the first five years after this estimate was made, 1890 to 1894 inclusive, there were 793 admissions. Now leprosy does not develop *d'emblée*: it may preserve its incognito for three to five years, or even longer, before it is compelled to declare its identity. It is probable that these 793 persons, and many more sent to the settlement, and many more never apprehended, were lepers on March 31, 1890, when the board of health reported that there were only about 100 lepers at large.

As bearing upon this point, I may be permitted to quote from my article on "Leprosy and Hawaiian Annexation" (*North American Review*, November, 1897): "We may now inquire what has been the result of thirty years' crusade against this gigantic evil, which is slowly sapping the life-blood of the Hawaiian race. Is leprosy on the increase, or is it in process of extermination? Taking the records of the leper settlement as a basis of comparison, there would seem to be no hopeful signs of its extinction. In the first twenty years of its establishment, to January 1, 1886, 3,076 lepers were sent to the settlement; in the next ten years, 2,049. This large relative increase of admissions may not be due to an actual increase in the number of lepers in the islands, but to more active and vigorous methods of segregation. Again, in the first-mentioned period the number of lepers at the settlement ranged from 200 to 800, the average being about 500. In recent years the number has varied from 1,000 to 1,200.

"As bearing upon the question of the increase or decline of leprosy, it is interesting to compare the opinions of the government physicians which appear in the last reports of the board of health. A few of them assert that there is as much leprosy as ever; most of them, however, sound a more hopeful note, and declare there are few or no known cases of leprosy in their respective districts. Notwithstanding this optimistic view, the fact remains that the annual consignment of lepers to the settlement shows little diminution in number. This yearly increment of fresh admissions which goes to recruit the ranks of the rapidly dying population of Molokai is made up of previously undiscovered cases. All the indications point to the existence of a vast deal of latent leprosy, which, as the disease develops into a recognizable form, must continue for many years to come to furnish a constantly recurring series of subjects for the leper colony."

As regards the actual *percentage* of lepers in the Hawaiian race, it is, for obvious reasons, an unknown and unknowable quantity. Any one familiar with the natural history of leprosy must recognize that it is impossible to compute the number of lepers in any country or community by the methods ordinarily employed for the detection and registration of disease. Only advanced cases are recognizable by inspection. In every country where leprosy is endemic, a large number of persons are infected months and years before it is known to themselves or others. The disease may exist, and commonly does exist, for years without visible external signs in the face or exposed parts. Now it is precisely by ignoring these incipient cases, or treating them as a *quantité négligé*, that the Hawaiian board of health has been led into promulgating its *perennially* hopeful but perpetually disappointing prognostications as to extinction of leprosy in these islands. These cases are sure to develop, and sooner or later furnish a contingent to the population of Molokai.

Again, the rigorous policy of segregation adopted by the board of health is indirectly a cause of its partial failure. The leper settlement is not a popular institution among the Hawaiians, and a leper is not apt to present himself for examination when he knows that a verdict of leprosy carries with it a sentence of life-long imprisonment, from which death is the only release. As a consequence, lepers use every possible precaution to conceal all incriminating evidence of the disease, and when concealment is no longer possible they are often secreted and cared for by their relatives and friends.

With a knowledge of these facts, I do not believe with Dr. Day that Hawaii is freeing herself of leprosy

with "the most gratifying results" and "with a thoroughness which hardly needs any assistance from the United States." I would, however, by no means detract from the great value of the work done by the Hawaiian board of health. Without its system of segregation, however imperfectly carried out, I believe that the leper population of these islands would be two or three times as large as it now is; and I take pleasure in testifying, as I have often done before, that in no country has the unfortunate leper been treated with so much humanity and with such liberal provisions for his comfort as in Hawaii.

PRINCE A. MORROW, M.D.

NEW YORK, December 5, 1898

THE PORTABLE BATH TUB.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the November 19th issue of the MEDICAL RECORD, Dr. C. J. MacGuire published an account of "A Convertible and Portable Bed-Bath." This tub resembles very closely one described and figured by me in the *Boston Medical and Surgical Journal* for November 19, 1896, which I had made for use in the Massachusetts General Hospital, and has been used there and to some extent in private practice in Boston ever since. Both are made of rubber sheeting with sides to be blown up with a bicycle pump. In fact there is practically no difference between the two tubs. Like Dr. McGuire, I have found the tub of great benefit and very easily managed.

CHARLES W. TOWNSEND, M.D.

BOSTON, MASS.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 10, 1898:

	Cases.	Deaths.
Tuberculosis	162	157
Typhoid fever	33	15
Scarlet fever	134	6
Measles	117	3
Diphtheria	151	35
Laryngeal diphtheria (croup)	15	7
Cerebro-spinal meningitis	0	2
Chicken-pox	57	0

The Showman in Medicine.—The *Indian Medical Gazette* says: "Do medical men at home thirst for yellow journalism in their medical newspapers? Are they carried away by an ecstasy of admiration for Barnum's show, which is now perambulating the provinces? The spectacle of the talented editor of *The Practitioner* offering his readers as a *bon mot* the stale old student's story of how the features of a patient's fundament made a greater impression on some celebrated surgeon (Syme, in this instance) than his face is pitiful; but what are we to think of the hundreds of practitioners at the Edinburgh meeting of the British Medical Association, who received with applause a kinematographic representation of two surgical operations performed for the purpose in record time by a Parisian surgeon? The patient's life may or may not have been jeopardized to provide this show, and when obtained it may have been a very pretty sight as well as a novel advertisement for the operator; but surely its exhibition was in execrable taste, and the council should never have allowed such a prostitution of surgery to occur. A phonographic representation of the sounds accompanying anæsthesia and of the bystanders' remarks should have been added to complete the display of bad taste."

Bubonic Plague.—The report of the late Dr. Otto Muller, based on the result of the scientific expedition to Bombay for the purpose of study of the plague, has just appeared. When Dr. Muller arrived in Bombay, the average daily mortality was reported to be one hundred cases a day. In reality, however, the mortality was much higher, as a great many were secretly buried at night, especially in those cases which had not been reported to the authorities. This was about February 20, 1898. Up to this time, exact scientific examinations were not known. The attending physicians in Bombay were so busy with their patients that no time was left for their scientific investigation. Through the courtesy of Dr. Choksap, the physician in charge of the Arthur Road hospitals, both clinical and cadaveric material was placed at the disposal of Dr. Muller's commission, and thus the scientific work began. In all, about seventy exact clinical histories were utilized, and of these forty-seven were investigated post mortem; thus detailed bacteriological and anatomical results were attained. The result of the pathological bacteriological studies proved the disease to be of a distinctly infectious nature. Although several varieties of the disease were met with, the most frequent form found in this investigation was the septicæmic-hemorrhagic form. A peculiar characteristic phenomenon was the formation "bubo" in the axilla, in the cervical region, in the inguinal, which was surrounded by a large amount of œdema. In the various organs hemorrhages were found, and in every case there was a characteristic tumor of the spleen. The various lymph channels of the body seemed to show a distinct evidence of participation, more frequently acute degenerative changes of some of the most vital (internal organs) of the body. A second variety showed distinct emboli in the lungs, liver, and kidneys. In a third form there was a primary bubonic pneumonia without any participation, or very little, of the lymph ducts or glands. The disease invades the body in the majority of cases through the skin. In a second series of cases the infection gains an entrance to the body, without doubt, through the lungs. In a third variety of cases (minority), the tonsils and the roots of the hair offer points of entrance for the disease. In not one single case could the gastro-intestinal tract be shown as the point of entrance. In a series of cases in which death did not take place, in a few days a softening of the lymph glands of buboes was noticeable, which resulted in a very profuse suppuration. The clinical picture is the following: A dull, constant headache, with delirium, dizziness, imperfect articulation. Patients able to get out of bed and walk seem to tumble from side to side, as though in an alcoholic stupor. The disease commences without any premonitory symptoms, with a sudden high fever, at times chills, severe headache and dizziness, and in some instances vomiting. The disease seems to be characterized by the development of painful and enormous buboes and extreme cardiac weakness. The buboes, in the beginning very small, are noticeable from the first. In some rare cases they may not show activity until several days after the disease has thoroughly developed. On the ninth day of the disease they either result in suppuration or commence to be absorbed. Patients having glandular enlargements of the cervical and maxillary glands present the worst forms of the disease. Death results from the rapidly approaching heart failure. The frequency of the pulse is from 160 to 180, and in many cases reaches as high

as 200 a minute. In some instances consciousness was retained to the last minute; other patients were constantly delirious from the beginning. A peculiarity noticeable in many cases was the desire of patients to leave the bed and run away. Subcutaneous hemorrhages were noticeable prior to death, whereas in the beginning the skin was clear and dry. Vomiting and also diarrhœa, while present, were not noticeable at stated intervals. The ophthalmoscopic examination was always negative. The diagnosis is very easy in typical cases. The difficulty in making the diagnosis was presented in those cases in which the buboes were either absent, as in bubonic pneumonias, or in those cases in which the buboes appeared later in the disease. The positive diagnosis rests on the bacteriological examination of the sputum and the course of the disease. The period of incubation is from four to five days. The pest bacillus is the etiological factor and cause of the disease, and is very easily found. The germs are found in the secretions of the various organs, in the spleen, in the glands. The latter show more microorganisms in this disease than in any other infectious disease known. The bacilli can be found in the blood of the living, in the sputum of a case of bubonic pneumonia, and in the pus of the bubo. When we inject animals with the pest bacilli, similar changes to those found in man can be produced. Rats seem to be very susceptible to cultures of these bacilli. Therapeutic results with pest serum were not noticed. The disease is disseminated from patient to patient, or from animal to man, or from clothes or dust, infected with the pest bacilli, and in poor hygienic conditions. This explains the cause of the disease, and proves that the most rational form of treatment consists in the isolation of patients afflicted with the bubonic disease and the best form of disinfection of the excreta. It it impossible to believe that the disease can be carried great distances by means of infected clothing, but it is possible that the disease is transmitted by means of rats, which abound on all ships. Dr. A. Marmorek, chief of the Pasteur Institute in Paris, of antistreptococcus fame, has been experimenting recently with bubonic serum, and the results of his work are being carefully watched.

The Manufacture of Cripples to be let out as decoys for the alms of the charitable is said to be a flourishing industry in some parts of the Pyrenees. It would appear that this is not one of the many inventions which make the "so-called nineteenth century" famous in the records of the ages. Fabricius Hildanus, in his chapter on preternatural tumors, relates the following story: "In the year 1593 there was seen in Paris a boy of fifteen or eighteen months, the skin of whose head was so much stretched that it greatly exceeded the size of a natural hydrocephalus. The father and mother of the child carried him about from place to place as a monstrosity. As the concourse of people was great, the magistrate suspected that there was some fraud in the matter and clapped the father and mother into prison. Being put to the question (a euphemism for the torture) they confessed their crime; to wit, that they had made on the top of the head right down to the muscles a small hole, through which, having pushed a syringe, they blew air between the skin and the muscles in such a fashion that, little by little and repeating the process every day, they had made the swelling. The syringe being taken out, they stopped the hole with wax or something of the kind." —*British Medical Journal.*

The Climate and Temperature of Porto Rico.—Porto Rico, although small, is undoubtedly the most healthy of the islands which we have wrested from Spain, and in those happy days to come, when by the help of American money and engineering skill the present decidedly unsavory condition of matters hygienic has been rendered sanitary and wholesome, the potentialities of the place as a health resort will doubtless be fully recognized. From accounts received we learn that, with the exception of imported disease, Porto Rico even now, despite its rudimentary drainage and water system, is healthy to a degree. Although the temperature is high in the summer months, it is by no means oppressive; there is a constant daily sea breeze, the nights are cool, and insects—those pests of tropical lands—may almost be said to be conspicuous by their absence. Appended is a temperature chart of Porto Rico for September, taken with great care at the camp of the first regiment, United States volunteer engineers, one mile west of Ponce, at an altitude of three hundred feet, by Lieut. and Surg. Charles J. Proben. This will be of interest to the many friends of the regiment, and should also tend to clear from the minds of many Americans the wrong impression which has been created by the reports of the insalubrity of Porto Rico.

Winds are usually east; southeast after 8:30 A.M., continuing all day till sundown. In the wet season rains occur daily, usually in afternoon about three or four o'clock, as a rule accompanied by sea breeze (east-southeast).

There is a difference of from twelve to eighteen degrees between the temperature in the shade and that in the direct rays of the sun: September 6th, 12 M., temperature in the sun, 104° F.; September 20th, 12 M., temperature in the sun, 113° F.

The lowest temperature occurred on September 22d and 23d, when it rained incessantly for two days.

The average mean temperatures are as follows: 6 A.M., 72⅔ F.°; 9 A.M., 86⅓° F.; 12 M., 89⅔° F.; 3 P.M., 85° F.; 7 P.M., 80° F.

Highest temperature recorded, September 20th, 12M., 96° F.; lowest temperature recorded, September 7th, 6 A.M., 68° F.

A Microbe-Proof House.—The following description of a novel dwelling was given in the *Leeds Hospital Magazine:* "The oddest domicile on earth is that recently erected at Yokohama by an eminent German bacteriologist. It is a microbe-proof house built of glass blocks. There are no window sashes and the doors when closed are air tight. The air supply is forced into the room through a pipe and is filtered through cotton wool to cleanse it of bacteria. To insure further sterilization the air is driven against a glycerin-coated plate of glass, which captures all the microbes the wool spares. The few microbes brought into the

house in the clothes of visitors soon die in the warm sunlight with which the house is flooded. The space between the glass blocks, of which the house is built, is filled with a solution of salts, which absorbs the heat of the sun so that the rooms are much cooler than those protected by the thickest shades. In the evening the interior is heated by the salts, radiating the heat they have absorbed during the day."

"IN THE SPRINGTIME YOUNG MEN'S FANCIES."

All nature wakes, spring flowers blow,
Thoughts turn to Aphrodite.
And balmy south winds whisper low,
"Hydrarg. chloridum mite."
—*Southern Medical Record.*

Men of the Name of Smith.—At some inquests recently held at St. Bartholomew's Hospital the name of Smith was well in evidence. Two of the deceased persons were John Smith and Charles Smith, but not in any way related. In the first case death was due to being run over by a cab driven by Josiah Smith, and two relatives of the deceased, named Smith, were present to hear the evidence, besides a brother of the cabman. In the case of Charles Smith both parents were present. Inspector Walter Smith of the city police was also present, and two of the jurymen were also of the same surname. Thus in all there were no less than eleven Smiths present.—*Lloyd's Weekly Newspaper.*

Hypnosis as practised by the ambulance surgeons of this town promises soon to obviate the necessity of police aid in "taking in" patients wild from the effects of insanity or of such natural causes as overindulgence in ardent potations.

Health Reports.—The following cases of small-pox, cholera, and plague have been reported to the supervising surgeon-general of the United States Marine Hospital service during the week ending December 10, 1898:

		Cases.	Deaths.
Small-Pox—United States.			
Alabama, Mobile	November 28th	1	
Colorado, Denver	November 26th	2	
Fort Collins, Larimer County	November 26th	3	
Trinidad, Las Animas County *	November 26th	1	
Georgia, Jasper County	January 14th to November 26th.	2	
Jones County	January 14th to November 26th.	300 (est.)	4
Iowa, Hamburg, Fremont County	November 26th	2	
Lacona, Warren County	November 26th	2	
Michigan, Detroit	December 3d	Present.	
Ecorse Township	December 3d	Present.	
Ohio, Cincinnati	December 2d	1	
Texas Laredo	December 6th	..	1
Laredo	December 7th	4	
Virginia, Norfolk	November 30th	5	
Norfolk	December 5th	4	
Norfolk	December 6th	2	
Norfolk	December 7th	2	

* Origin of the disease in the localities named is New Mexico.

Small-Pox—Foreign.			
Africa, Lorenzo Marques	September 1st to 30th	3	3
Belgium, Antwerp	November 5th to 12th	3	6
Brussels	November 12th to 19th	..	1
Brazil, Rio de Janeiro	October 15th to 21st	13	3
Ecuador, Guayaquil	November 5th to 12th	..	1
England, Liverpool	November 12th to 18th	2	
Southampton	November 5th to 12th	1	
Russia, Moscow	November 5th to 12th	17	5
Odessa	November 4th to 10th	1	1
St. Petersburg	November 5th to 12th	4	2
Turkey, Constantinople *	October 17th to November 7th.	..	55

* Small-pox is reported as raging fiercely in Constantinople. Vaccination does not appear to be a protection. Persons vaccinated only eighteen months previously are attacked. The authorities are doing their utmost to check the epidemic.

Yellow Fever.			
Mexico, Mexico City, one case of yellow fever.			
Cholera.			
India, Bombay	November 1st to 8th	..	1
Calcutta	October 8th to 22d	..	5
Madras	October 22d to 28th	..	5
Madras	October 28th to November 4th.	..	14
Plague.			
Austria, Vienna	October 29th to November 5th.	..	1
India, Bombay	November 1st to 8th	..	63
Madagascar, Tamatave	November 30th	Present.	

On November 26th, plague was reported present in San Francisco, Cal., in the Chinese population. The report has been officially denied.

Virtues of Spinach.—Prominent specialists claim that spinach is the most precious of vegetables, on account of its medicinal and strengthening properties. The emollient and laxative virtues of spinach, owing probably to the salts of potassium it contains, have been long known. It is excellent for the liver, and as a consequence freshens the complexion. Some vegetables contain a relatively large dose of iron. According to Bouissingault, the proportion is 0.00074 of iron in 100 parts of French beans, 0.00083 in 100 parts of lentils, and in spinach very much larger. The chemist Binge has proved that spinach and yelk of egg are proportionately richer in digestible and assimilable iron than all the most renowned ferruginous remedies. Its great value and growing importance are shown in the fact that spinach is already an active ingredient in several new and very salable tonics.—*Sanitary Record.*

THE EPIDEMIC OF FEVER WHICH PREVAILED AT KEY WEST, FLA., AUGUST, SEPTEMBER, AND OCTOBER, 1898.[1]

BY JOHN W. ROSS, M.D.,
SURGEON, UNITED STATES NAVY.

Origin and History.—The disease under consideration was first recognized and declared epidemic about the middle of August, upon the occasion of its breaking out in the marine barracks, near the centre of the city. It is directly traceable to the steam transport *Iroquois*, which arrived at Key West on the 5th of July, loaded with wounded from Santiago de Cuba.

A distinguished surgeon of the regular army (Major Gorgas), recently invalided home from Santiago, where he had been for several months in command of a large hospital at Siboney, has written me that the large majority of fever cases at Santiago were much like those at Key West; that they were not yellow fever; no one considered them dengue; most considered them malarial; that the mortality was almost *nil*, but that there were a number of deaths from yellow fever.

This officer had yellow fever a number of years ago, and has treated it frequently since. At the close of our epidemic I sent him a description of the fever which had prevailed here, together with clinical charts of a number of the cases.

On July 5th, three hundred and sixty wounded men and officers from the first fighting at Santiago were

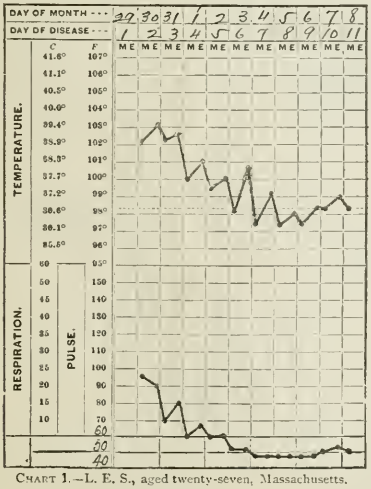

CHART I.—L. E. S., aged twenty-seven, Massachusetts.

landed in Key West by the *Iroquois* without any quarantine detention, upon the certificate of the ship's surgeon that there was no sickness on board. The enlisted men were sent to hospital. Three officers and two correspondents went to a hotel. One of these correspondents (Mr. J. C. K——) was taken ill on the 7th of July. He was laid up in the hotel for about ten

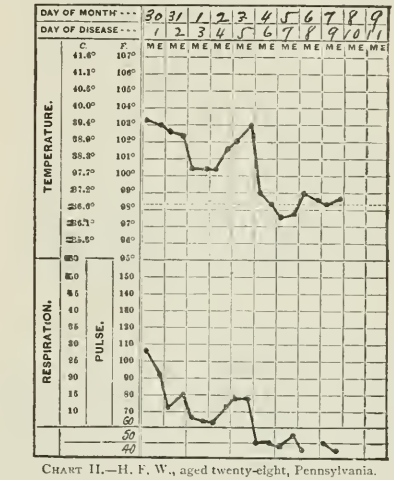

CHART II.—H. F. W., aged twenty-eight, Pennsylvania.

days, during a portion of which time he had fever. He left for the North July 17th. He is said to have been very weak at the time of his departure. His attending physician considered his illness due to heat prostration, from which he had suffered at Santiago.

A colored chambermaid, who nursed the correspondent and took care of his room, was attacked with fever about two weeks after the beginning of his illness. Ten or twelve days later three or four other cases occurred in rapid succession in the hotel. From that time on there were almost constantly cases of the disease in the hotel, until the 10th or 15th of September. The manager, every employee, and three guests—twenty-two persons all told—had it.

During the time that this outbreak was running its course, very few guests were in the hotel. It had been crowded to overflowing with military officers and newspaper correspondents, the latter largely predominating, from the beginning of the Spanish-American war to about the middle of June, when they all left for Santiago.

In the month of July, Second Lieutenant N——, United States Marine Corps, had the day's duty, every alternate day, at the marine barracks, near the hotel. He spent much of his spare time at the hotel, that being the principal rendezvous for military people in and about Key West. Lieutenant N—— slept one night out of every two in the barracks, and the other nights in his room near by. July 31st, he was taken down with a fever, and had, according to Assistant Surgeon Marcour, who treated him, a severe attack, resembling closely the fever which became epidemic afterward. He was discharged from the sick list August 11th, but was not strong enough to resume his duties until August 13th. Between these two dates he spent his afternoons in the barracks.

[1] Being a report to Surgeon-General W. K. Van Ruypen, United States Navy, and published with his permission.

I learned of three other young military frequenters of the hotel, who had rather severe attacks of the prevailing fever during the month of August. Through the courtesy of the physicians who attended them, I

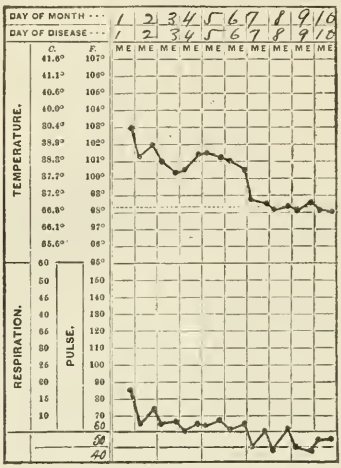

Chart III.—E. C., aged twenty-two, Massachusetts.

obtained the records and clinical charts of two of these cases (Nos. 19 and 20).

On the 13th of August the fever broke out in the marine barracks, formerly a cigar factory, where fifty-four enlisted men had been, for two hot Key West months, crowded together. In their principal sleeping- and living-room, moderately well ventilated, each man had an average air space of less than five hundred cubic feet. The first sergeant states that this room was very warm and close at night—almost unbearably so on rainy nights when the windows had to be closed. From the 13th to the 17th of August, inclusive, ten of these men were attacked with fever. All the marines, except the ten sick and thirteen others presenting suspicious symptoms, were promptly removed from the barracks to a camp outside the city. The thirteen suspected men were, at the same time, quartered in a house adjoining the barracks. After this no other cases occurred among the men in camp. None occurred among the suspects until August 30th, an interval of twelve days. From August 30th to September 7th inclusive, four of the suspects were attacked with the fever (charts Nos. 1, 2, 3, and 4). September 8th, the whole of the marine command, fifty-two men rank and file, including Assistant Surgeon Marcour, sailed for New York. Four patients, not well enough to travel, one hospital steward, and one first sergeant, were left behind in the barracks. The hospital steward went down with the fever September 26th, eighteen days after beginning to nurse Private Barnes (chart No. 4). Prior to being detailed as nurse, he had been prescriptionist, fairly isolated from the infected portion of the building. The first sergeant, the last of the marines, fell ill October 5th (chart No. 9).

During the third week of August, about the time the fever appeared in the marine barracks, cases began to occur in other parts of Key West, and by September 1st the entire city, with the shipping at the wharves, had become infected.

Through the *Iroquois* is one only of the many ways that the epidemic fever probably got into Key West. There seems to be no reasonable doubt that the same fever prevailed in Cuba and at Tampa prior to and at the time of its appearance at Key West. There were numerous opportunities about that time for its importation here from Santiago and other points in Cuba by our smaller war-vessels, which were constantly passing to and fro, Key West being the naval base. I know of several instances where our blockading vessels, immediately after having had Cubans (some of the latter ill with "calentura") on board, returned to Key West, where they underwent no quarantine detention. One of these vessels carried some insurgents, together with their clothing and bedding, from one Cuban port to another. There was, prior to the middle of August, constant and unrestricted intercourse between Key West and Tampa.

The epidemic reached its maximum about the 1st of October, after which it steadily subsided, until by the 1st of November it had practically disappeared—all the susceptible having probably passed through it. Very few cases occurred in the town after October 15th. From the estimates of the leading medical men here, it appears that upward of five thousand cases of fever occurred during this epidemic. The State health officer, who made a house-to-house inspection, states that at least one-third of the seventeen thousand inhabitants of Key West had the prevailing fever during the epidemic. After satisfying themselves, early in the epidemic, that there was little or no danger in the disease, nearly all the natives avoided the trouble and expense of seeking medical advice.

The last cases but one—eleven in number—that fell under my charge, were on board the United States steamer *Pompey*. The *Pompey*, a collier, arrived at Key West from Norfolk, October 10th, and positive orders were given by the commandant, upon my recommendation, that she should hold no communication,

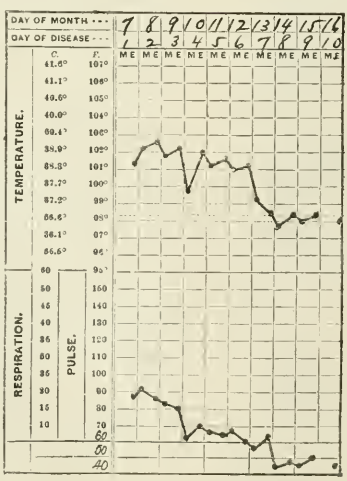

Chart IV.—M. P. B., aged twenty-two, New York.

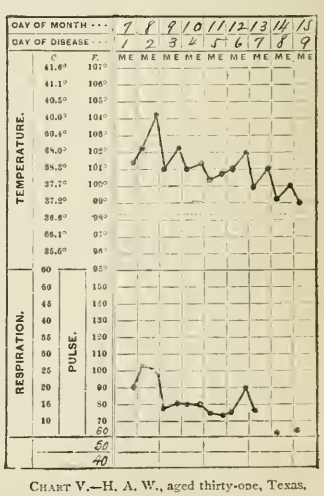

Chart V.—H. A. W., aged thirty-one, Texas.

that could possibly be avoided, with the shore. October 11th, five workmen from shore began work on board the *Pompey*. The same day the *Pompey* went

alongside the coal schooner *Susie M. Plummer*, and lay there during the following two weeks, during which time she received the *Plummer's* entire cargo of coal. While the *Pompey* was coaling from the *Plummer*, ten men and five boys from shore worked at the coaling and in the bilges of the *Pompey*, going backward and forward between ship and shore, night and morning. The fever probably got aboard the *Pompey* from the *Plummer*. The latter was infected, having recently had cases of the fever on board. I had seen two quite severe cases in the *Plummer's* crew. The interval between the time the *Pompey* hauled alongside the *Plummer* and the occurrence of the first case of fever (chart No. 12) on board the former vessel—that is, from October 11th to October 21st—was ten days. Ten other cases appeared on the *Pompey* during the 23d, 24th, and 25th of October, after what may be considered an incubation stage of from twelve to fourteen days. Seven of the *Pompey's* cases occurred in the topgallant forecastle, where nineteen men slept with an average air space of only eighty cubic feet for each man. This topgallant forecastle was ventilated by six 9-inch air-ports on the ship's sides, and one 9-inch deck ventilator overhead. This place was open aft, except when closed by curtains in rainy weather. There was an additional 9-inch ventilator in the deck above the topgallant forecastle, but it was kept permanently closed. Three of the *Pompey's* cases (charts Nos. 13, 14, and 15) were in the persons of the chief petty officers, who, with three other men, slept in the petty officers' room between decks. The capacity of this room, in which six men slept, was one thousand cubic feet—only one hundred and sixty-seven cubic feet to each man. There opened into it three 9-inch air-ports on the side, and one 9-inch deck ventilator overhead. Ventilation through the three air-ports was pretty effectively cut off, from the 11th to the 26th of October, by the schooner *Plummer*, which lay alongside, almost against these apertures. To make a bad matter worse, it rained almost constantly for eight or ten days while the *Pompey* was coaling, and the weather was very warm. The *Pompey's* seven worse cases (charts Nos. 12, 13, 14, 15, 16, 17, and 18) were sent ashore October 24th and 25th, when first seen by me.

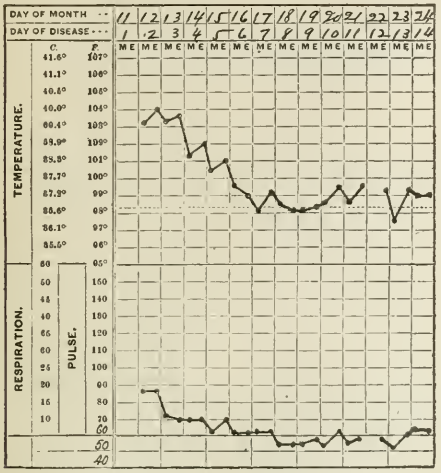

Chart VI.—J. M. F., aged fifty-six, Bahama Islands, W. I.

I recommended that the men be broken out from their quarters under the topgallant forecastle and between decks, and made to sleep under awnings on the upper deck. The overcrowding being relieved, no additional cases occurred on the *Pompey* during the last week that she remained here, although there were twenty-four men on board who had not had the fever. No cases occurred among the officers. As soon as the *Pompey's* men, who had been sent ashore, began to convalesce, they were taken back to their ship, which promptly left for Washington, D. C. The vessel had no medical officer on board when this outbreak of fever occurred. One joined her the day she left.

August 15th, the cases of fever which had occurred on the 13th, 14th, and 15th among the marines in the barracks were pronounced yellow fever by the attending medical officer, Assistant Surgeon Marcour, United States Navy (he had acquired familiarity with that disease during the epidemic in Louisiana the preceding year). A consultation of six physicians was immediately held at the barracks, and the cases, after examination, were unanimously pronounced suspicious. The agent of the State board of health, one of the consultants, stated at the time that if those cases among the marines were yellow fever, he had been treating cases of yellow fever at the hotel. This and many other statements, lay and professional, indicate the similarity between the two sets of cases. Another conference of physicians was held at the barracks on the following day, August 16th. The members of this conference were: the agent of the State board of health, two Marine Hospital medical officers, two prominent local physicians, and Dr. Marcour. At this conference the diagnosis of yellow fever was unanimous. This was officially announced by the State board of health, and Key West was immediately quarantined against by the rest of the country.

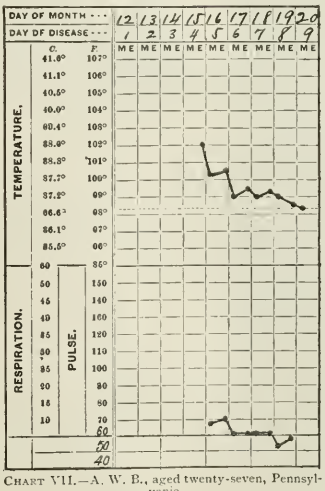

Chart VII.—A. W. B., aged twenty-seven, Pennsylvania.

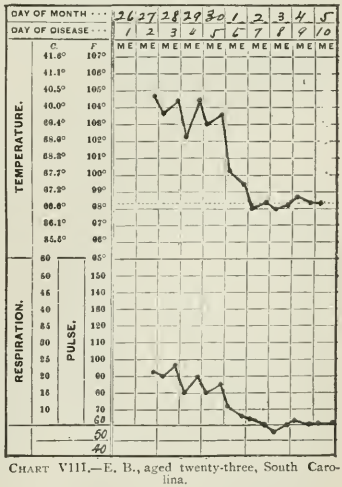

Chart VIII.—E. B., aged twenty-three, South Carolina.

Within the succeeding week three other yellow-fever experts and myself were sent here. These three were the State health officer of Florida and two Marine

Hospital surgeons. The State health officer and the junior Marine Hospital expert pronounced the cases among the marines dengue. The senior visiting Marine Hospital surgeon (one of the most distinguished and experienced yellow-fever authorities in the United States), after about ten days of careful study of the Key West puzzle, as he called it, concurred in the diagnosis of dengue. The surgeon in command of the United States Marine Hospital here, one of the six members of the second conference, maintains his original diagnosis of yellow fever, as do also the two local physicians of the second conference and Assistant Surgeon Marcour. The two remaining members of this conference subsequently changed their diagnosis from yellow fever to dengue.

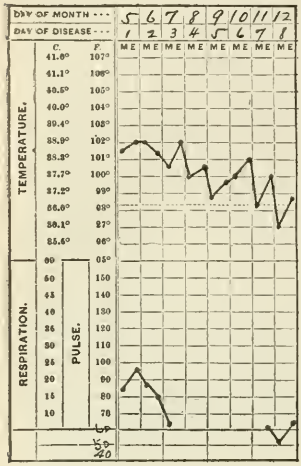

CHART IX.—C. E. D., aged thirty-one, New York.

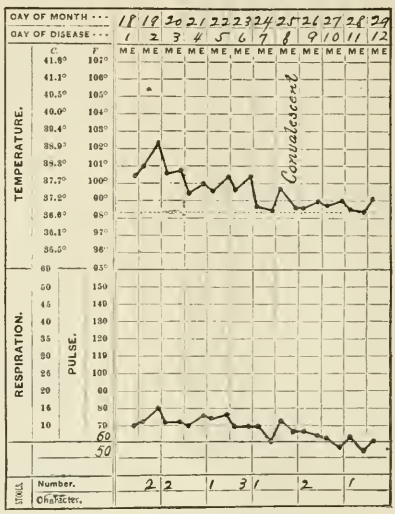

CHART X.—F. P. G., aged fifty-one, Ohio.

During and at the end of my first week's study of the cases among the marines and others, I was unable to believe that the prevailing disease was either yellow fever or dengue. I was rather hoping that it would turn out to be the latter, as I wished to get away from the hot weather and plague of mosquitoes as early as possible.

Then came the second group of cases among the marines (charts Nos. 1, 2, and 3), presenting, as it seemed to me, the symptoms, markedly the objective, of the first stage of yellow fever, and I reported them as such. A little later on came two similar but more serious cases (charts Nos. 4 and 6), and I felt certain that they also were yellow fever. One of the latter (chart No. 6) was so much more severe than any I had seen before, that I confidently expected my diagnosis would soon thereafter be verified by the occurrence in Key West of grave and fatal cases, as transpired in Fernandina in 1888. At the same time with these two cases occurred two others (charts Nos. 5 and 7), which, although in one of them (chart No. 5) the patient was very ill, I could not call yellow fever. They both presented a peculiar eruption (to be described hereafter), and I reluctantly recorded them as dengue, ignoring, as others have apparently done, the fact that dengue is not the only fever with an eruption.

Finding myself between the two horns of a dilemma, I, on the 26th of September, got a few days' leave of absence, and ran over to Havana, to refresh my recollections of "genuine" yellow fever, particularly the mild cases. In a large military hospital, the Alfonso XIII., I saw yellow fever in its different stages. The mild cases in the first stage appeared to me very similar indeed to the more serious ones I had been studying in Key West, especially in the first two or three days of the latter. Nevertheless, after my return to Key West I did not see another case which I could call yellow fever, although I observed several which before my visit to Havana I should probably have recorded as such. There was something in the *tout ensemble* of the Havana cases, stamping them as genuine, which was lacking in the Key West cases. About the only tangible difference which I could be sure of was that in the expression of the face in the Key West cases there were more apathy and hebetude than in that of the Havana cases.

Before leaving this division of the subject, it is proper to give a brief account of an interesting case of fever which occurred in Key West eight or nine days before the arrival of the *Iroquois*. The patient had been living in Key West for ten or twelve years. The attack began June 27th, with slight chilliness. Its clinical chart, No. 21, shows the temperature curve and pulse rate. Other symptoms were: pains in the head, back, and legs; flushed face; injected eyes; small pointed tongue, with coated centre and red edges; slight jaundice of conjunctivæ on second day, increasing till the fifth day, when it was well marked in eyes, face, and neck, then gradually fading away; albumin in urine, twelve per cent. on the second day, fifteen per cent. on the fifth day, after which it decreased steadily, and disappeared on the sixteenth day. Recovery was complete. The case was diagnosed as yellow fever by the competent medical gentlemen who had charge of it, and the patient was kept isolated. As no connection whatever could be traced between this case and any which preceded or followed it, the attending physician does not consider that it had anything to do with the subsequent epidemic.

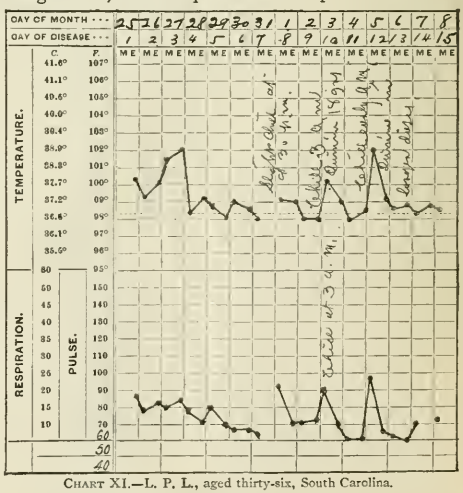

CHART XI.—L. P. L., aged thirty-six, South Carolina.

(About the beginning of the third week of July last, I had under my charge in the Naval Hospital, Pensacola, several cases of fever very closely resembling, objectively and subjectively, the average cases

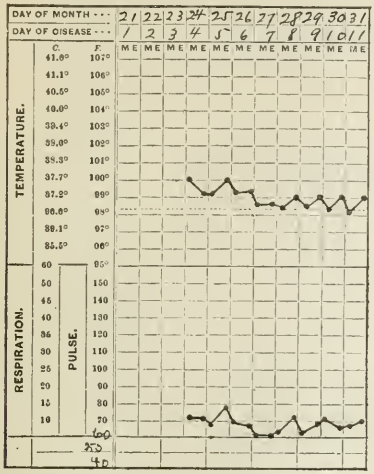

Chart XII.—J. M. G., aged forty-three, New York.

which occurred in Key West during the late epidemic. In one of these Pensacola cases, the facies, eruption, temperature, etc., were so much like measles that my diagnosis was morbilli—with an interrogation point after it—prostration too great for measles. The said cases were among the Florida naval reserves, who enlisted at Tampa, July 6th, and left on the 7th or 8th for the navy yard, Pensacola. As there had been no fever of the kind at the Pensacola naval station prior to the arrival of these men, and as a fever very similar to it was rife at Tampa when they left that place, it is almost certain that the patients contracted the disease at Tampa. The incubation could not have been less than from twelve to fourteen days.)

Phenomena.—When not otherwise indicated, the figures and percentages given below are based upon the combined records of fifty-eight cases; thirty-one of them observed by an accomplished and careful medical officer residing in Key West; nine by Assistant Surgeon Marcour, United States Navy; and sixteen by myself. I have fragmentary records of numerous other cases seen by me in various parts of the city and on ships in the harbor, which I could not visit regularly.

The first eleven of the accompanying clinical charts are of the naval and marine cases which began and ran their course during my service in Key West. Those of the cases among the marines, which occurred prior to my arrival on the 23d of August, form a part of the report, already submitted, of Assistant Surgeon Marcour, who was in charge of the medical department of the Key West naval station prior to my arrival.

The disease which prevailed in Key West during the epidemic recently ended was an acute, highly infectious, continued fever, unusually uniform in its course and duration, as shown by the foregoing history and the clinical charts.

The most prominent features of this fever were:

(1) A long incubation period, from twelve to fourteen days, as indicated by the following cases, the only ones in which I was able to find a more or less reliable starting-point.

The patient of chart No. 5 arrived at Key West from Norfolk, Va., August 28th; he was attacked by the fever, September 7th—ten days after his arrival. During the interval he slept on board a vessel alongside the wharf, in an infected quarter of the city.

The patient of chart No. 10 reached Key West from New York, October 4th; he was attacked October 18th—fourteen days after arrival. He had slept every night in a room and bed in which a man had had the fever. The said room and bed remained vacant, without having been disinfected, during the interval.

The patient of chart No. 11 arrived at Key West from New York, October 10th; he was attacked October 25th—fifteen days after arrival. He had slept every night in a small stateroom and bed, not disinfected, in which an officer whom he relieved had just gone through with a case of fever.

The eleven cases on the *Pompey*, direct from Norfolk, Va., occurred from twelve to fourteen days after the men were first exposed to infection.

The chambermaid at the hotel was attacked two weeks after beginning to nurse Mr. Klein.

The patient of chart No. 8 was attacked by the fever eighteen or nineteen days after he began to nurse patient of chart No. 9.

The incubation period of patients of charts Nos. 1, 2, and 3 was apparently not less than twelve days, that having been the interval between the time they were attacked and the occurrence of the last preceding case among the marines.

In addition, the Pensacola patients were attacked about fourteen days after they left Tampa.

(2) Suddenness of invasion—chill in about one-half, brief prodromes in minority, several days' malaise, anorexia, etc., in a few cases.

(3) Rapid rise of temperature to average point of about 103.2° F. during first one or two days, followed by a less rapid, rather steady decline, reaching the normal about the seventh day.

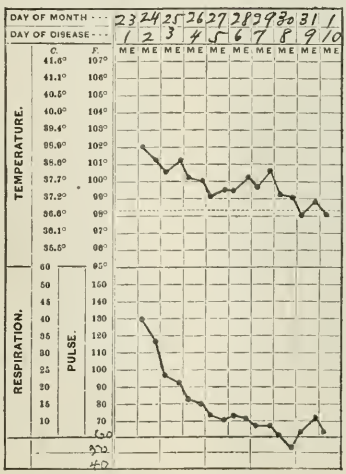

Chart XIII.—A. P., aged twenty-two, Germany.

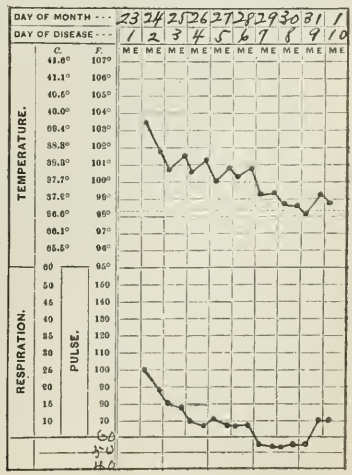

Chart XIV.—E. D., aged twenty-seven, Ireland.

(4) One paroxysm only, no relapses, very few if any sequelæ.

(5) A peculiar facies, impossible of correct description; during the first few days a combination of the facial appearances of yellow fever, typhus, and measles, without the catarrh of the last, and not enough alertness, anxiety, and jaundice for yellow fever. There were slight icterus of scleræ in about one-half, and icteroid tinge of face in minority. There was only one case with positive jaundice, and this was thought at the time by nearly all the physicians, myself included, who examined it, to be hepatogenous. The color during latter part of pyrexia and first part of convalescence was sallow, dirty looking, and dusky red.

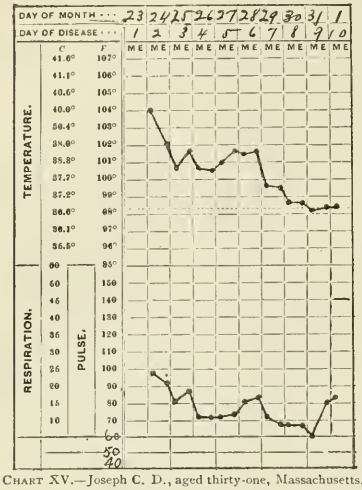

Chart XV.—Joseph C. D., aged thirty-one, Massachusetts.

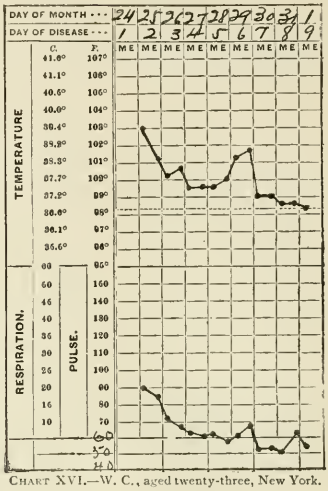

Chart XVI.—W. C., aged twenty-three, New York.

(6) Capillary stasis and sponginess of the gums, with tendency to bleed, in the majority of cases.

(7) Pains in front of the head and in the back of almost every case, severe in majority. Pains in the extremities and joints were less constant and less severe.

(8) Constipation in all except two of our fifty-eight cases, obstinate in some, moderate in most.

(9) Great debility, sometimes prostration, from the first, in a large majority of cases—out of all proportion to the severity of the other symptoms.

(10) Pulse generally much slower in proportion to temperature than usual in pyrexia. (My experience, corroborated by that of many others, is that this discrepancy often occurs in tropical and sub-tropical countries in smokers and coffee-drinkers, compelled by illness to stop the use of tobacco and coffee.)

The lack of correlation between pulse and temperature, characteristic of yellow fever (according to some authorities)—that is, a falling pulse rate simultaneous with a rising temperature—existed in about one-half the cases during some period of their course. This was generally transient and always irregular.

(11) A more or less contracted tongue, dryish, covered, except at the tip and edges, with a whitish or yellowish-brown fur, in almost every case.

(12) An eruption, from the fourth or fifth to the seventh or eighth day, in about twenty-five per cent. of the cases—rubeoloid, non-crescentic, at first disappearing under pressure, afterward permanent. It was generally on the chest, abdomen, and extremities; rarely on the face, neck, or dorsum of hands. I did not see it once in the palms. This eruption in a few cases ended with slight branny desquamation.

Small, muddy-looking, subcuticular spots on chest, shoulders, and flanks, preceded and accompanied the above-described eruption in five cases seen by me—three of them naval (charts Nos. 5, 9, and 10) and two civilian. In two of these (charts Nos. 5 and 10) this subcuticular maculation persisted for about a week after the beginning of convalescence. On the patient of Chart No. 5 this eruption was thought at the time by several of us to be the terminal eruption of dengue, although it was not roseolar in character. Not until I saw the second instance of this maculation (chart No. 9) did I pay much attention to eruptions, except to see whether or not they indicated dengue. Those I had seen were neither initial nor terminal, and I attached no importance to them, considering them accidental or the unimportant exanthemata which frequently accompany yellow fever. After having been struck by the eruption of patient of chart No. 9, I observed the integument more closely, and found a morbilliform eruption in nearly one-half of my cases.

(13) Albuminuria in about twenty-two per cent. of the cases, of short duration and small amount—in three cases five per cent.; in others from one to two per cent. (One case, in which albuminuria was found on the third, fourth, and fifth days, was thrown out of the above computation upon discovering that the patient had a muco-purulent urethral discharge.)

(14) Active epistaxis in one case—oozing of blood from posterior nares in five cases. I was informed of three cases of epistaxis, one of them critical, in his practice, by a local practitioner.

(15) Black vomit in two cases (not included in our fifty-eight), both in the practice of Cuban physicians,

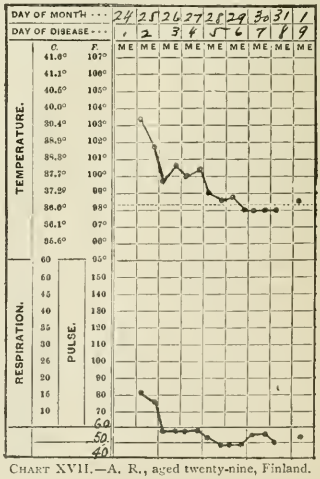

Chart XVII.—A. R., aged twenty-nine, Finland.

who pronounced them paludal fever. There was no suppression of urine in either case, and both ended in recovery.

(16) Not so much attention as it deserved was paid

to the spleen. Upon my arrival I examined the spleens of Assistant Surgeon Marcour's ten marines, then in the beginning of convalescence. I found in six or seven of them a moderate enlargement of the

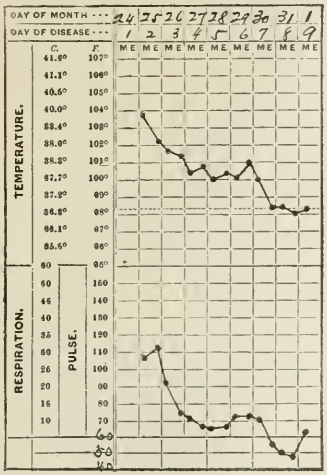

Chart XVIII.—H. Van E., aged twenty-seven, Holland.

spleen, and called Dr. Marcour's attention to it. After that, having satisfied myself that the prevailing fever was not malarial, I examined the spleen in those cases only which showed malarial symptoms.

(17) Anorexia, usually well marked in the majority, and continuing well into convalescence in a minority of the cases.

(18) Insomnia, more complete and constant than in ordinary fevers of corresponding intensity. Several patients were absolutely unable to sleep for three and four days and nights, after the first night of attack.

(19) Falling of the hair occurred in three of my cases during convalescence—in one of them by handfuls.

(20) Mortality rate very low.

The fever was not epidemic before the 15th of August, and there were very few cases of it in the city after October 15, 1898. The population of Key West is said to have been from eight hundred to one thousand larger in the summer and autumn of 1897 than in the summer and autumn of the present year.

The official records of Key West show that there were seventy-seven deaths from August 15 to October 15, 1897; and ninety-five deaths between August 15 and October 15, 1898. The same records show that between the middle of August and the middle of October, 1898, three deaths were reported as from "pernicious fever," while during the same period of 1897 no deaths were reported in Key West from that cause—whatever it may be. Another death stands recorded, August 24, 1898, as from "infectious fever." The records show four deaths from "senility" between the middle of August and the middle of October, 1898, and no deaths from "senility" during the corresponding period of 1897.

These figures make it seem extremely probable that the epidemic fever which recently prevailed in Key West caused, directly and indirectly, not less than eighteen deaths during the two months of its prevalence.

Recapitulation and Remarks.—After weighing carefully all the evidence within my reach, I am forced to the conclusions:

First, that the fever recently epidemic in Key West was neither yellow fever nor dengue.

Second, that the epidemic points more directly to the diagnosis of typhus exanthematicus than to that of any other classified disease.

These two propositions seem to be demonstrated by the facts set forth in the foregoing account of the epidemic. Some of these facts deserve further elaboration:

(*a*) Overcrowding and defective ventilation, the classical causes of typhus fever, evidently determined the outbreaks on board the *Pompey* and in the marine barracks. Removal of these conditions was immediately followed by cessation, more or less permanent, of the outbreaks. Probably ochlesis had much to do with the rapid spread of the epidemic in Key West, one-fourth of whose population is Cuban. It is a well-attested fact that these Cubans, everywhere and at all seasons, sleep together at night in their bedrooms "like sardines in a box," with all the doors and windows closed. During the day, however, they live out of doors. It is well known that in cities, where typhus fever prevails, the low lodging-houses and night-shelters, in which human beings sleep closely crowded together, furnish the greatest number of cases.

(*b*) The incubation period averaged about twelve days in all cases where reliable data could be obtained. The average incubation period of yellow fever is four or five days; that of dengue is two or three days; and that of typhus twelve days.

(*c*) The temperature curve resembles that of typhus—compare the accompanying clinical charts with charts Nos. 2, 3, 4, 5, 6, 9, 10, and 11 of Licéaga's article on typhus fever in the "Twentieth Century Practice." Since the introduction of the clinical thermometer, it has been found that defervescence is not so rapid in typhus fever as was formerly thought and taught. The instrument of precision has shown

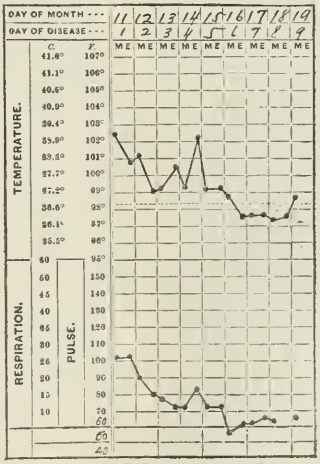

Chart XIX.—F. E. S., aged twenty-four.

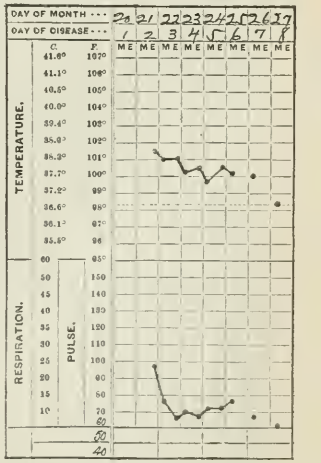

Chart XX. L., Lieutenant, U. S. A., aged twenty-five.

that the termination of the pyrexia of typhus is by lysis rather than by crisis.

(*d*) Reviewing them as a whole, the facial appear-

ances of the Key West cases seen by me were much like those of mild typhus. Prof. John Guiteras, in his admirable monograph, "Diagnosis of Yellow Fever," says: "The appearance of the face is that of typhus fever during the first forty-eight hours of this disease, or like that of measles before the eruption breaks out, with a more or less pronounced icteroid hue." During the first three days, a mild case of typhus resembles closely the first three days of the first stage of yellow fever.

(*e*) The remarkable absence of relapses and sequelæ was indicative of typhus. Relapses are the rule in dengue, and sequelæ are common after yellow fever.

(*f*) The eruptions were decidedly more like those of typhus than of any other disease with which I am acquainted. The two instances of subcuticular mottling observed by me about October 7th—one on the patient of chart No. 9, the other on a young civilian—first suggested typhus fever to me. Then I recalled that I had already seen the same peculiar maculation in other cases—one of them in the case of the patient of chart No. 4, during the second week of September; the other that of a merchant captain, who was under my charge during the third week of September. The more

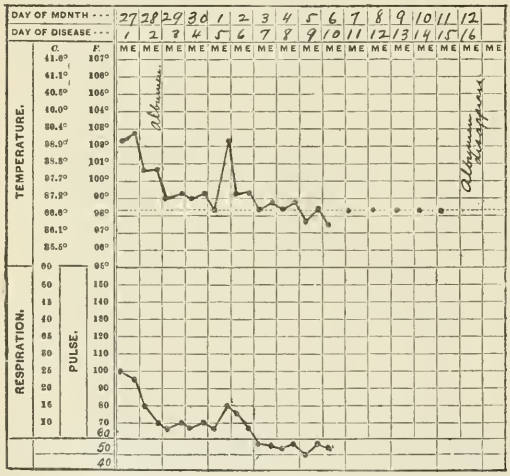

Chart XXI.—P., aged twenty-eight, New Orleans.

I thought over the Key West cases which I had observed, and compared them with what I could recall of some cases of typhus fever which occurred in a ward under my charge in a hospital on Blackwell's Island, N. Y., nearly twenty-eight years before, I became impressed with their similarity.

(*g*) The albuminuria points to typhus. Licéaga, in his description of typhus, states: "Albumin is frequently found. . . . On the fifth day of the disease we may find hyaline casts and pigment granules." This is substantially what other observers have noted. In the Key West cases albumin did not occur in the urine often enough, regularly enough, or in sufficient quantities for yellow fever. It was found altogether too often, however, for dengue.

(*h*) The Key West fever was apparently the same as that which previously and synchronously prevailed at Tampa, and which, as I have understood, all the physicians who investigated it there agreed was not yellow fever. The Key West cases were evidently the same as "the large majority of fever cases at Santiago," which, according to Major Gorgas and most others, was not yellow fever, and "no one considered them dengue."

(*i*) The late epidemic was arrested by exhaustion of susceptible material, and not by cool weather, as shown by the outbreak on board the *Pompey* and the case on the *Accomac* (chart No. 11) a week or more after said epidemic had practically ceased to exist, and the fact that at the time the weather was hot. The mean temperature during October, 1898, was 76.8° F.; the mean temperature from November 1 to November 15, 1898, was 76.4° F.

(*j*) War, squalor, famine, and filth—the factors so potent in the production and development of typhus fever—existed at Santiago, when the *Iroquois* sailed from that place for Key West.

The sanitary condition of Key West was, at the same time, extremely favorable for the development and spread of typhus fever, upon the introduction of the virus of that disease. The city has no system of sewerage; the waterclosets are simply pits dug in the coral rock composing the island upon which the town is situated. These pits are emptied, theoretically, whenever they get full. As this operation costs the owner from $10 to $15, it is done as rarely as possible on the majority of the premises. The odors of decomposing human excreta and putrescent animal matters pervade the atmosphere of the streets in many parts of the city, especially at night and early in the morning. Licéaga writes: "Infections through fecal matter in process of decomposition is the only cause to which could be attributed many small epidemics. . . . Dr. de Avellano, member of the superior council of health of the City of Mexico, states: "Innumerable are the houses in which an inspection made on account of an outbreak of typhus fever shows sewers without any flow, stopped up with fecal matter in process of decomposition. I have records of many very curious observations concerning infected houses, in which the epidemic ceased the moment the closets and sewers were cleansed."

The *de-novo* origin of typhus fever, so ably advocated by Murchison and other high authorities, is still on the cards. Pasteur himself is a supporter of the autochthonous theory of typhus fever, as shown by the following quotation from his writings: "There are other virulent diseases which appear spontaneously in one country or another, such as, for example, typhus fever in camps. Without any doubt the spores of the microbes which give rise to these diseases are scattered everywhere. Man carries them in himself, perhaps in the intestinal canal, without much injury; but they may at any time become dangerous, when their virulence becomes progressively increased under conditions of overcrowding, of successive reproduction on the surface of a wound, or in some other manner."

(*k*) One of the strongest arguments to show that the fever which prevailed during the recent epidemic was not yellow fever, is that it attacked numerous persons, both Key Westers and Cubans, who had had yellow fever in former epidemics of that disease. The patient of chart No. 6 had a severe case of yellow fever on board a man-of-war in 1862.

(*l*) The mortality rate was entirely too low for yellow fever in such a city as Key West, in such a climate, within ninety miles of Havana, and where frost has never been known. There was during the epidemic an unusual number of strangers in Key West, mostly imported workmen—about four hundred of the latter—employed upon the army and navy fortifications, machine shops, coal sheds, docks, etc., in process of construction. There must have been many non-immune children in Key West, born subsequently to the last yellow-fever visitation of 1890.

(*m*) The rarity of anything resembling the initial eruption, terminal eruption, terminal fever, relapses,

and other symptoms peculiar to dengue, should alone exclude that disease.

The reasons for doubting that the fever recently epidemic in Key West was typhus are: the mildness of the cases, the shortness of the cases, the rare occurrence of critical discharges, and the extremely low rate of mortality.

These, which seem to me departures in degree and not in kind, may be attributable to a modification of typhus fever by the subtropical climate and warm weather, which tend to prevent overcrowding and to promote ventilation and cleanliness. In our Gulf States, typhoid fever is milder and less fatal than at the North; so much so, often, as to be almost unrecognizable. May not its congener, typhus, depending so much, as it does, for its virulence upon overcrowding, undergo a still greater modification, even to becoming so benign as to be mistaken for dengue in a climate where the people live, except when asleep, in the open air?

In "An American Text-Book of the Theory and Practice of Medicine," vol. i., p. 135, Dr. Pepper writes, concerning typhus fever: "In 1880 a fatal outbreak occurred at the town of Blackwood, N. J. I had an opportunity of studying it. . . . At first the cases were a mild type, and distinguished with difficulty from typhoid. Severe weather came on. The sanitary condition of the almshouses became very bad, and the disease assumed a grave type. In the early part of the outbreak all the cases recovered; later the mortality was almost fifty per cent."

Dr. Hutchinson, in his article on typhus fever in Pepper's "System of Medicine," describing the different varieties of that disease, says: "In addition to these there are certain other varieties, arising from differences in degree. These differences are sometimes owing to diversities in the constitution and habits of the patient, sometimes to variations in the character of the epidemic, and are sometimes not readily explainable. One of these is the mild form, in which the symptoms are those of moderate fever, and in which the disease may run its course in seven days. In this form the temperature may never rise above 102° F., the eruption be absent or very scanty, and the characteristic stupor or dulness be wholly wanting. Unless complications arise, recovery invariably takes place."

Should the Key West epidemic of 1898 be found to have been one of typhus fever, it may throw light upon some of the former much-discussed epidemics in different parts of the South, in which such strong disposition has been shown to claim everything for dengue.

The cordiality shown me by my professional brethren, both visiting and resident, in Key West, is highly appreciated by me.

I am especially indebted to Dr. J. W. V. R. Plummer, city health officer; and to Past Assistant Surgeon G. M. Guiteras, United States Marine Hospital service, in command of the Marine Hospital, for innumerable courtesies and assistance, both professional and social.

I was particularly impressed by the excellent manner in which Assistant Surgeon R. O. Marcour, United States Navy, carried himself and discharged his duties. He showed very unusual tact, judgment, discretion, and courage in the difficult and responsible situation in which he suddenly found himself, upon and immediately after his discovery of the epidemic.

U. S. Naval Station, Key West, Florida,
November 15, 1898.

Getting Ready.—Visitor: "Why did you say that gentleman who went out was your biographer? I am sure it was Dr. Jones." Invalid: "Same thing! He is at work on my life."

ECTOPIC OR EXTRA-UTERINE PREGNANCY.[1]

By E. M. POND, M.D.,
RUTLAND, VT.,
SURGEON TO RUTLAND HOSPITAL; CONSULTING SURGEON TO PROCTOR HOSPITAL.

When requested to prepare a paper for this society I asked myself, What subject will be of equal interest to both physician and surgeon? In answer, I decided to take "Ectopic Gestation, or Extra-Uterine Pregnancy," for the following reasons:

1st. That these cases come under the care of the general practitioner, and upon his ability to diagnose them often rests the life of the patient.

2d. That the surgeon is generally called, and he must be able to confirm the diagnosis and treatment.

3d. That the general practitioner often is not as familiar with the condition and is not as prompt in his action as the case demands.

I cannot go into details, but will confine myself to leading points in pathology, diagnosis, and treatment.

That extra-uterine pregnancy is one of nature's mistakes, no one will question. The ovum in its passage from the ovary to the uterus, as a rule, is impregnated in the Fallopian tube; exceptions occur when the ovum is free in the peritoneal cavity, there coming in contact with the spermatozoa and afterward possibly entering the tube of the opposite side. If for any reason the impregnated ovum is arrested in its passage to the uterus, it forms adhesions for itself and grows, constituting ectopic gestation.

The causes favoring its occurrence are diseased tubes, *i.e.*, by strictures, dilatations, diverticula, twistings, displacements, etc.

The ovum may become arrested at any place in its course, *i.e.*, at the ovary (forming ovarian pregnancy, which is very rare), at the fimbriated end of the tube, in its middle, or at the uterine end. The last three may give somewhat different symptoms. As the ovum grows in the fimbriated end of the tube, the tube enlarges, and after a certain time either ruptures or, what is common, its contents are aborted from the fimbriated end into the peritoneal cavity. This may or may not be followed by severe hemorrhage; the ovum then either dies, or makes a new attachment and continues to grow, forming abdominal pregnancy, this possibly going to full term.

The form starting in the middle of the tube is very liable to rupture at from the sixth to the eighth week; exceptions are when it progresses to the third or eighth month. The ovum in some cases dies before the tube ruptures, forming a tubal mole or a hæmatosalpinx, or is absorbed. Rupture may take place into the peritoneal cavity or into the broad ligament.

The symptoms of ectopic gestation are often very clear and again are masked. Often no symptoms appear until the patient is taken with severe pains and fainting, dependent upon rupture and hemorrhage.

A typical case is as follows: A woman who has been regular stops menstruating, is a little sick at the stomach; the breasts are sore, possibly containing a little milk. She thinks herself pregnant. A week or two later there may be a slight flow, which is serous, containing some shreds; this may be repeated at varying intervals. Suddenly she is seized with agonizing pains in the lower abdomen and becomes faint, pale, cold, and possibly pulseless, either soon dying or after a while rallying, according to the severity of the hemorrhage. If she recovers from the first attack others are almost sure to follow, which are as a rule associated with the watery, shreddy uterine discharge. If with this history the uterus is found by vaginal or rectal examination a little enlarged, and a tense, fluctu-

[1] Read before the Vermont State Medical Society at Brattleboro, Vt., October 14, 1898.

ating, pulsating tumor or an ill-defined mass is found on either side or posterior to the uterus, it makes the chain of symptoms complete. This type is illustrated by the following:

Mrs. S——, aged twenty-four years, no children; history of anteflexion and stenosis with diseased tubes and ovaries. Menstruation normal up to last period, when it ran over one week. The flow was very slight, watery, and shreddy. A few days later the patient was taken with severe cramps and faintness. The pain was exceptional in situation, being located in the groin, at about the centre of Scarpa's triangle. Vaginal examination was as follows: Uterus anteflexed, left tube and ovary diseased but not much enlarged. Right tube distended to about the size of the thumb, tense and elastic, with active pulsation of the vessels of that side. Diagnosis of tubal pregnancy was made, and operation advised. Counsel was called, who did not agree with the diagnosis, and operation was delayed. The pain and faintness recurred every few days, and vaginal examination showed increasing size and pulsation of the right tube. Operation was finally consented to twenty days from the first symptoms, *i.e.*, two months from the time of the last normal menstruation. A large amount of blood was free in the peritoneal cavity, and the left tube was the seat of a recently ruptured tubal pregnancy. The patient made a good recovery.

Instead of a slight uterine discharge menorrhagia may occur.

Mrs. M——, thirty-five years old, with one child of ten years, whose previous health was good, gave the following history: Menstruation, formerly normal, was delayed two weeks, when it came on with excessive menorrhagia and severe uterine and abdominal pains. She had had some symptoms of pregnancy and thought she was miscarrying. The pain and flowing continued for three weeks and she was constantly getting worse. I saw the patient three weeks after the first symptom, *i.e.*, nine weeks from the last normal menstrual period. She was given ether, curetted, and a careful examination made. A mass was felt over the right broad ligament, with active pulsation of the vessels and some localized peritonitis. A diagnosis of extra-uterine pregnancy was made. The case being out of town and not prepared for cœliotomy the operation was delayed until the next morning. The abdomen being opened, it was found filled with clots and liquid blood, and an active hemorrhage going on. The broad ligament being clamped and the clots removed, the right tube was found ectopic and ruptured. This as well as the other tube and ovary were removed, and the abdomen was flushed and drained. A good recovery followed.

A patient who has once had ectopic gestation may have a second attack if the opposite tube and ovary are left. I have seen one such case. The first attack this patient had was reported by me in the MEDICAL RECORD of December 5, 1891, and was the first of my cases. It is briefly as follows:

Mrs. H——, aged twenty-four years, married four years; was never pregnant. Menstruation delayed two weeks, when she was taken with violent pains in the lower abdomen, more on the right side, with collapse, and a pulse of 120; the temperature was subnormal. Three days later a similar paroxysm occurred and she began to flow; this was watery and shreddy. In a week the patient was better. November 3d, thirty-three days from the time she should have menstruated and eighteen days from the first pain, she was taken with the third paroxysm of pain, which continued for the next few days. She again began to flow, and was semi-conscious, with a pulse of 140 and a subnormal temperature. By vaginal examination a tumor could be detected on the right side; the uterus was large and retroverted, and pulsation was active about the cervix, vagina, and broad ligament; the bowels were tympanitic. The patient finally rallied, and the temperature rose to 103 F. The diagnosis was extra-uterine pregnancy. The following day the abdomen was much softer and fluctuation present. Upon percussion the abdomen was flat anteriorly, and tympanitic posteriorly and laterally. The diagnosis was rupture of the sac and fluid blood in the peritoneal cavity. The hypodermic syringe confirmed the diagnosis of blood in the abdomen. On the following day an operation was performed by Dr. Horace Packard, of Boston. The abdomen was filled with blood and clots, and the right tube the seat of a ruptured ectopic gestation.

Two years later I saw the patient's husband, who gave me the following history: She had skipped a period of two weeks, was nauseated, and had an attack of pain with faintness; felt the same as she did with the sickness two years before. I was just starting for the World's Fair, and so advised him to see his physician, and if necessary have another operation, as it seemed a certain case of a second extra-uterine pregnancy. A little later Dr. Packard removed the left tube, which was ectopic. The patient made a good recovery. The condition of the abdomen in the first attack was somewhat peculiar, *i.e.*, a tympanitic abdomen at night, followed by a soft fluctuating abdomen in the morning, with flatness anteriorly and tympanitic areas laterally and posteriorly. The introduction of a hypodermic needle into the abdomen, while it was followed by no bad results in this case, is not a safe procedure and is not necessary in making a diagnosis.

During the attack of pain the pulse is rapid, the temperature generally subnormal, and the patient suffers from shock; the amount of shock generally depends upon the severity of the hemorrhage. After rallying from the shock the temperature generally rises.

If the outer end of the tube is involved the ovum may be expelled from the end of the tube without rupturing it, or a hemorrhage may take place from the fimbriated end of the tube. In this case the characteristic pain is not present, and the faintness depends upon the amount of hemorrhage.

I was called in consultation and afterward witnessed an operation on the following case. I can only report it imperfectly from memory: The patient, a strong young woman, thirty-three years of age, had had symptoms of pregnancy and had not menstruated for two months. She had had no pains, but did not feel right, so consulted her physician, who, finding an enlargement in Douglas' cul-de-sac with active pulsation, diagnosed ectopic gestation. The diagnosis in my mind rested between pregnancy in a retroflexed uterus and ectopic gestation; the sound passed in an anterior direction away from the mass, which excluded uterine pregnancy. The operation revealed the right tube prolapsed in the posterior cul-de-sac, distended, and adherent to the uterus; the fimbriated end was the seat of an ectopic gestation, and an active hemorrhage was taking place from the end of the tube. In this case the severe pain and the slight menstrual disturbances so characteristic of this trouble were absent.

After a ruptured tubal pregnancy the ovum may die and the blood and other products become encysted and absorbed, or it may break down into an abscess.

Mrs. X—— gave a history as follows: Six months before she thought she was pregnant; she had skipped a menstrual period and afterward had irregular flows and severe abdominal pains; this was followed by a long sickness, with pain and fever. Upon examination, a good-sized abscess was made out over the right broad ligament; it was adherent to the peritoneum anteriorly. A gush of pus followed an incision, and afterward a mass, the size of the hand, was removed; this was supposed to be the remains of a fœtus, which

examination by a pathologist confirmed. A rapid recovery followed.

If the ovum does not die after rupture or expulsion from the tube it forms new attachments and continues to grow, and may go on to full term, when it is either delivered by an operation, or else after a spurious labor the fœtus dies, the watery parts are absorbed, and it is either encysted, when it may remain for years, or suppurates with gradual expulsion through the vagina or rectum, or is impregnated with lime salts, forming a lithopedion.

I was called to operate in a case that I can only imperfectly report. A woman in middle life became pregnant, and, while not well, passed to full term. Pains started and her physician was called. Upon examination he saw it was not a normal labor. The growth was large and resembled an ovarian cyst. A trocar was introduced and a few pints of fluid were removed; a hard mass still remained. The tumor refilled in a few days and was again tapped; this time pus was removed. I saw the patient a few days later. The abdomen was about the size of that of a woman at seven months; pus was oozing from the old trocar insertion. Upon vaginal examination the uterus was found small and pushed to the right; the growth was soft, and a hard mass, resembling a fœtus, could be made out. The patient was in collapse, so an operation was not performed. Later an autopsy was refused. While not knowing the exact condition, I have always considered it a case of abdominal pregnancy at term, with spurious labor and death of the fœtus.

In abdominal pregnancy symptoms similar to those of early tubal pregnancy are noted, followed by a tumor, gradually increasing in size; later fœtal movements and heart sounds are noted, with other physical signs as in normal pregnancy. The menstruation is irregular, often lasting a long time. Upon vaginal examination the uterus is found a little enlarged but empty, and the fœtus and sac are above and to one side. Extra-uterine and intra-uterine pregnancy may occur at the same time.

Dr. Howard Kelly reports the following: "The late Dr. H. P. C. Wilson, of Baltimore, had the good fortune to save both the extra-uterine and intra-uterine child in the case of a woman, twenty-four years old, in her fourth pregnancy. She bore a female child in easy labor, April 15, 1880, a month before the calculated time. It was at once evident to both patient and midwife that there was another child. An examination showed that the tumor in the abdomen was perfectly independent of the uterus, and, auscultating it, fœtal heart sounds were detected. An effort was then made to delay operation at least twenty-three days, until the full term of the intra-uterine gestation had arrived. The patient had several attacks of colic and labor pains, which were quieted by opiates. The operation was performed May 11, 1880. The abdomen was opened and a sac exposed which ruptured under slight manipulation, discharging about two litres of amniotic fluid, and a male infant, weighing eight pounds, was delivered. The child lay well flexed in the abdomen, with buttocks down and back turned forward. The sac was sewed to the abdominal incision and drained. The patient died of sepsis ninety hours after operation."

Interstitial pregnancy has some symptoms in common with tubal pregnancy. Examination will reveal an enlargement at the horn of the uterus, with active pulsation; the uterus will be enlarged. This form may rupture into the uterus, broad ligament, or peritoneal cavity. Rupture takes place later than in tubal pregnancy, and the hemorrhage usually is severe.

The diagnosis of ectopic gestation as a rule is easy; still mistakes often occur. I have seen one case of a retroflexed pregnant uterus giving almost a positive history of extra-uterine pregnancy; with physical signs by vaginal examination also confirmatory. No sound was introduced, but the patient miscarried some days after pains first started. I have also seen a case of ectopic gestation simulating pregnancy in the retroflexed uterus; in this case a diagnosis was important, and a sound was introduced into the uterus, which was found in normal position and empty. A lateral uterine displacement may also be misleading. Appendicitis, hydrosalpinx, pyosalpinx, and tumors may at times simulate extra-uterine pregnancy, but one should always bear in mind the previous history as well as the physical signs.

Mrs. K—— called at my office with the following history: She was twenty-five years of age; had one child ten years old; had had one miscarriage. Six years before she had pelvic peritonitis; she had not been pregnant since. She had run over her period two weeks, had morning sickness, and sore breasts with a little milk upon pressure. She had had a slight bloody uterine discharge for a few days before; the pulse and temperature were normal. She thought herself pregnant. Upon examination, the uterus was found slightly retroflexed; the right tube and ovary were a little enlarged, and to the left of the uterus was a tumor, the size of a small lemon, tense, fluctuating, with active pulsation of the vessels of that side. Ectopic gestation was suspected. A week later her condition was about the same, but the growth seemed a little larger. Pulsation of the vessels was still very active. One week later, *i.e.*, eight weeks from the last normal menstrual period, she was taken with severe abdominal pains, faintness, cold sweat, and other signs of collapse. The temperature was subnormal and the pulse was 120. The face was anxious. A slight uterine hemorrhage was present. Examination revealed about the same conditions as before. A diagnosis was made of tubal pregnancy with rupture, and an immediate operation was advised. Some delay occurred, so that the operation could not be performed until the following morning. When the abdomen was opened no blood was found in the peritoneal cavity. The left tube was enlarged to about the size of a large lemon, and was firmly adherent to the uterus, intestines, and pelvis. It was of a deep blue color and very vascular. After a tedious dissection this was removed without rupture. The tube and ovary of the opposite side were found diseased and also glued into the pelvis. They were removed. The wound was closed without drainage. Rapid recovery followed.

Examination of the specimen showed a beautiful condition of unruptured tubal pregnancy, although a little rounder. Upon section a few ounces of matter looking like coffee-ground fluid escaped; no blood clots were found. The ovary was intimately connected with the mass. With all the symptoms of extra-uterine pregnancy, both general and physical, we here had a tube filled with fluid looking like coffee-grounds. This patient was not hysterical and knew nothing about extra-uterine pregnancy.

The treatment of extra-uterine pregnancy is by immediate operation. As soon as the diagnosis is made one should operate, for one cannot tell when rupture, possibly with fatal hemorrhage, may take place. In cases left without operation all the children and seventy-six per cent. (Martin) of the mothers will die. By early operation the mortality should not be over six or eight per cent. (Kelly).

If the child is viable, an operation should be performed at once; if nearly so, operation should be delayed until the child is viable. Operation in these advanced cases is hazardous for the mother, as the placental circulation is active and vascular adhesions are numerous. The chief danger is hemorrhage at the time of operation and sepsis in cases in which all the

placenta and membranes cannot be removed. If the child has just died it is better to wait a few weeks, unless the symptoms are urgent, as the circulation in the placenta will then stop and it will become loosened, thus lessening the danger of hemorrhage and making its removal much easier.

Time will not allow me to say more.

THE PROPER READING-DISTANCE.

By NORBURNE B. JENKINS, M.D.,

KNOXVILLE, TENN.

At a distance of several metres or yards little or no muscular effort is required for the normal eye to see objects distinctly; but an extreme exertion of the ciliary muscle, which controls the crystalline lens, is necessary if the vision be directed to an object a few centimetres or half-inches distant from the eye.

The following may illustrate the work of the muscles of the eye in reading at several distances: A sheet of paper, about twenty centimetres (eight inches) square, printed with type sufficiently large to be easily read at five or six metres or yards, is placed at this distance from a person with normal or emmetropic eyes. Practically no contraction of the muscles of convergence or of the ciliary muscles is necessary in order to read the type. Should the paper be placed a metre or yard from the eyes, the ciliary muscles and the muscles controlling the motions of the eyeballs are called upon for additional work, but no inconvenience is occasioned to emmetropic eyes by prolonged vision at this distance. If the paper now be placed within a few centimetres or half-inches of the eyes, the ciliary muscles contract to their utmost. The internal recti likewise are in a state of extreme exertion, in accomplishing the convergence necessary, in order that both eyes may see the same type at the same instant. The muscles are no longer adequate to the increased tension. They become exhausted and the vision is embarrassed. The type is alternately blurred and distinct, in consequence of the alternate failure and recovery of the muscles. Should this process continue for many minutes, pain and vertigo come on, and the sufferer is forced to direct his vision from the paper.

The nearer objects approach the eyes, the greater will be the necessary muscular effort and the sooner will the muscles refuse to perform their functions; the farther the type is held from the eyes, the less is the requisite muscular effort; hence it is probable that the farthest point at which distinct reading-vision is possible is the proper distance for continuous reading. Probably this point is more than thirty-five centimetres (fourteen inches) distant from the eyes, and is dependent upon the strength of the muscles, habit, and the visual acuity.

It may be observed that persons who use both eyes in reading, and who without lenses read for hours with comfort, usually hold the reading at a greater distance than thirty-five centimetres (fourteen inches) from the eyes. Such persons probably are hyperopic, emmetropic, or slightly myopic, and have less difference than 0.5 D in the refraction of the eyes, or less astigmatism than 1.25 D—rarely as much as 0.75 D.

Owing principally to the elasticity of the crystalline lens, many persons under the age of thirty-five are able to read continuously at a nearer point than thirty-five centimetres (fourteen inches), notwithstanding there may exist a considerable error of refraction. Perfectly fitting lenses are the more necessary for astigmatic persons past middle age, since the lenticular and muscular elasticity is greatly diminished, and astigmatic aberration is then corrected only by the cylindrical lens. It may be overcome by the convex lens, which magnifies the type rather than makes it clear in outline. If astigmatism in the aged is not corrected, reading is possible only by magnifying the type; and the stronger the convex lenses used, *i.e.*, the more the type is magnified, the nearer must the reading approach the eyes. If the lenses are too powerful, the muscles which control the eyeballs are overtaxed and binocular single vision becomes impossible; consequently one eye suppresses its retinal image, which often results in an amblyopia of greater or less degree. By the suppression of the retinal image of one eye the emmetropic watchmaker may, by the hour, wear on the fellow eye a powerful convex lens (say 10 D or more) without inconvenience. Should he place such a lens on both eyes, owing to the inadequacy of the muscles of convergence, binocular single vision would be impossible, except with the aid of powerful "base-in" prisms.

It is probable that persons who cannot read continuously with comfort at a greater distance than thirty-five centimetres (fourteen inches) are prevented by one or more of the following conditions: Disease; an uncorrected or an improperly corrected astigmatism of 0.5 D or more; an uncorrected or an improperly corrected hyperopia; an uncorrected or an improperly corrected presbyopia; an uncorrected or an improperly corrected difference of 0.25 D or more in the refraction of the eyes; an astigmatic correction in the absence of astigmatism; an hyperopia of more than 5 D; an astigmatism of more than 3.5 D; an anisometropic correction in the absence of anisometropia; an improperly corrected myopia; loss of equilibrium of the ocular muscles, resulting from the graduated tenotomy or from the injudicious use of the prism.

Assuming that an astigmatism of 0.5 D or more is present in from forty to eighty per cent. of persons, and that a difference of 0.25 D or more in the refraction of the eyes exists in from thirty to seventy per cent. of persons, the above-suggested statements are probably not unwarranted.

It is likely that the complete estimation of astigmatism is as difficult as any procedure that ever confronts the oculist. It is not unusual to find an astigmatism of from 0.5 D to 2.5 D unobserved or but partially estimated by the best of refractionists.

In the absence of disease, of astigmatism of more than 3.5 D, and of hyperopia of more than 5 D, it is probable that all persons who have a distant vision as good as $\frac{6}{6}$ ($\frac{20}{20}$), with or without lenses, may, when perfectly fitted with reading lenses, read at the proper distance for hours with perfect comfort.

The robust and those who read but little may be affected with as much as 2 D of astigmatism, and yet may use simple convex reading-lenses without serious inconvenience even as late in life as the sixty-fifth year.[1]

Absinthe Drinking.—Absinthe drinking concerns the French people more than it does the American or English, as in France the habit is prevalent, while elsewhere it is hardly heard of. When absinthe, the essence of a plant known as Artemisia absinthium, is mixed with alcoholic drinks, it adds its special action to that of alcohol. It produces dizziness, and, finally, an epilepsy, which differs in no way from the ordinary disease of that name. Absinthe intensifies the alcoholic effects, and it is claimed that it anticipates and overshadows them. It acts more swiftly than alcohol, causing greater excitement, frightful hallucinations, especially of sight, and, as French authors, such as Laborde, Motet, Melangée, Magnan, and Legrain, affirm, "the drunkenness of absinthe is, moreover, of unprecedented violence and presents the greatest danger."—*Medical Jurisprudence of Insanity.*

[1] Myopia of more than 2 D has not been considered in the above article.

NOTES ON THE TREATMENT OF PULMONARY TUBERCULOSIS.

By FREDERICK W. SMITH, M.D.,

SYRACUSE, N. Y.,

SECRETARY OF THE TUBERCULOSIS COMMITTEE, NEW YORK STATE BOARD OF HEALTH; MEMBER OF THE ONONDAGA COUNTY MEDICAL SOCIETY, SYRACUSE ACADEMY OF MEDICINE, AND THE AMERICAN PUBLIC HEALTH ASSOCIATION.

The treatment of tuberculosis no doubt seems to many a worn-out, threadbare subject. Probably no other single subject has been given so much attention by the medical profession, and owing to the fact that one-seventh of all the deaths of the world is still caused by tuberculosis, the matter of the treatment of this disease doubtless deserves all the attention it has received.

After all that has been said and done by the most eminent members of our profession toward the prevention and cure of consumption, the fact remains that it still deserves the first place in our efforts for the alleviation of human suffering and distress. I shall not attempt in this paper to offer anything new or original, but some recent experiences have prompted me to call attention to methods of treatment which I believe to be most valuable, and which are, I am sure, much neglected, and by many physicians entirely overlooked or disregarded—and this notwithstanding they are obviously the most rational of all methods of treatment for pulmonary tuberculosis. In the general management of tuberculosis, we are confronted with two great problems:

First, its prevention.

Second, its arrest or cure when once established.

When, in 1882, Koch discovered the tubercle bacilli and cause of tuberculosis, its infectious nature at once became positive (though often before clinically proven) and the methods of prevention plain; yet but little practical advantage was gained by way of medical treatment. Briefly, the prevention of tuberculosis is accomplished:

First, by strict attention to personal and general hygiene.

Second, by the proper management and immediate disinfection of all tuberculous sputum.

Third, by a careful municipal or town inspection of dairy cattle and abattoirs, thereby insuring pure milk and wholesome meat, and giving a guarantee against the dangers of bovine tuberculosis.

Fourth, in addition to the foregoing, segregation as far as it is possible and practicable to practise it.

In the establishment of public sanatoria for the indigent tuberculous is a field for the philanthropist, far reaching and great, almost beyond comprehension in its possibilities for good in the alleviation of suffering and the prolongation and saving of human life. Here are certainly grand opportunities for those who are fortunate enough to be able to do something for posterity.

The arrest and cure of consumption or pulmonary tuberculosis are of late becoming matters of common observation, and the question of most interest is how its arrest or cure can be best accomplished. The best results in its treatment cannot be accomplished by any special system or method of treatment, but by the election of the best combination of methods, or by individualizing treatment so as to meet the requirements or idiosyncrasies and peculiarities of each patient. The faculty of being able to individualize patients and treatment is of especial value in the treatment of consumption, and goes far toward the successful management of any disease.

While the discovery of the specific cause of tuberculosis has resulted in very much good in the general management of the disease, it has not as yet resulted in the material practical advantage that we might have expected in its medical treatment.

The continued presence of the living tubercle bacilli causes tuberculous disease in a favorable subject. "The multiplication of the tubercle bacilli and the absorption of their specific poison cause emaciation and death." To remove or destroy the bacilli without injury to the infected being, before irreparable damage has been done, is the chief object of all treatment. That the bacilli find the most fertile soil in the systems of those of feeble constitutions, low vitality, and impaired digestion, living in conditions of unsanitary environment, is well known. It is also well known that in the battle for supremacy the bacilli cannot win over a constitution which is thriving under proper nutrition.

First in importance in the successful treatment of tuberculosis are a proper altitude and atmosphere. To the late Dr. Alfred L. Loomis, more than to any other man, belongs the credit of demonstrating the importance and value a proper climate plays in the treatment of tuberculosis. Unfortunately only a small proportion of consumptives can avail themselves of the favorable influences of the North Carolina mountains or our own Adirondacks, and the remaining very numerous and ever-present unfortunates must have exclusive home treatment.

Second in importance is hygiene. As in the prevention of the disease, so in its cure, attention to personal and general hygiene plays an important part. Early and routine exercise in the open air, wherever the patient be situated, must always be insisted on for all patients able to be about.

Third, nutrition. The matter of the nutrition of consumptives is of itself too large a subject for a small paper. Suffice it to say that as far as possible a nitrogenous diet is quite necessary and always best assimilated. Many patients can digest ground beef and gain and improve upon it, when they cannot assimilate milk. Some can assimilate and with advantage partake of a considerable quantity of nuts. Certain it is that all tuberculous patients cannot be nourished alike. Always in this disease every effort must be made to encourage the taking and favor the assimilation of the most nutritious and stimulating diet. Forced or improved nutrition increases vital power, and increased or improved vitality purges the system of morbid products or processes.

Fourth, general medication. This cannot be specific, neither can we follow in a series of cases any definite or rigid rule or scheme of treatment; but we must meet impending conditions or indications, which are varied and many. Over-medication by the stomach, I believe, is a too common error in treatment, and often by its digestive disturbances prevents the more important factor of proper nutrition. There are, I believe, but two medicines worthy of special mention connected with the treatment of tuberculosis, and if given early and in sufficient quantity and judiciously they might almost be called specific in this action. They are, mentioned in the order of their value, iodoform and creosote. The use of cod-liver oil must not be insisted on regardless of the ability of the patient to assimilate it. It has, I believe, but little virtue beyond its nutritive value.

Fifth, in addition to general medication, as usually implied and to which I desire to call your special attention, is what has been termed "topical" or "intrapulmonary medication"—that is, the administration of medicine by inhalation. By inhalation, both local and constitutional effects of certain medicines can be produced as quickly and as surely as by any other way; and this method, properly employed in conjunction with other treatment, is, I believe, bound to yield a large percentage of favorable results. The remedies that can be used to the best advantage by inhalation are iodoform, creosote, pine-needle oil, terebene, menthol and eucalyptus in combination with albolene,

glymol, and glycerin. Owing to personal idiosyncrasy, one or more of these remedies cannot always be used, but the amount of these substances that can be given and tolerated by inhalation in a majority of cases is quite surprising. For this form of treatment, there are several vaporizing or nebulizing apparatuses that can be satisfactorily used.

Dr. Burroughs, of Asheville, who has had large experience in this method of treatment, recommends the daily use by inhalation of "five grains of menthol, twenty drops of terebene, twenty drops of oil of pine needles, twenty drops of eucalyptus, and twelve to twenty drops of creosote in one-half ounce of glymol." By the inhalation treatment germicidal remedies can be placed in close proximity to diseased tissues, if not in actual contact with millions of tubercle bacilli, where they may exert their beneficial effect; and it seems rational, at least, that remedies thus applied will act more surely than if required to find the way from the stomach to diseased parts through the circulation after the various changes by the process of assimilation. The constitutional or toxic effect of gases, vapors, or contaminated atmospheres is a fact well established and of common observation, and why this method of the therapeutic administration of certain remedies in pulmonary tuberculosis has not before become of more general use I am unable to say. It is rational, practical, and easy of administration, and proven of much value. For some months past I have been using this method with marked and positive and uniformly good results, and I have come honestly to believe that a physician who attempts to treat this disease without the aid of "intrapulmonary medication" neglects an imperative duty. In addition to the foregoing, I also desire to call attention to and urge the more frequent use by inunction of some animal fat, preferably that of the pig. Its use in this manner is especially advantageous where the appetite and digestion are poor, and inability to assimilate cod-liver oil has been demonstrated. Of course it is well understood that to obtain favorable results in treatment by any method or combination of methods, the disease must be recognized early and treated vigorously.

Not enough physicians are availing themselves of the advantage of the use of the microscope in the early diagnosis of tuberculosis. By an earlier diagnosis and a more vigorous treatment on the lines here suggested, I am certain a much larger percentage of patients can be cured or saved for years of comparative comfort, happiness, and usefulness.

Clinical Department.

DERMATITIS MEDICAMENTOSA.

By WALLACE W. RYALL, M.D.,
BURBANK, OHIO.

I HAD a strange case fall under my care on Monday morning, November 14, 1898. Rhoda G——, four years old, had been suffering with toothache on Saturday and Sunday. "Diamond oil"—composed of alcohol, gum camphor, tincture of capsicum, oil of sassafras, hemlock, cedar, aurantii florum, cajeput, and sulphuric ether—was applied, and on Monday morning an erythematous rash appeared all over the body, being the worst on the face. The parts were swollen and very itching. Without much treatment, except a wash of a solution of boracic acid and one of carbolic acid to allay itching, the little one recovered by Wednesday morning. What drug or drugs in the "oil" caused the dermatitis? The patient was perfectly healthy up to the time the tooth began to bother her.

A CASE OF ATROPHY OF THE UTERUS AND OVARIES.

By MARTIN F. SCHUH, M.D.,
NEW YORK.

MRS. FRIEDA W——, aged twenty-three years, married, born in Germany. The patient looks healthy and well nourished. She always enjoyed good health until four years ago, when she had an attack of peritonitis, from which she recovered after being confined to bed for three weeks. She had never given birth to children. She did not menstruate until her seventeenth year; the flow was always regular, lasted two days, and was quite profuse. About three years ago menstruation suddenly stopped and the patient thought she was pregnant, and when she saw no further signs of it she consulted a physician, who prescribed iron, etc., but without any avail.

One year after that the patient called on me. I examined her and found no signs of atrophy of the uterus or ovaries. I employed iron and uterine tonics, like my predecessor, but with no better result. I lost track of the patient until December, 1897. I then advised her to let me curette her; she consented. At the time of operation her uterus was about three inches in length, and the ovaries could be distinctly felt. This still did not aid in bringing about her menstruation. I lost track of the patient again until November 1, 1898. I then sent her to St. Mark's Hospital, and there put her under an anæsthetic to enable me to examine her better.

Upon examination I found a uterus about one-half inch long, with an opening in the cervix about the size of a pin-head. It was impossible to feel any ovaries. The peculiar feature about this case is that a year ago the uterus was about three inches in length, and it was possible to feel the ovaries.

A CASE OF PELIOSIS RHEUMATICA WITH PALLOR, BUT UNUSUALLY HIGH BLOOD COUNT.

By C. N. B. CAMAC, M.D.,
NEW YORK.

THE following case is of interest as indicating how fallacious pallor may be as an indicator of anæmia. On July 18, 1898, Mr. L—— was sent to me for blood examination by Dr. Frank Mathews, of New York. During February, March, and April, Mr. L—— had suffered from joint pains and vague pains across the shoulders, both of which later became sufficiently severe to confine him to his bed. The initial seat of the attack was the knees. When he was seen in July, the arms, legs, and trunk were covered with hemorrhagic spots, ranging in size from that of a pinhead to that of the blunt edge of a pencil. He stated that according as he wore high or low shoes the tops of the shoes determined the limit of the purpura. The pressure of garters, moreover, caused the spots to disappear, they reappearing when this pressure was removed. The case, from the history and appearance, was clearly one of purpura rheumatica. There was very marked pallor, and in order to determine the extent of this supposed anæmia Dr. Mathews wished an accurate count of the blood. Following is the report on the blood: The blood flows freely from puncture; deep, dark color; clots readily. W. B. C., 22,000; R. B. C., 6,004.000; ratio, 1 in 277. Hæmoglobin, 75–85 per cent. I regret not having taken dried specimens at the time, for the patient left for a long cruise the day after I saw him, making it impossible to do so subsequently. From fresh specimens and the stain (Toison solution) used in counting, the increase in the W. B. C. was of the polymorphonuclear variety. This I accounted for by the presence of a follicular tonsillitis. Consider-

ing, however, the high red count, the ratio of reds to whites was but little disturbed; the interest therefore centres about the unusually high red count in spite of the pallor, the hæmoglobin value at the same time being so very low in proportion. It is difficult to account for this, unless one associated the condition with the vasomotor disturbance, as seen in neurasthenia.

In the MEDICAL RECORD of June 25, 1898, M. P. Jacobi reports several cases of high red count associated with neurotic conditions, and cites J. K. Mitchell's observations on the increase after massage. To these I add the case of Miss W——, an undoubted neurasthenic, seen with Dr. Broun, August 13th. This case in spite of marked pallor had a red blood count approaching 5,000,000. Cabot treats very briefly of the blood count in purpuric conditions and reports no cases. When an actual hemorrhage has occurred the high red count immediately after hemorrhage has been noted by Thayer, in a case reported with chart of blood count in Osler's "Practice" (2d edition, p. 721). Dr. Thayer writes me in reference to the case just cited: "There was a most profuse hemorrhage on the 20th, and you see [referring to chart] how small the fall was on the 21st. Your case is most interesting. I know of no instance in which such an increase has been found."

I make no effort to explain these conditions. The possibility, however, of a peripheral engorgement, due to the loss of vasomotor tone, has more than once suggested itself. The dermatographia so active in the skin of neurasthenics is active evidence of this vasomotor instability. Is the purpuric condition an even more advanced state of unstable vasomotor tone, and is the peripheral blood count not a true index of the blood value of the system?

BROAD-LIGAMENT FLAP TO CLOSE OPENING IN RECTUM.

By J. F. BALDWIN, M.D.,

COLUMBUS, OHIO,

PROFESSOR OF OPERATIVE GYNÆCOLOGY, OHIO MEDICAL UNIVERSITY; GYNÆCOLOGIST TO PROTESTANT HOSPITAL, ETC.

SOME months ago I was called upon to operate in a case of fecal fistula, the fistula being of something like a year's duration and following an operation made by a colleague in a neighboring city for the removal of a small ovarian cyst. Both ovaries had been involved, but the operator was able to remove only one. On examining the patient the fistula was found passing directly backward, and from this fact and the character of the fæces discharged I concluded that it entered the rectum. The fistulous tract was dissected out in the usual way, its walls being found to consist of bladder and uterus in front, with exudate and intestinal adhesions at the sides and behind. On getting to its inner end it was found to enter the rectum by an opening about the size of the thumb-nail. There was great infiltration of the edges of the opening and the surrounding adhesions were very firm. Owing to the friability of the tissues I found it impossible to close this opening in the bowel. While hesitating for a moment as to what procedure I should adopt, my eye fell on the broad ligament, and my course was at once determined. The ligament was detached from the uterus down a sufficient distance to give me a free flap, and this flap was then brought around so as to cover very nicely the opening in the bowel. It was stitched fast with catgut, the remaining ovary removed, though not without considerable difficulty, and the incision closed without drainage.

Recovery was uneventful, and the patient left the hospital in about three weeks from the date of operation.

Progress of Medical Science.

The Significance of the Ovaries in Reference to the Origin of Sex.—Three years previous to the appearance of the "Schenk theory" Seligson, of Moscow, submitted a treatise on "The Arbitrary Procreation of Male and Female," based on the belief that each ovary contained different germs, the right containing the germs for the masculine, the left for the feminine, offspring. Von Winckel shows the invalidity of this belief by the following observation: In 1891 a woman was operated upon for left ovarian tumor. The entire ovary was removed. Since then she has given birth to five living children, three of whom are girls and two are boys. The theory of Seligson is, therefore, only a fancy and his conclusions are entirely worthless.—DR. WINCKEL, *Deutsche Praxis*, August.

A New Catheter.—The inherent uncertainties in the cleansing and sterilization of such instruments as catheters, vaginal and wound irrigators, etc., which are often for long periods of time in close contact with highly infectious material, has led M. B. Freund to experiment with a mode of construction which seems to obviate the difficulties. Instead of closed tubes of narrow lumen forming ideal lurking-places for dirt and contaminating elements, his appliances represent a little more than half of the usual instrument, split lengthwise. This leaves simply a long open gutter all of whose edges and angles are rounded and accessible, and which may be rendered sterile by chemico-mechanical means, without the use of heat, a thorough scrubbing with soap and water, followed by a washing with bichloride solution, lysol, or alcohol, sufficing to render it absolutely germ free. In point of practicability the instruments of this design were found to be in no way inferior to those of closed calibre, a stream of fluid flowing freely along the groove and showing no inclination to leave it. Catheters with a cylindrical extremity, the groove not running quite to the beak to facilitate introduction, acted perfectly in drawing the urine, and the various irrigators that were tested were equally satisfactory. The instruments described were of hard rubber or metal.—HABKANÄH, "Chirurgisch-gynäkologische Paxis," "Volkmann's klinische Vorträge," No. 226, October, 1898.

Three Hundred and Sixty Gall-Stone Operations.—Hans Laehr ("Die Resultate von drei hundert und sechzig Gallenstein-Laparotomien," "Volkmann's klinische Vorträge," No. 225, October, 1898) condenses his experience during the past eight years in the surgical treatment of surgical cholelithiasis. It is significant that nearly one-half of the whole number of operations recorded has been done since 1896. The total number of patients was 307, 255 being women and 52 men. The mortality was 11.7 per cent. However, of the 42 deaths reported, 30 were due to causes not directly traceable to the operation (advanced stages of carcinoma, purulent cholangeitis, etc.), thus reducing the actual death rate to 3.8 per cent. Laehr attributes much of his success to the very rigid asepsis practised. He does not use rubber gloves, but his method of sterilizing his hands takes about half an hour, and to diminish chances of infection all of his operations are done with but one assistant and one nurse. Another point of importance is the careful preparation of the patient by means of purgation and by bathing. The cases operated upon may be classified as follows: (1) Those in which the calculi were situated either in the gall bladder itself or in the cystic duct, and admitted of removal by cystostomy, cysticotomy, etc.; 180 operations were done. Of these 128 were immediate and 5 two-staged cystostomies, 7 were cystendyses, 37

cysticotomies, 2 extra-peritoneal "ideal" cystostomies, and 1 cysticolithotripsy; although inflammation and suppuration were present in two-thirds of the cases only three deaths resulted. (2) The condition of the gall bladder was such that it was either useless to the individual or even a source of danger, through the presence of ulcers, fistulæ, etc. In these, as in other cases where cysticotomy seemed less difficult than cystostomy, complete extirpation of the viscus was practised. (3) The calculi had already gained the common duct. In 46 instances they were removed by choledochotomy and in 1 by choledochotripsy; four deaths. (4) Nineteen cases in which instead of the encysted gall stones other morbid processes were found, such as gastric ulcer, floating kidney, etc., or where the gall bladder was free from calculi, but had contracted adhesions to intestines, stomach, and belly wall. (5) Besides the cholelithiasis there were present as complications advanced carcinoma of the liver, of the common bile duct, of the stomach, of the pancreas, diffuse purulent cholangeitis, cirrhosis of the liver, septic peritonitis, etc., which made treatment difficult or impossible; there were 46 cases, 27 ending fatally. What is needed is greater care in the diagnosis, and an effort should always be made to recognize one of the following conditions: (*a*) Gall stones in gall bladder without occlusion of the cystic duct; apt to be confounded with gastric affections. (*b*) Gall stone in gall bladder with temporary occlusion of the cystic duct. (*c*) Cholecystitis, hydrops, and empyema of the gall bladder. (*d*) Pericholecystitis, adhesions. (*e*) Acute occlusions of the common bile duct. (*f*) Chronic occlusion of the common bile duct. Jaundice is usually absent in conditions *a* to *d;* in *e* and *f* it is generally but not always present. The conclusion is drawn that in suitable cases operation is to be recommended, and gives permanent relief (not a single case of recurrence was observed), and the patient's chances are better the sooner his condition is recognized and subjected to surgical treatment.

Action of Alcohol and Its Uses as a Food Accessory.—We may briefly summarize the present state of our knowledge as to the action of alcohol and its uses as a food accessory: (1) It is to some extent a food, but is seldom taken except as a stimulant. (2) It can be used up in the body as a source of energy and heat, but the heat produced by it is rendered worse than useless owing to the greater heat loss brought about by the dilatation of the vessels of the skin. (3) Alcohol is of no use to healthy men who take sufficient food for their daily wants. (4) In moderate doses, and well diluted, it is not harmful to healthy men under ordinary conditions. (5) Alcohol acts injuriously in all cases of exposure to great cold or to severe and continuous exertion, such as in Arctic expeditions or mountain-climbing. (6) If taken with meals in moderate doses it is often beneficial, as, after much of the alcohol has been absorbed, the secretion of hydrochloric acid increases often to more than double the proportion to which it otherwise would attain. The secretion of acid also continues longer than when no alcohol has been taken. (7) Alcohol seldom has this stimulating effect if the stomach is diseased.—Dr. A. Lockhart Gillespie, "The Natural History of Digestion," page 355.

Albuminuria during Pregnancy.—Charles, as the result of his researches, offers the following conclusions: (1) In most pregnant women there is a certain degree of auto-intoxication; this is the normal toxæmia of pregnancy. (2) In lesions or disease of the kidney or liver the toxic condition becomes aggravated and may lead to grave complications, notably uræmia. (3) Toxæmia of renal origin is the most common, associated with albuminuria and œdema. (4) Albuminuria is not the cause of eclampsia, but a symptom owning a common origin. (5) Grave complications, such as coma, dyspnœa, paralysis, may prove fatal in the absence of eclampsia. (6) In most cases toxic eclampsia breaks out in albuminuric women; albuminuria is therefore an important precursory sign which should not be neglected. (7) The author's statistics show that 1 pregnant woman in 40 is albuminuric, and that of 4 albuminurics 1 develops eclampsia; eclampsia without albuminuria is rare—1 case in 9—and is less serious. (8) Albuminuria alone without eclampsia has often serious or fatal consequences—in 110 cases 8 women and 20 children died; there were 61 premature labors, 8 post-partum hemorrhages, and 3 cases of threatened convulsions. (9) Albuminuria should be looked for in all pregnant women. (10) Every albuminuric pregnant woman should be actively treated, a milk diet being the best. (11) In case of threatened danger premature labor is indicated and gives excellent results.—*Indian Medical Gazette*, September.

Air Emboli in Placenta Prævia.—Dr. F. Zorn, of Memmingen (*Münchener medicinische Wochenschrift*, 18), reports the case of a woman who had already borne twelve children and had been well, until one morning about four o'clock she awoke with hemorrhage from the genitals. About eight o'clock this became more profuse, and Dr. Zorn, who was called by the midwife, found the pains weak but of long duration. Vaginal examination showed the presence of large coagula; the os was wide open, the placenta covering the internal os; the head was felt by ballottement. Upon the arrival of an assistant the patient was prepared for operation under chloroform narcosis. The placenta, which encircled the entire os, was then perforated at a point opposite that on which the head impinged, the membranes were ruptured, podalic version was performed, and delivery effected. The placenta was delivered by the Credé method. The condition of the mother was good, the pulse full, hemorrhage slight. Inertia uteri occurred and the bleeding increased in spite of hot douching and the administration of pulverized ergot (0.5 gm. three times in two hours). About three hours after the birth of the child the patient became very restless, and tried to sit up; her face became anxious, the pupils dilated, corneæ dusky, sweat on forehead, with frequent thready pulse. Within ten minutes the patient recovered completely, but a peculiar rapid and deep respiration appeared. This also disappeared; but within half an hour the patient relapsed into her former condition, and recovered for the second time, only to relapse for the third time with symptoms of heart failure. From this attack she never recovered. Twenty-six hours later cross section of the uterus showed at the placental site square and slit-shaped vascular openings, some filled with clots, others entirely empty. Pressure caused the escape of blood mixed with air. The left ventricle and auricle were entirely empty. Upon section of the right ventricular wall numerous small and large air bubbles escaped from the cut surfaces. The entire right ventricle was filled with air bubbles. The right auricle in addition to these air bubbles contained also a small quantity of fluid blood. Putrefaction did not in this case enter as a factor. The writer concludes that primarily the air reached the placental site at the time of the passage of the surgeon's arm into the uterus, and then after the birth of the child was secondarily forced into the venous system by the massage given the uterus.

Verruca Vulgaris.—Apply green soap spread on flannel; keep on day and night, if possible. At the end of a fortnight scrape off the wart.—Vidal.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, December 24, 1898.

MALIGNANT TUMORS AND ERYSIPELAS.

THE question of the action of erysipelas and other acute infectious processes upon the course of malignant growths, or certainly some forms of them, persists in coming up from time to time, and the number of cases of apparent cure which must be considered well authenticated is steadily increasing. By "well authenticated" we mean cases in which a careful clinical and microscopical history is available. Richardson (in *Annals of Surgery* for December, 1898) reports a case which undoubtedly comes in this category, and which is of further interest from the fact that the infectious process did not have the ordinary symptoms of erysipelas, but was a deeper inflammation with the formation of much pus. The growth was a recurrent small round-celled sarcoma, and was of large size and, as it appeared, inoperable. During the healing of the operation wound infection occurred, and there were severe local and systemic disturbances. After the subsidence of these the tumor began to disappear, and eventually left no sign of its existence. Such results, even when occurring only once in many cases, must make us think of greater possibilities and stimulate us to investigation, though progress must necessarily be slow on account of the uncertain and unmanageable nature of the agent. Several writers have reported similar experiences often among a series of failures or doubtful results, and the idea seems now pretty firmly fixed that the erysipelatous process, and perhaps some other acute bacterial infections, exercise a powerful and sometimes destructive effect upon the cells which constitute certain malignant new-growths. All observers agree that sarcoma is the form of growth most regularly influenced by such treatment, and that carcinoma is very little and very irregularly affected. As we have noted, our agent is unmanageable and dangerous, and unfortunately, it is most dangerous when most efficacious. The virulent cultures of the erysipelas coccus have given the most satisfactory results as far as the growth is concerned, but in several instances have caused death from their own action. If the explanation of the results in these cases is that the bacteria, by their metabolism, produce certain substances which we may call toxins, fatal to those cells which have assumed an atypical course of growth and form the neoplasm, and thus cause them to disintegrate and be absorbed, we ought to be able to discover some way for the regulation and accurate application of such qualities as these particular organisms possess. If we can do this, we may yet have a very potent weapon against sarcoma, and possibly along similar lines may be able to combat the more dreadful carcinoma. Most experimenters have spoken of the necessity, or at least the usefulness, of making injections of these bacterial agents into or near the growths. If the favorable action of such material is systemic in character, the result ought to be as good, no matter where the injection is made, but if the action is purely local, like a caustic or a local antiseptic, we should reasonably expect only a local result, and consequently no *cure*. Experience has, however, shown that better results have been obtained by local injections, and the explanation probably is that the action is systemic and through the circulation, but that perhaps when used locally the virus has less chance to become attenuated and reaches its objects of attack in a more concentrated form. It is clear that a substance depending upon a more or less coarse local action could have no effect upon a metastasis which might be microscopic, and in the cases of sarcoma reported as cured we are justified from the descriptions, even without proof, in concluding that there were metastases, and that the action of the agent was systemic. The treatment of malignant disease is one of such great importance that we ought carefully to consider everything from scientific sources upon the subject, and, though it is a mistake to be sanguine, we must in connection with this subject rather seek explanations than deny facts. Whether the destructive action of these bacterial poisons upon the cells of malignant growths helps the theory of their parasitic origin is very doubtful.

THE ORAL METHOD OF TEACHING THE DEAF AND DUMB.

IMMENSE strides have been made in the methods used to teach those afflicted with deafness and dumbness to be able to communicate with ease among themselves and with their fellow-creatures. In no country has this advance been more marked than in the United States. The obstacles in the way of teaching deaf-mutes were for long believed to be insurmountable, but, thanks to the persistent and ungrudging labors of a small band of earnest men, these difficulties have been successfully overcome, and at the present time a deaf and dumb child can in most instances be taught to earn his own living, and instead of being regarded as a useless encumbrance becomes an independent member of society. As may be well believed, however, this happy result has not been reached without the expenditure of infinite pains and trouble. In order to show the great change that has come over the minds of experts in treating the deaf and dumb within the past thirty years, we will first quote the opinions of Mr. Turner, one of the early principals of the American School at Hartford, Conn., and then give an extract from the 1898 report of Mr. Job Williams, the present principal of the American School. In 1867 Mr. Turner

said: "The attempt to teach articulation has never been a part of the regular system of instruction of the deaf and dumb, and I hope never will be. We can give them a measure of vocalization—imperfect, to be sure—we can teach some of them to pronounce, parrot-like, words something in the way we do; but we cannot make them (the deaf-born) understand the use of vocal language, with its articulation, its emphasis, its point. It has never been done; it can never be done."

In 1898 Mr. Williams made use of these words: "The aim of all school instruction should be to aid the pupil to master the English language in order that he may have easy communication with the hearing world about him through the English language, by spoken English where possible, but where that proves impossible, by written or spelled English.

"Even a small degree of speech is valuable. Teach speech, speech, speech by all means and to the fullest degree, and use it whenever practicable, in school and out of school. Encourage it at all times, and let non-English means of communication be discouraged wherever the English language will answer equally well. English, either spoken, written, or spelled, is in the main the language of our school exercises."

The history of the rise of the oral method is both instructive and pathetic. The late Hon. Gardiner Greene Hubbard, of Washington, D. C., had a little girl who was deaf, and it was due to his unsparing efforts to devise a better method of instruction than the one then in use, for the sake of his deaf child, that the present oral system in this country sprang. There has recently been a somewhat sharp controversy between the exponents of the oral system and those who support the sign-language method. Mr. Alexander Graham Bell, the champion of the oral system, puts the case plainly for the supporters of articulation:

"I believe in the use of natural actions and natural gestures as hearing people employ them—not in any other way. I believe it to be a mistake to employ gestures in place of words, and natural pantomime or sign language of any sort should not, I think, be used as a means of communication. I do not object to manual alphabets of any kind in the earlier stages of instruction. I prefer the pure oral method to any other, but I would rather have a deaf child taught through De l'Epée signs than not educated at all. I think there are two classes of deaf persons who should certainly be taught by oral methods, the semi-deaf and the semi-mute; and I think that all the semi-deaf should receive the benefits of auricular instruction. . . . In my preference oral methods come first, the manual alphabet method second, and the sign-language method last."

In an article published in the MEDICAL RECORD of April 2d of this year upon the training of the deaf, we gave statistics of the number of schools for the deaf throughout the world and of the methods used in teaching therein. We then pointed out that in the great majority of schools for the deaf outside this country the pupils were instructed by means of articulation and lip reading. In North and South America teaching by signs still holds sway. We do not question that the deaf and dumb are as well and as carefully taught in the United States as in Europe, but if it has been shown that the oral method is the better—as it certainly appears to have been shown—why, then, should it not be universally adopted here? Of course oral methods differ. In Europe several modes of teaching by speech and other vernacular means are practised, but according to all published accounts the instruction of the deaf and dumb in lip articulation has in this country been brought to a high state of perfection. It would then seem to be surely advisable to have one efficient uniform system in force throughout the continent.

THE PREVALENCE AND PERVERSITY OF KISSERS.

DESPITE persistent effort on the part of several of our contemporaries to put an end to kissing, the practice has been quite generally continued, especially by youthful and thoughtless persons, and in some quarters the custom has seemed even to increase and flourish. In addition to the dangers already pointed out new ones have arisen.

In a kissing contest for £5 a side, which has just been declared off in a small town in Lancashire, the challenger sank exhausted at the seven-hundredth smack; his opponent having scored eighteen hundred in the hour.

Over in Germany at about the same time a young lover wrote to his sweetheart that he sent her ten thousand kisses. She sent back word that that was all well enough on paper, but that he had not the nerve to perform the feat in a truly manly way. This challenge was likewise accepted, and ten hours' time was allowed with brief intervals for malt refreshments. At the end of the first hour the score was two thousand and the condition of both active and passive participant good. One thousand more were added in the second hour, but at the seven hundred and fiftieth kiss on the third round the young man's lips became paralyzed and he lost consciousness. This fate, which some might consider merited, should prove a warning to promiscuous kissers as well as to those who concentrate with persistence. It is not paralysis alone, but insanity, which may follow such efforts.

Only a few weeks ago a middle-aged man attempted the feat of embracing every woman on a busy shopping street of this city. He had to be locked up by the police to prevent his over-exertion; but these efforts in his behalf were not timely enough, for the next day he was found to be a raving lunatic. During the past week a man of sixty years, whose name indicated his disposition, went mad after an attempt to kiss all the women on an elevated train. Sometimes the effects are remote, or what the French would call *à résistance;* that is, the husband of the party kissed becomes enraged almost to a point of madness. In Morristown, for example, a husband has been suing his coachman because the latter kissed the wife of the former; but it was shown that the coachman merely allowed himself to be kissed repeatedly without returning the salute, and the law holds that this constitutes no cause of action. Thus we see that so many

effects are directly or indirectly attributable to osculation that the whole chapter of its pathologic and sociologic features will have to be rewritten. Certain it is, in view of the more recent exploits of our young impressionable and ambitiously amatory naval hero, that we are rapidly accumulating data which may enable us in time to form entirely new theories on lip service, and new notions on the actual working capacity of the puckering muscle.

PECULIAR PEOPLE.

The name "peculiar people," adopted by certain persons who are banded together to believe certain things and to act in certain ways, is so much more appropriate than that by which others holding similar beliefs are known, that it is earnestly hoped the term "Christian science" may be forever banished. The force of this must appeal to all, whether within or without the fold.

Those who know most deeply the teachings of the Concord seeress and her followers need not be told that the precepts and practices are essentially unchristian and eminently unscientific. On the other hand, it needs but the most casual acquaintance with the preceptors and practitioners to discover their glaring peculiarities. If a man approaches you with the statement that "there is nothing so material about disease as to prevent its cure by a belief that it does not exist," and he tells you he is "peculiar," you are much more apt to become interested and not to wonder at him the next day when you meet him hurrying to a dentist's with a jumping toothache. And right here is another evidence of peculiarity—that a believer will employ a dentist when he will spurn a doctor.

Physicians have been truly patient in long-suffering, and it is time an end was made of this merry madness which so mixes the practices of religion and medicine. Some States have already insisted on the lines being sharply drawn between the two, and that those who desire to enter as competitors with us must possess themselves of the requisite diploma. Judges have frowned upon their practices from the bench, lawyers have held the matter up to ridicule, preachers have instructed their hearers, and journalists have done their part. The physician, however, either from modesty or indifference, alone of all the liberal-minded leaders of thought whose duty it is along with others to instruct and protect the ignorant, has made but feeble protest. When he does speak, it should be in a voice rising from every State, and long and loud enough to penetrate to every legislative hall. Its tones should not be uncertain, but a demand should be made that existing medical laws be enforced and wherever necessary new ones be enacted. By their own showing, it is a new system of medicine rather than a new religion which these peculiar people claim the right to practise without permitting the law to inquire into their qualifications. As enlightened citizens, if in no other capacity, physicians have a clear and pressing duty to perform.

News of the Week.

The Influenza.—In connection with the present invasion of influenza, which has been officially declared to be epidemic in New York City, the following table of deaths from this disease, which the board of health has had prepared, is of interest:

	1890.	1891.	1892.	1893.	1894.	1895.	1896.	1897.	1898.
January...	264	1	281	5	71	242	16	10	0
February .	30	0	109	4	33	165	18	28	8

Clinical Conferences on Diseases of the Skin.—Dr. L. Duncan Bulkley is now delivering his annual course of clinical lectures in dermatology at the New York Skin and Cancer Hospital on Second Avenue and Nineteenth Street. The lectures are given in the out-patient hall of the hospital every Wednesday afternoon at 4:15 o'clock. The course is free to physicians and is well attended by practitioners, both resident and visiting.

State Superintendent of the Poor.—President Stewart, of the New York State board of charities, has designated Secretary Hebbard to exercise the authority appertaining to the position of superintendent of State and alien poor, recently made vacant by the death of Dr. Charles S. Hoyt.

A Suit Against the New York Hospital.—The State board of charities has requested the attorney-general to institute proceedings against the Society of the New York Hospital, in New York City, to require the managers thereof to permit an inspection by the board's representatives of the hospital maintained by the society, and to make an annual report of its financial and other operations on the blanks provided by the board. This action is the culmination of a long dispute between the board of governors of the New York Hospital and the State board of charities. The contention of the Society of the New York Hospital is that it is not amenable to the law affecting charitable institutions. Its reports have always been made direct to the legislature, and it has refused to permit the board of charities to inspect its records, and will not use the blanks provided by the board in making a report of its expenditures and receipts.

The Report of the American Pediatric Society.—The following appeared in the *Archives of Pediatrics* for December, 1898: "The publication in mutilated form by the Medical Record of the American Pediatric Society's report on scurvy, we beg to say was not the fault of the recorder. Duplicate copies of complete corrected proof were sent to all the journals who

were to receive the report. The responsibility of the recorder ceased with the mailing of the proof copies, for he could not enforce their correct publication. If the society publishes its reports in all kinds of journals, it must expect to see them sometimes mutilated, as they have been in some instances each year." The responsibility for the publication in "mutilated form" of the report rests wholly upon Dr. Floyd M. Crandall, recorder of the American Pediatric Society. The report was published in the MEDICAL RECORD at his request, and exactly as it was sent by him, without additions or omissions. The existence of a minority report was unknown to the editor of the MEDICAL RECORD until a note from Dr. Caillé, the author of the minority report, called attention to its omission. If there was any mutilation of the American Pediatric Society's report it was done by the recorder of the society and not by the editor of the MEDICAL RECORD. We hope we have made our meaning plain.

The Insane of Havana.—A despatch to *The Sun* says that Dr. Archinard of the American commission has reported that there are three hundred and fifteen insane patients in the Havana asylum. Of these one hundred and seventy are sick and the remainder are starving and have no clothing. During the past year seven hundred and twenty patients died of hunger. The American commission has ordered fifty thousand pounds of food to be supplied to the insane asylum.

Circular of Information for those Seeking Appointment as Contract Surgeon in the United States Army.—The following requirements are exacted by the board of examiners: Evidence of graduation at a regular reputable medical college, diploma to be submitted to the board. Proof of hospital or other professional experience will be of benefit to the candidate. Candidates must be in good health, of reasonably sound physique, and citizens of the United States. The examination is of a practical nature, embracing hygiene, practice of medicine, pathology, and surgery. In addition a thesis on some professional topic will be prepared by the candidate. The following questions submitted to former candidates are published as a guide to applicants: 1. What chemical and physical qualities of water would lead you to suspect its potability? 2. What are the varieties and pathology of felon? 3. What is Widal's test? 4. What are the modern methods of treating diphtheria? The pay of acting assistant surgeons is $150 monthly. The applicant must be free from physical defects which would incapacitate him for the military service. For further information address Major H. S. Kilbourne, surgeon United States army, Army Building, 39 Whitehall Street, New York City, president of board of examiners.

A Thaumaturge or ——— .—Some one given to understatement recently spoke of the "Christian scientists" as "pests," and thereby drew forth a letter to *The Sun* from the high-priestess of the sect. Among other things the veracious writer says that she has "healed consumption in its last stages, that the M.D.'s, by verdict of the stethoscope and the schools, declared incurable, the lungs being mostly consumed." She also "healed malignant tubercular diphtheria (*sic*) and carious bones that could be dented with the finger, saving them when the surgeon's instruments were lying on the table ready for their amputation." She was called to New Hampshire to see a patient who was said by her physician to be dying of pneumonia, and she immediately restored her. She has "healed at one visit a cancer that had so eaten the flesh of the neck as to expose the jugular vein so that it stood out like a cord."

The Crusade against Tuberculosis in England.—The Prince of Wales called a meeting recently at Marlborough House to devise measures for infusing greater energy into the movement in England to cope with the increase of tuberculosis.

The Hospital Stamp Scheme, by means of which a fair amount of money was raised last year for the benefit of the London hospitals, has this year fallen flat. Philatelists have decided that they are not real stamps, since they will not be received for postage, and so they do not care to add them to their collections.

Dr. S. S. Adams, of Washington, lectured by invitation of the faculty before the seniors of the University and Bellevue Hospital Medical College, December 20th, at the hour of the usual pediatric lecture. His subject was: Fevers in children, their significance, general diagnostic value, and antipyretic treatment.

Dr. J. Francis Calef, of Middletown, has been appointed Surgeon-General on the staff of Governor-elect George Lounsberry, of Connecticut. Dr. Calef is a graduate of the Yale Medical School, in the class of 1880.

Smallpox at Norfolk.—There are about fifty cases of smallpox under treatment in the pest-house at Norfolk, Va. All of them are negroes. Some cases were discovered one night among the prisoners at the station-house, and, as a consequence, the police court suspended the following day.

Dr. Thomas H. Manley was, on the 15th of this month, re-instated as visiting surgeon to Harlem Hospital. Dr. Manley was one of twenty-eight physicians removed by the late Commissioners of Charities, to make room for medical-college appointees. Under the present *régime* all the hospital appointments are taken from the control of the colleges.

The Smoke Nuisance.—The health-board inspectors are apparently unable to cope with the growing smoke evil in this city, and the president of the board has requested that the police report on all violations of the law in this regard. Accordingly, any patrolman who happens to see a chimney belching out black smoke will be required to report his discovery to the sergeant at the station house, who will report to the captain, who will notify the inspector, who will tell the deputy chief, who will forward the news to the chief, who will report to the board, which will have the facts laid before the health board in order that its

inspectors may investigate them and report on them to the chief inspector, who will then report to the board that the law is being violated.

"The Medical Dial" is the name of a new monthly medical journal, published in Minneapolis, under the editorial management of Dr. J. W. Macdonald. The first issue is dated December, 1898.

The University of Berlin.—About eleven thousand students are in attendance in the different faculties at the University of Berlin this year, one hundred and fifty of them being Americans. Of the total number about six thousand are regularly matriculated, the others being simply auditors who are admitted to the lectures but cannot come up for a degree. Among these are two hundred and thirty women.

The Study of Tropical Diseases in England.—In addition to the London school for the study of tropical diseases, a similar one is to be established in Liverpool. A resident of that town has promised an annual donation, amounting to about seventeen hundred and fifty dollars, to maintain a laboratory in Liverpool for the study of tropical diseases, and the scheme will be carried out by a joint committee of the Royal Southern Hospital and of University College. A laboratory for immediate investigation will be built opposite the hospital, while prolonged research will be carried on in the pathological laboratory of University College. The Royal Southern Hospital receives constantly a large number of cases from the West Coast of Africa, as Liverpool is the centre of the African trade.

An Anti-Spitting Ordinance in Indianapolis.—Dr. E. D. Moffett, member of the city council of Indianapolis, and active in good sanitary work for the city, has fathered an ordinance, which will doubtless be passed, forbidding spitting on the sidewalks, in cars, and on the floors of public buildings of the city. He is backed by the public sentiment of all decent citizens, and by the good and representative women of the Indianapolis Sanitary Association. It is to be hoped the ordinance will be enforced, and not become a dead letter.—*Indiana Medical Journal.*

The Thirteenth International Medical Congress.—At a meeting of the organizing committee, held in Paris on November 15th, the arrangements for the forthcoming Thirteenth International Medical Congress were completed. The date of the meeting is fixed for the week August 2d to 9th, 1900. The work of the Congress will be distributed among five groups of sections composed as follows: Biological Sciences: Descriptive and Comparative Anatomy; Histology, Embryology, and Teratology; Physiology and Biological Physics and Chemistry; Anthropology. Medicine: General Pathology and Experimental Pathology; Bacteriology, Parasitology; Pathological Anatomy, Medical Pathology, Hygiene and Medical Pathology of Infancy; Therapeutics and Pharmacology; Neuropathology; Psychiatry; Dermatology and Syphilography. Surgery: General Surgery; Surgery of Children; Urinary Surgery; Ophthalmology; Laryngology; Rhinology, Otology. Obstetrics and Gynæcology: Obstetrics; Gynæcology. Public Medicine: Hygiene, Preventive Medicine, and Epidemiology; Forensic Medicine; Military Medicine and Surgery; Naval Medicine; Colonial Medicine. French is the official language of the Congress for all international relations. In the general meetings and in the sections German and English as well as French may be employed.—*The British Medical Journal.*

The Population of France Increasing Slightly.—An official report recently issued in Paris shows that the population of France in 1897 increased 108,088 over that of 1896. This is due to a decrease in the death rate, the birth rate showing no increase.

Suicides of Children in Germany.—The statistics of German schools, recently published, for the decade from 1887 to 1896 inclusive, show that 407 pupils of the state schools committed suicide in that period. Of these, 331 were boys and 76 girls, all under fifteen years of age.

Cremation in Australia.—A bill to regulate cremation, drafted by the council of the Cremation Society, has been introduced into the Legislative Council of Victoria. It provides that trustees of cemeteries may undertake cremation instead of burial, and expend moneys for that purpose and charge fees. No cremation is to take place without the production of two special medical certificates.

Family Insanity.—Three brothers in a town near Albany recently went insane. The first died in the State Hospital at Poughkeepsie, the second was adjudged insane after examination by a commission, and the third was seized the following day while brandishing a couple of revolvers with which he wished to kill some people who, he said, were shadowing him with the design of kidnapping. There is no previous history of insanity in any branch of the family, and no cause for the triple outbreak is known to exist.

The Dangers of a Medical Practice.—A New York drummer was recently found dead in his bed in a Cincinnati apartment house. The wife made a complaint to the police that her husband had been killed by the physician, who had given him an overdose of morphine. The latter admitted having given the man, who was suffering from delirium tremens, two hypodemic injections of one-fourth of a grain each of morphine. The coroner after an examination found that death was due to acute alcoholism and not to opium poisoning.

A Malarial Conundrum.—The Rome correspondent of the *Lancet*, commenting on the claim of Grassi to have preceded Bignani in the discovery of the malaria-bearing mosquito, suggests that it would "be of interest to know the distinguishing marks of his 'special mosquitoes,' so as, *inter alia*, to understand how it is that in Rome, where there are no mosquitoes properly so-called, malaria is prevalent, while in Florence, where mosquitoes (properly so-called) abound, there is no malaria at all."

Prohibiting the Importation of Pathogenic Microbes.—The government of Victoria, Australia, has put its collective foot down on the attempts of scientists to introduce strange microbes into the country. A medical man who recently returned to Melbourne from India, where he had been studying the plague, brought with him a stock of plague bacilli. The authorities of Melbourne strongly objected to the bacilli being imported and asked for their surrender. The medical man is said to have declined to give up the microbes unless compensated to the amount of fifteen hundred dollars, whereupon the authorities seized the culture tubes and destroyed them.

Intervention vs. Interference.—Dr. Winn, editor of the *Richmond Journal of Practice*, protests against the use of the word "interference" when one speaks or writes of operative or surgical treatment. He holds that the proper word to employ in this sense is "intervention," and he hopes to learn in time of its general adoption by writers on surgical subjects. We think, however, that, in the case of an assault upon a patient by disease, the surgeon has a perfect right to "interfere" in behalf of the patient. It's all in the point of view.

Poisoning from Clothes.—The New York *Herald* of December 4th, in its London letter, says: "The *Lancet* calls attention this week to new danger to life of poisoning by one's own clothing. The discovery was made by Dr. Godfrey Taunton, a physician in the General Hospital at Birmingham. First, one workman came to the hospital suffering acute agony from a severe rash on his wrists. Another man entered complaining of the same thing, but in addition he had the same rash on his knees. Soon after many others, all in one employ, appeared at the hospital suffering alike. Then it transpired that the workmen had been served with new overcoats. The cloth was found to contain zinc chloride. The day being wet, the men absorbed some of the poison when it was brought into contact with the skin, causing severe pain and a most irritating itch."

Hospital for Tropical Diseases in London.—The *London Times* in a recent issue says: "The arrangements of the Colonial Office for promoting the study of tropical diseases would appear, from a circular just published, to have been carried very nearly to completion. The circular sets forth that the directors of the Seamen's Hospital at the Albert Docks, which offers exceptional opportunities for studying cases of tropical disease, are providing the necessary buildings and teachers for the accommodation and instruction of the medical officers who may hereafter be selected by the Foreign Office or the Colonial Office for appointment in the tropics, and these facilities will also be made available for medical men without official status, but who, either as missionaries or in any other capacity, may desire to proceed to countries where the special knowledge in question will be required. There will, in short, be established in London a distinct school of tropical medicine, to be supported partly by a subsidy from the government, partly by the fees of students, and partly by the voluntary contributions of the public, and having for its object to instruct young practitioners who have completed the ordinary professional curriculum and obtained a legal qualification to practise in various forms of special knowledge which in this country possess scarcely more than an academic interest, but which in tropical and sub-tropical regions are of daily application in the cure of disease and in the preservation of life."

An Even Tally.—During one week in November the number of boys born in London was exactly the same as that of girls, namely, 1,348. During the same week the births exceeded the deaths by 1,290.

The American Gastro-Enterological Association.—The next annual meeting of this association will be held in Washington in May, 1899. The president of the society is Dr. D. D. Stewart, of Philadelphia, and the secretary Dr. Charles D. Aaron, of Detroit, Mich.

The "Archiv für physikalisch-diatetische Therapie in der ärztlichen Praxis" is the title of a new monthly journal devoted to hydrotherapy, gymnastics, massage, and "diet cures," which is to appear in January, 1899. The editor is Dr. Ziegelroth, of Berlin; the publisher, Max Richter, of the same city.

American Mission Hospitals in Ceylon.—A hospital for women and children has been opened at Jaffna, Ceylon. The funds were collected by the Misses Leitch, and the hospital was handed over to the American Mission. At Inruville a hospital has also been opened under the American Mission. This latter institution has been placed in charge of Dr. Isabella Curr.

Degrees for Christian Scientists.—Mrs. Mary Baker Eddy, the founder of Christian "Science," has just completed the examination of a class of about seventy students and has conferred upon them a degree of the Massachusetts Metaphysical College empowering them to go forth as "healers and as teachers of this system of medicine, whose only crowned head is divine sovereignty, whose only priest is spiritualized man."

School Inspection in Japan.—The minister of education of Japan has issued an order that inspectors shall visit the public schools of the empire once every month during school hours and report upon any matter of defective sanitation which may come under their notice. Hitherto the law has required the inspectors to visit the schools only at the beginning and the end of the school year.

Hospital Enterprise.—The editor of the *Cincinnati Lancet-Clinic* relates a story of hospital enterprise that, we regret to say, is not unique. A wealthy citizen of a neighboring city applied to a hospital to secure the services of a trained nurse for his daughter, upon whom a surgical operation was to be performed. The hospital authorities suggested that it would be better to send the young woman to the hospital, for there the surgeon's services would be given free, and as a further inducement the father was informed that he could

secure a room, board, and all needed nursing in the hospital for eight dollars per week, while a good trained nurse would charge him twenty dollars per week to do her work in his home. The offer was naturally accepted, and after a little bargaining the man agreed to pay two dollars extra per week, which he was assured would provide his daughter with all possible needs while she would be an inmate of the hospital.

Insane in Indiana.—According to the Indiana State board of charities, the number of insane in that State is approximately forty-three hundred, or one in six hundred and seventy-five of the present population. The proportion of insane in Indiana is less than in the States of Ohio, Michigan, Illinois, Wisconsin, Minnesota, and Iowa. In some of the New England States, however, it is only about half what it is in Indiana.

Fixing the Blame.—A clergyman in Wales is reported by *The Lancet* to have preached a sermon recently, in the course of which he said that "diphtheria is now prevalent in our midst, and many parents, made disconsolate by the deaths of their children, in their moments of despair have doubtless felt inclined to blame Providence. Do not blame Providence; blame the Swansea corporation, and blame yourselves for allowing the laws of sanitation to be ignored."

The New York Mycological Club, which was founded in 1897, now has over one hundred members. The objects of this club are "to identify and classify the larger fungi of the United States, especially the edible species and noxious and poisonous kinds which may be mistaken for them; to arouse a wider appreciation of the value of a cheap and abundant food supply, which in America is comparatively neglected; and to hold exhibitions, give lectures, and issue publications pertaining to the subject." The statement is made that over sixty varieties of edible mushrooms have been collected by members in the neighborhood of New York since the club was established.

The Late Colonel Waring and the Streets of New York City.—In the *Cosmopolitan* for December is a short but eulogistic article on the late Colonel Waring, in which his methods of clearing the snow from the streets of New York are compared with those now in force, needless to say by no means in favor of the measures employed by his successor. A brief sketch is given of Colonel Waring's way of overcoming the difficulties in his path, and reference is made to the differences of opinion in regard to the appropriations as follows: "Then came a dispute about appropriations. Colonel Waring demanded what was right. The public took sides with Waring. From that time out he held the public confidence. He was so highly respected that even the meanest and mangiest curs refused to bark at him in print. His lesson in organization has not been lost. The city of New York will not permit a reversion to old methods." Certainly the citizens of New York should not permit a reversion to the old slipshod methods of street cleaning, and they should distinctly impress this fact upon the minds of the powers that be. During the late blizzard, however, it appeared as if there had been a decided lapse.

The British Pharmacopœia.—An edition of twenty thousand copies of the new British Pharmacopœia has been exhausted, and a second edition is on the press.

A Clerical Pelopathist.—A German Lutheran pastor has developed a new therapeutic system, or rather has revived an old one, which consists in remaining in constant contact with mother earth. Those who cannot always lie in mud must roll about in it until they get a thick coat, and then refrain from rubbing it off. At night the sick must sleep on the ground. The reverend gentleman says man was created from mud, and so he must resort to mud for his re-creation when ill. He is at present building a sanatorium for the accommodation of his large and ever-increasing clientèle.

The Tsetse-Fly Disease.—A committee, which was appointed some time ago by the British Royal Society to investigate the tsetse-fly disease, has made its report. It finds that the disease affects a greater variety of animals than was at first believed. It also states that no means of prevention or cure has yet been discovered. Dieting appeared to have no effect upon the course of the disease. Inoculation with kindred parasites from the ordinary rat was tried; also the injection of bile from diseased animals, this fluid having been found to be soon fatal to the micro-organism, when mixed with infected blood in a test-tube. Serum was taken from diseased animals and from those which were either immune or decidedly refractory, but without the slightest effect. Even young animals, born from infected mothers, are no more resistant than others.

A New York Philanthropist in St. Louis.—A few days since a man was shot in a thickly settled part of the city. A crowd assembled, and Dr. W. E. Aughinbaugh, of New York, who was passing, turned his attention to the wounded man. The police arrived shortly after, and found the doctor working to revive the unconscious victim. They mistook his hypodermic syringe for a revolver! They immediately placed him under arrest, in spite of the protests of the crowd and his evident innocence! Although he made no resistance and signified his willingness to go to headquarters, this was not allowed. The majesty of the law, as impersonated by its officers, wished to make a show of force, and they proceeded to do so—tearing his clothing and ignominiously loading him into the patrol wagon, in which he was taken to headquarters. No explanation or communication with friends was allowed; he remained in a cell two hours, and was then discharged with a lame apology for the hasty conduct of the officers.—*The Medical Fortnightly.*

Col. W. H. Forwood, assistant surgeon-general, has been relieved from duty as attending surgeon, United States Soldiers' Home, near this city, and ordered to San Francisco for duty as chief surgeon of the department of California, to relieve Lieut.-Col. J. V. D. Middleton, who is about to retire from active service.

New Officers of the New York Academy of Medicine.—The following officers of the Academy were elected at the stated meeting held December 15th: *President*, Dr. William H. Thomson; *Vice-President*, Dr. Herman Knapp; *Trustee*, Dr. E. G. Janeway; *Treasurer for the Trustees*, Dr. W. F. Cushman; *Member of the Committee on Admissions*, Dr. Reginald H. Sayre; *Member of the Committee on Library*, Dr. A. Caillé; *Delegates to the State Society*, Drs. J. H. Huddleston, E. Le Fevre, L. F. Bishop, J. Arthur Booth, and James Ewing.

Protestant Hospital in East St. Louis.—A new building is about to be erected for the Protestant Hospital in East St. Louis, Ill. The corner-stone was laid with Masonic ceremonies on October 29th.

Variola Feared in England.—An epidemic of smallpox may be looked for in 1899, according to Sir R. Thorne's annual report to the London local government board. It seems that so many exemption papers have been granted that, while the proportion of unvaccinated children was previously less than twenty per cent., it is now about fifty per cent.

Anonymous Communications.—"A constant reader," "Medicus," "Q," "A bewildered friend," and all other correspondents who have sent to the MEDICAL RECORD letters without name and address are respectfully notified that their communications have been deposited in the waste-basket. The name of a correspondent will not be published, if the writer wishes to conceal it, but the writer must send his name with his letter if he wishes the latter to be published or even to be read by the editor.

The Consumption of Beer in Germany.—Statistics recently published show that the inhabitants of Berlin drink two hundred and six quarts of beer each annually, and those of Munich, whose thirst is proverbial, imbibe five hundred and sixty-six quarts each in the course of a year, or a little over three pints a day.

Taking Advantage of the Day of Rest.—The milk inspectors in a town in England had for some time made a practice of examining milk at irregular times and without warning, until the milk-dealers concluded that honesty was the best policy, indeed the only practical policy. These examinations, although irregularly made, had always been conducted on week-days. A long series of tests had failed to show any adulteration by the dealers, and then the inspectors decided to make an examination on a Sunday, with the result that over six per cent. of the samples of milk obtained were found to be adulterated. Hereafter the inspectors will make their unexpected visits occasionally on Sunday as well as on week days.

How About Cooking It?—Dr. Durham, an English advocate of vegetarian ideas, says the way to prevent disease among meat-eaters is to carry out thorough sterilization by heat, in order to destroy the poisons.

Hospital for Infectious Diseases in Baltimore.—The city council of Baltimore has passed a resolution appropriating the sum of sixty thousand dollars for a hospital for contagious diseases.

Death of a London Inebriate.—Jane Cakebread, for years one of the most notorious figures in the London police courts, died a few days ago. She held the record for convictions upon charges of drunkenness and disorderly conduct, having been found guilty of those offences about three hundred times.

Turning a Patient Out to Die.—The London Hospital authorities recently turned out in the street a patient who had acted indecently in the ward and had used profane language. They apparently regarded him as simply vicious and failed to recognize him as a dement. A policeman found him and took him to the Whitechapel Union Infirmary, where he died shortly afterward, and at the autopsy he was found to have had cerebral softening.

Obituary Notes.—DR. NATHAN SHERWOOD KING, of Yonkers, died at his home on December 11th, of pneumonia. He was born in 1824 at Fishkill, and was graduated in arts from Williams College in 1849, and in medicine from the College of Physicians and Surgeons in 1852. He leaves a wife and one married daughter.—DR. JOHN STILLWELL SCHANCK, emeritus professor of chemistry at Princeton University, died in Princeton on December 16th, aged eighty-two years. He was graduated in arts from Princeton University in the class of 1840, and in medicine at the University of Pennsylvania Medical School in 1843. For several years he practised medicine in Princeton, and in 1847 he took charge of the Museum of Natural History in Princeton University, delivering lectures on zoölogy, anatomy, and physiology. In 1856 he was elected to the chair of chemistry, and held it until 1892, when he was created professor emeritus.—DR. C. HOLMES MCNEILL, of Jersey City, died at his home on Jersey City Heights, on December 18th, from heart disease. He was graduated from the medical department of New York University in 1861. He had been a member of the board of health of Jersey City for three terms.—DR. ROBERT B. BAISLEY, of East Rockaway, died Saturday. He was born in Flatbush and was graduated from the College of Physicians and Surgeons in this city in 1842. He settled in East Rockaway in 1850, and has practised there since that time.—DR. EDWIN MINER, of Brooklyn, a prominent homœopathic practitioner and for many years chief of staff of the Homœopathic Hospital, died at his home on December 18th. He was born in this city in 1838. He was a graduate of the New York Homœopathic Medical College and Hospital in 1870.—DR. CHARLES S. HOYT, superintendent of the State and alien poor, died at his home in Canandaigua, N. Y., on December 13th, of pneumonia. He had grown old in the State service as a member of the office staff of the State board of charities, and was secretary of the board for many years.—DR. FRANK ARCHER BOTTOME died at his home in this city on December 20th, of pneumonia. He was born in Bridgeport, Conn., in 1865, and was graduated from the medical department of Columbia University in 1889. He was attending physician to St. Joseph's Hospital, and was connected with the clinic of nose and throat diseases at Roosevelt Hospital.

Society Reports.

THE SOUTHERN SURGICAL AND GYNÆCOLOGICAL ASSOCIATION.

Proceedings of the Eleventh Annual Meeting, Held at Memphis, Tenn., December 6, 7, and 8, 1898.

THE association met at the Gayoso Hotel, under the presidency of Dr. Richard Douglas, of Nashville, Tenn. Prayer was offered by BISHOP GAILOR. DR. ALEXANDER ERSKINE, of Memphis, delivered an address of welcome on behalf of the local profession, which was responded to by PRESIDENT DOUGLAS. After the disposal of routine business, the scientific session was opened with a paper by DR. WILLIAM E. PARKER, of New Orleans, La., entitled

Gunshot Wounds.—Dr. Parker described the hospital conditions in Cuba and the wounds seen by him made by the modern bullet. He spoke of some experiments made under the direction of Major and Surgeon L. A. LaGarde, of the regular army, as to the relative penetrating powers of the Mauser, Krag-Jorgensen, and Springfield rifles. With ammunition of the years 1896 and 1897 the Mauser, fired at a distance of three feet from the muzzle into seasoned yellow-pine posts, penetrated thirty-four plus inches. With ammunition of 1895 it penetrated thirty-two plus inches; with ammunition of the past year the Krag-Jorgensen, fired at the same distance, penetrated twenty-four plus inches, and the Springfield but five inches; yet many lodged Mausers were found, and he was told by one of the Spanish chief surgeons that but six lodged Krag-Jorgensens were found by them. In regard to wounds of special regions, flesh wounds, as a rule, healed under one dressing. In the few cases that did not, the sloughing was at the points of entrance and exit, and not along the whole track of the bullet. Explosive effects were not seen by any of the surgeons. He had hoped to present some statistics as to the wounds of the war, but they could not be obtained. Wounds of the brain did well. The speaker had heard of at least five cases that were still alive and doing well. But one case of wound of the spinal cord was operated upon, and the patient was doing well. This patient had paralysis of both legs and of the bladder and rectum. Some spicula of bone had been removed from the cord. At this time the patient had perfect use of the right leg and partial use of the left, and had entire control of his bladder and rectum. While the speaker had not in any way modified his opinion that laparotomy should be performed for abdominal wounds occurring in civil life, yet with the small modern bullet and lack of proper facilities this operation should not be attempted in the field, unless there should be symptoms of hemorrhage. About fifty per cent. of these patients recovered without operation. Chest wounds did well and caused but little trouble. In cases of wounded vessels, the hemorrhage did not seem greater than in wounds caused by other bullets. When nerves were injured, nerve suture was not attempted, on account of the rush of work, but the speaker thought it should be attempted as soon as possible. None of the hospitals had a sufficiently large number of surgeons or hospital-corps men, but those who were there were efficient.

Penetrating Wounds of the Abdomen, with Reports of Cases, was the title of a paper by DR. F. W. MCRAE, of Atlanta, Ga. At the outset, the essayist referred to a resolution passed unanimously by the association at its Nashville meeting in 1896, to the effect that in all cases of penetrating wounds of the abdomen it was the duty of the surgeon to make an exploratory incision, so as definitely to determine whether the viscera had been injured or not. Since then a few able surgeons had dissented from this opinion. The propriety of surgical interference in cases of penetrating gunshot wounds of the abdomen would depend on one of three things: (1) The general condition of the patient; (2) dangerous internal hemorrhage; (3) wounds of the stomach or intestines, large enough to permit extravasation. Dr. McRae quoted from contributions to this subject by Senn, Nunez, Winslow, Budinger, Vaughan, Woolsey, Robson, Chauval, Michaux, Klemm, and others; and said that from the conflict of opinion and advice given by these and various other surgeons one was at a loss, in many cases, to know just how to proceed. His own convictions, based on sixteen cases which he narrated, were positive. While he had the greatest admiration and respect for the surgical opinions of Senn, he should be recreant to his convictions were he to accept the proposition of non-interference laid down by that writer in his recent contributions to the subject. In most of the cases which had come under the speaker's observation in which grave lesions of the abdominal viscera had existed, the symptoms of internal injury had been practically *nil*, and the positive signs of grave damage almost entirely absent. In conclusion, the speaker reiterated his firm conviction that every case of penetrating wound of the abdomen, in which there was reasonable doubt as to injury of the abdominal viscera, should be subjected at least to an exploratory operation. This enabled the surgeon either to be absolutely sure that no injury had been done to the viscera, or to repair, as far as possible, such injuries when they existed. The mortality following a simple exploratory operation *per se* was so small as not to weigh against the much greater mortality that necessarily followed the expectant plan of treatment. In the cases he had seen, the general and local signs had been so misleading and enigmatical that prior to the operation a conclusion on his part as to internal conditions would have been entirely guesswork.

The Practical Management of Bullet Wounds of the Abdominal Viscera.—This paper was read by DR. HORACE H. GRANT, of Louisville, Ky. Observation and experience with operators meeting frequently with this lesion had determined that penetrating wounds of the abdomen demanded laparotomy at the earliest possible moment after diagnosis and thorough inspection of the entire region endangered. It had been established that not only was the mortality in untreated wounds of the abdomen almost one hundred per cent. when the intestines were perforated, and very high in wounds of the solid viscera, but it became less promising every advancing hour, until by the second day peritonitis set in and destroyed the hopefulness of the prospect. Within the past two years the speaker had operated upon four cases. In each case the patient was seen early, in no instance later than four hours. In three, resection of the intestine was necessary. Three of these patients recovered; the fourth died from septic peritonitis, due to the escape of a large quantity of fecal matter before operation. The autopsy disclosed a perfect intestine.

These three papers were discussed together.

DR. W. L. ROBINSON, of Danville, Va., said he had seen a good many cases of gunshot wounds of the abdomen, and nearly all of the patients had died either with or without operation. Early operative interference might have saved some of them.

DR. G. S. BROWN, of Birmingham, said he knew of several cases of gunshot wounds of the abdomen that had occurred in and around Birmingham, in which the patients had recovered without operation. Personally he had operated in five cases, of which one patient had recovered. In this case there had been no perforation of the intestine. Undoubtedly diarrhœa and starva-

tion, mentioned by Dr. Parker in his paper, had something to do with the favorable results. The intestines were most liable to be perforated when full.

Dr. Willis F. Westmoreland, of Atlanta, said the results of gunshot wounds of the abdomen on the battlefield should not be compared with those met with in civil life. It was not a question of operating, so far as fatal results were concerned, but the manner in which the operation was done.

Dr. W. E. B. Davis, of Birmingham, thought that Dr. Parker's paper was not an argument against operative procedures for abdominal wounds. Surgeons on the battlefield did not have the same facilities for operating on penetrating wounds of the abdomen that they did in civil practice, and which were necessary for the proper care of cases. If a man sustained an injury to the intestine, and his abdomen was not opened, death might be expected. In twenty or more cases operated on by him and his brother, all of the patients seen twenty-four hours after the injury had died. This was not an argument against operative interference, but against late operation. Statistics impressed surgeons with the importance of early operation.

Dr. George A. Baxter, of Chattanooga, believed it was not necessary in many instances to open the abdomen in cases of gunshot wounds, and he cited a number of cases in which recovery took place without operative interference.

Dr. John T. Wilson, of Sherman, Tex., advocated early operation in cases in which the surgeon was convinced that perforation had taken place. The character, technique, and rapidity of the operation were very important. In operating, the intestines should be exposed as little as possible.

Dr. W. L. Rodman, of Louisville, said that while for the last ten years he had pursued the practice of operating on penetrating gunshot wounds of the abdomen, after hearing the paper of Dr. Parker and reading the recent contributions of Senn and others he doubted whether he as well as other surgeons might not have gone too far in operating in so many of these cases; at the same time, he did not wish to be understood as advising a masterly inactivity when the environments for operative interference were favorable.

Dr. Westmoreland said that, given a case of perforation of the intestine, particularly when there was extravasation of contents, instead of being masterly inactivity it was criminal inactivity for a surgeon not to operate.

Dr. Parker, in closing the discussion on his part, said that he had tried to make a clear distinction between the plan of treatment of gunshot wounds of the abdomen met with on the battlefield and those encountered in civil life. He was strongly opposed to laparotomy on the battlefield, on account of the conditions that exist. In civil life, however, the thing to do in cases of gunshot wounds of the abdomen was to get in and out of the belly as soon as possible consistent with good work.

Dr. Moran believed that a large proportion of the operations undertaken late for gunshot wounds of the abdomen would terminate fatally.

Dr. Grant stated that practically all patients operated on after twenty-four hours would perish. It was impossible to diagnosticate perforation of the intestines with any degree of certainty. If a patient was seen within eight or ten hours after the receipt of a gunshot wound of the abdomen, under favorable surroundings, whether the bullet had penetrated or not, the skilful surgeon would not hesitate to do at least an exploratory operation, because it would not hurt the patient, but might probably save his life.

A Plea for the More Correct Application of the Emmet Methods in Plastic Surgery was presented by Dr. W. D. Haggard, Jr., of Nashville, Tenn. The pioneer work of Sims was feelingly referred to. It was a unique circumstance in the annals of surgery that the instruments which made the feat of Emmet possible, and the fundamental principles of his success, had remained unchanged. It was not so much the truth of homage to unprecedented genius, as the truth of the great principles he enunciated and the perfection of his devices. The extension of the method of Sims in fistula to injuries of the adjacent soft parts was made by Emmet. The evolution and perfection of the operation on the cervix were traced. Dr. Haggard described the mechanics of the production of rectocele associated with the common transverse tear of the posterior vaginal wall involving the pelvic fascia, which was the essential pathology in this injury. The rational correction of this complex condition, then, would not be to sew the labia together, which was the popular procedure in one class of operations, nor to denude an arbitrary area of fanciful shape on the rectocele and bring the edges of the raw patch together, after the fashion of another class; it would rather be, in the language of Emmet, "to catch up the retracted pelvic fascia at such a point and in such a manner as to take in the slack, as it were, of the fascia throughout the pelvis." By this procedure the displaced posterior vaginal wall was certainly lifted up and drawn forward in contact with the vesico-vaginal septum. As the steps of the operation advanced the displaced anus was lifted upward and forward, the everted tissues at the vaginal outlet were gradually rolled in, and the separated levator ani muscles brought together. The speaker described the essential features in detail. The classical operation for the complex tear of the perineum was more amenable to pictorial description, and he believed was more generally understood. He minutely depicted it. In every branch of art there was a troop of imitators, who followed so closely the hall-marks of the original that the specious could scarcely be distinguished from the genuine. So closely were mannerisms copied in literature, art, sculpture, and the drama, that the imitators created a distinctive school. This accuracy of duplication was rendered possible by faithful and scrutinizing study of the original pattern. The unlimited opportunities for the study of models in the arts were obviously impracticable in plastic surgery. We could not all have the privilege of seeing the peerless Emmet, although a distinguished fellow of this association said that every one who aspired to do this work ought to do so. Dr. Haggard regretted that many of Dr. Emmet's pupils did not or could not copy his methods, and he did not hesitate to say that those who did conscientiously strive to imitate him fell very short in their efforts, but they had at least the satisfaction of having a correct conception of the highest ideals in surgery.

The Treatment of Complete Rupture of the Perineum by Dissecting Out the Sphincter Muscle and Its Direct Union by Buried Sutures.—Dr. Howard A. Kelly, of Baltimore, Md., read a paper on this subject. He said that the results of the best methods of the treatment of complete tears of the perineum were not entirely satisfactory in a large percentage of cases. The control over liquid motions and flatus was as a rule not secured immediately, and it was usually necessary to encourage the patient by telling her that she "would have to learn to control the muscles in the course of time." Such a control, more or less perfect, was gained in the course of several months. This defect in our present procedures was due to a faulty approximation of the sphincter ends, which lay buried in a pit, and which were therefore difficult to bring into accurate, firm apposition by sutures embracing a considerable quantity of tissue surrounding the sphincter ends. Dr. Kelly proposed, therefore, the deliberate

dissection and freeing of the sphincter ends, drawing them out about one and one-half centimetres from the tissues, cutting off the scarred ends, and effecting a direct union of the freshened ends by two or three buried catgut sutures. He was led to do this operation by his experience in a case which had been operated upon six times with a result which, judged by superficial appearances, was perfect, and yet the patient had no control over her bowel functions. He made a semilunar incision around the anterior periphery of the anus, and found the right sphincter end buried in scar tissue in the median line, while that of the left side was ectopic and attached out under the ischial tuberosity. The sphincter ends were united directly by buried catgut sutures, the skin wound was closed, and union took place *per primam*. In addition to these buried catgut sutures, a splinting suture of silkworm gut was passed through the middle of the sphincter near the edges of the wound and on up through the septum, splinting the ends together and taking the tension off the catgut. He had since taken the hint given by this case and adopted a similar procedure in six cases of complete tear of the perineum due to confinement. Two additional cases were operated upon by Dr. W. W. Russell and one by Dr. Ramsay. In each instance there was a surprising difference between the new and older methods, noted at once in the earliest stages of convalescence, and the patient was immediately conscious of perfect control of her functions. The bowels should never be locked up. Great care should be taken not to leave any dead spaces in closing the remainder of the wound in the usual way, in order to avoid all risk of infecting the buried sutures. He recommended this operation only to those who possessed considerable skill in doing plastic operations and in securing a snug, accurate adaptation of the parts.

In the discussion, Drs. George H. Noble, of Atlanta, and J. Wesley Bovee, of Washington, D. C., added their testimony to the usefulness of the method described by Dr. Kelly, but certain features of the technique of which they modified.

The Treatment of Cancer of the Uterus was discussed by Dr. Lewis S. McMurtry, of Louisville, Ky. He said that the treatment of uterine cancer had not shared proportionately in the great advance of modern pelvic surgery. While other diseases which were long the opprobria of medical and surgical science and art had been made amenable to surgical treatment, the treatment of cancer of the uterus was practically where it was twenty years ago. Cancer of the uterus was a very common disease. Women were more subject to cancer than men, and in quite one-third of all cases of cancer in women the uterus was the seat of the disease. The disease occurred, as a rule, between the ages of thirty and fifty, attaining its maximum prevalence at the menopause. It was rare in unmarried and sterile women, and was most common with the mothers of large families. Race and environment had much to do with its development. It had been the experience of the essayist that the disease was proportionately rare in the negro race. From a careful statistical study, Billings declared that cancer was slowly but steadily on the increase, and that its greatest prevalence was in nations which had attained the highest state of civilization. In 1893 London alone lost 3,412 of her population from this disease, a percentage of 3.73 of the total death rate for the year.

Cancer of the corpus uteri was rare in comparison with the common exhibition of the disease in the cervix, but not so uncommon as was formerly understood. Cancer of the cervix originated (1) in the squamous epithelium of the vaginal portion of the cervix, (2) in the cylindrical epithelium of the cervical mucosa, and (3) in the epithelial lining of the cervical glands. Cancer of the body of the uterus originated in the epithelial structures of the endometrium. The treatment of uterine cancer consisted in a variety of operative procedures, leading up to the most recent operation of combined abdominal and vaginal extirpation. The names of Verneuil, Carl Braun, Schroeder, Pawlik, Koeberlé, and Byrne were associated with high amputation of the cervix with écraseur, cautery, and knife. High amputation, as practised by Schroeder, attained the greatest favor and maintained its position over hysterectomy until 1886. Prior to this time hysterectomy had such a high mortality (fifteen per cent.) that high amputation deserved preference. In 1886 the operation of total vaginal extirpation was revived by Martin, Leopold, and Olshausen. Since that time this operation had been very generally adopted, and was to-day the accepted treatment for the radical cure of cancer limited to the uterus itself. With the modern perfected technique the mortality of this operation was reduced to about four per cent.

Dr. McMurtry referred to the statistics of vaginal hysterectomy as given by Pozzi in the third edition of his treatise on gynæcology, an analysis of which did not strengthen or inspire confidence in the ultimate results of this procedure. He said that claims were being made for the permanent cure of uterine cancer by hysterectomy which could not be realized. Of all the subjects of uterine cancer who applied for treatment, only a small proportion were within the scope of a clean extirpation by vaginal hysterectomy. The large number of cases in which the disease recurred within a few weeks at the site of operation demonstrated that the operation was in most cases simply a resection, leaving behind sufficient disease for continued activity. His personal experience with this operation had been discouraging. Vaginal hysterectomy for cancer had never been a favored operation with him. During the past year he had operated in five cases, which were selected as most favorable for permanent cure. In all the disease was discovered early, and, so far as macroscopic evidence could show, it was limited to the uterus itself. The organ was normally mobile. Of these five cases treated by vaginal hysterectomy, two had recurrence—one in the bladder, the other in the vaginal fornix at the cicatrix—within five months after operation. These were selected cases in which the disease was early recognized; the patients were under fifty years of age and well nourished. The operation was done with a view of going far beyond the region of probable infiltration and removing the appendages with the uterus. Based on his own previous experience and that of other operators, it was doubtful if one of the three remaining patients would be living at the end of three years from the time of operation.

The histological structure of the uterus and adjacent organs was exceptionally favorable for disseminating this disease. The rich lymphatic distribution here was an active means of infection, but the studies of Cullen showed that the activity of lymphatic invasion had been exaggerated and that the common mode of infection was along contiguous structures. Extension was most rapid around the vaginal vault, forward and downward under the bladder, and in the base of the broad ligaments. The common invasion of the vagina by implantation about the cancerous cervix had suggested to Werder the method he had practised of total excision of the uterus and vagina by suprapubic operation.

In conclusion, Dr. McMurtry considered in detail the choice of operation for the several classes of cases of carcinoma of the uterus which were presented to the surgeon for treatment. For advanced cases, in which the entire field of evident invasion could not be removed, he advocated thorough curettage, scraping away necrosed tissue, emptying obstructed pus accumulations,

washing out débris, and establishing drainage and antisepsis. Such local treatment would reduce septic intoxication, prolong life, and promote comfort. All operations for radical cure should be limited to cases in which the disease was recognized sufficiently early for thorough removal of invaded structures. This would be best accomplished in the majority of cases by abdominal section and removal of the uterus from above, including liberal portions of adjacent structures, especially the upper portion of the vagina, where implantation from the cervix was so often found. While liberal excision of suspicious areas of tissue should be done, it would rarely be found necessary to remove the subperitoneal lymphatic glands, since their enlargement had been often found inflammatory in character instead of cancerous. The field of vaginal hysterectomy should be limited to the few cases of early diagnosis in which operation could be done before deep extension of the disease. Efforts for prophylaxis should be most diligent, and should be of universal application. All ulcerative and cicatricial lacerations of the cervix should be repaired as a prophylactic measure.

Dr. William L. Rodman, of Louisville, asked the members to give their experience relative to the frequency of cancer in the black and white races. He was rather surprised to hear of the infrequency of the disease in the negro woman. According to the last census statistics of Billings, cancer of the uterus was more common at all ages in the black than in the white race. This was also the experience of Matas, who had examined the records at the Charity Hospital in New Orleans. An examination of all deaths recorded by the Health Department of Louisville for the past thirty years corroborated the same view.

Dr. Ernest S. Lewis, of New Orleans, stated that, while he had not observed a very marked difference in the relative immunity of negro women to cancer of the uterus, still, if his experience was not at fault, he thought, owing to their uncleanliness, their mode of living, and to the more frequent accidents to which they were subject during labor, they were particularly prone to cancer of the uterus. With regard to the results of all operations for cancer of the uterus, he indorsed everything Dr. McMurtry had said. He could only recall one case of vaginal hysterectomy for cancer in which the patient lived for eight years, after which the disease returned, and the patient finally died. The disease was so liable to return that he considered any operation as palliative, and he believed that would be the result of the abdominal operation advocated by Dr. McMurtry, particularly in advanced cases; and if cases should be met with in the incipiency of the disease, in his opinion as much could be accomplished by the vaginal as by the abdominal operation.

Dr. Virgil O. Hardon, of Atlanta, said that during his seven years' connection with the Grady Hospital he had reason to believe that cancer of the uterus was more frequent in negro women than in white women. He had been led by his experience in the treatment of uterine cancer to the same conclusion as that reached by the essayist, except that he had been induced to go further. He had operated for cancer of the womb by vaginal extirpation, by the abdominal method, and by the combined method, and he had never yet operated upon a patient in whom recurrence did not take place sooner or later; and for this reason he had lost all confidence in operative measures as a means of effecting a permanent cure. However, he had no doubt, on theoretical grounds, that if cases could be seen sufficiently early a permanent cure might be effected by surgical interference.

Dr. Howard A. Kelly, of Baltimore, remarked that he was astounded at the trend the discussion had taken, because he had seen dozens of cases of cancer of the uterus that had remained well for a number of years after having undergone surgical intervention, the uterus being removed either by the vagina or by the abdomen. He found carcinoma of the uterus as frequently in negroes as in white women.

Dr. J. Wesley Bovee, of Washington, D. C., said that his experiences in the radical treatment of cancer of the uterus had been more satisfactory than what he had been hearing that day. He knew of a good many cases in which he had operated that had gone on for three years or more without a recurrence of the disease. He had done three operations after the manner described by Werder in the *American Journal of Obstetrics* of last winter, and he was much pleased. In each case he had adopted the abdominal rather than the vaginal route, believing a more radical operation could be performed by this method. He had great hopes for the future treatment of cancer of the uterus by complete abdominal hysterectomy, undertaken early.

Dr. William L. Robinson, of Danville, said that when the parts had become infected beyond the uterus, no dissection, however extensive, would ever remove the cause. When the disease had extended beyond the uterus, he believed that it was beyond the power of any surgeon to remove it thoroughly. Therefore, unless an operation could be done very early, he would not advise the removal of the uterus.

Dr. W. E. B. Davis was profoundly impressed with the position taken by Dr. Lewis as to the ultimate outcome of cases of cancer of the uterus, believing his position to be correct. There was no man in America who had had a larger experience in the treatment of cancer of the uterus than Dr. Lewis, and the profession were familiar with his great skill as a surgeon; hence his experience regarding uterine cancer was certainly valuable.

Dr. McMurtry, in closing the discussion, said he could not indorse the rosy view that Dr. Kelly took with reference to the ultimate results of the operative treatment of cancer of the uterus. He knew that Kelly's work in this direction had been extensive, and that his reports were sincere and reliable. But there were a great many surgeons, working in the same line, who have done thorough, faithful, skilful work in the radical treatment of uterine cancer, who doubted the future confirmation of Dr. Kelly's views.

Fractures Involving the Elbow-Joint was the title of a paper by Dr. John T. Wilson, of Sherman, Tex.

The Use and Abuse of Decinormal Salt Solution.—Dr. J. Wesley Bovee, of Washington, D. C., read a paper with the above title.

The term decinormal salt solution had been used interchangeably with artificial serum. Various compositions and strengths of the constituent elements of the blood had been used with the name decinormal salt solution. According to Kirkes' "Hand-Book of Physiology," salt existed in the blood plasma in the proportion of 5.546 parts per 1,000, and .6 per cent. was a good practical formula. Other ingredients, *i.e.*, egg albumen, had been added to the salt, which really made an artificial serum instead of decinormal salt solution.

Of the five different routes through which it was introduced, the intra-arterial, suggested by Dawbarn, was considered unsafe in all conditions and should not be practised. The subcutaneous was the most useful for general use. In emergency work the intravenous method would often be needed in severe hemorrhage, and the rectal enema of the solution would be found of great advantage in nearly all cases in which no bowel lesion was to be combated. In abdominal surgery the peritoneal cavity would be the place selected for its introduction, and even in vaginal opening of the peritoneal cavity, as in hysterectomy from this way,

the speaker had thrown considerable quantities into the peritoneal cavity, the hips being elevated at the time and the peritoneal opening closed directly afterward. The intravenous route, usually the most rapid, might be rendered slower than the subcutaneous by the difficulty of finding a vein and successfully introducing the cannula.

The physiological action of decinormal salt solution was to stimulate powerfully the cardiac ganglia and the nerve centres. The skin, kidney, and intestinal functions were stimulated markedly, and other organs were likewise affected. Osmosis was dedidedly promoted by it, and as a result of increased arterial tension the blood supply to the heart muscle was much increased. It had a hæmostatic effect when applied locally to raw surfaces, lessening oozing by stimulating and contracting the smaller vessels. According to Hayem and others, it augmented the number of red blood corpuscles. It was eliminated by the skin, changing the chemical reaction of the perspiration and heavily loading it with salt. The kidneys also carried away an enormous amount of it when large quantities had been introduced into the tissues. The lungs removed it freely, it having been noticed in crystals on the lips after its free use. Autopsies after its use under the skin showed a considerable quantity of it in the intestines, demonstrating that it was thrown off by this route.

The essayist then spoke of its use in general medicine. In surgery the principal indications for its use were shock, hemorrhage, and sepsis. In shock it should be employed early, on the table during operations, or even before the operation had been undertaken in bad cases, or after operation in milder ones. Severe hemorrhage was to be treated in the same manner, though only after the flow of blood had been checked. If the hemorrhage was severe, the intravenous route might be employed, it being about the only indication for this method. In the author's abdominal work he almost invariably left a considerable quantity of salt solution in the peritoneal cavity. Its salutary effect was produced by its action on the abdominal viscera with which it came in close contact. To prevent adhesions in the pelvis, one or two litres sufficed. It hastened absorption of stray or concealed blood clots, septic foci, or escaped fluids by carrying them well up into the abdominal cavity in cases of pelvic surgery. In hemorrhage it was probably best to infuse small quantities and often rather than one large quantity.

Judging from the reports of experimenters, the use of decinormal salt solution was not a harmless procedure. It was contraindicated in such conditions of the blood as hæmophilia, dyscrasias, deficient fibrin, etc. It would seem not unreasonable that such a strong stimulant coupled with its dilatation of the blood-vessels when used in large quantities, and specially when thrown directly into them, would be very harmful in such conditions of the circulatory apparatus as myocarditis, pericardial effusion, atheroma, arteriosclerosis, cardiac degeneration, bad valvular lesions, thrombosis, and recent cerebral apoplexies. Chronic diseases of the lungs, kidneys, or liver, especially if malignant, were apt to be aggravated by it. Active hemorrhage in any location was aggravated by it. The presence of toxins in the blood had been found to retard the elimination of decinormal salt solution, and, for that reason, only small quantities at a time should be employed.

It was necessary to avoid certain accidents and mistakes in using decinormal salt solution. The solution must be known to be sterile when it entered the tissues of the body, except when injected by the rectum, in which case sterility was of no moment. Air bubles should not be allowed to enter into blood-vessels or cellular tissue. The fluid must be of a sufficiently high temperature when reaching the body. Chills occurred from a cold solution and were dangerous to very weak patients. The vessel containing the solution, as well as the tube and needle conducting it, must be aseptic and thoroughly pervious; the tube should have a glass window that the rapidity of the current and the presence of any foreign body could be noted. When the solution was to be introduced through the skin, either into cellular tissue or vein, the local surface should be cleaned as much as the limited time would permit. Probably not more than a half litre should be injected into the tissue through one puncture, as localized necrosis and a septic inflammation have resulted from over-distention of the tissue spaces. Ordinarily not more than one ounce per minute should be injected into tissue or vein. Pulmonary œdema, dyspnœa, headache, vertigo, mental excitement, delirium, hallucinations, and severe pain in the left side occurred from over-distension of veins from too large an infusion.

In the discussion Drs. Parker, Johnson, Noble, Parham, Cartledge, Tiffany, Kelly, McMurtry, Baxter, McRae, and Brown spoke favorably of the use of decinormal salt solution.

The Conservative Treatment of the Diseased Ovary was the title of a paper by Dr. Joseph Taber Johnson, of Washington, D. C. The speaker said that the difference between the radical and conservative treatment of the diseased ovary was somewhat difficult to define, inasmuch as the most radical treatment under some circumstances was really the most conservative; while, in other cases, to conserve the best interests of some particular diseased ovary required the most radical surgery. In the early part of the present decade, quite a conservative wavelet swept over the country, and considerable harm was done to pelvic and abdominal surgery in the mild and gentle name of conservatism. Incomplete conservative operations were done, some of which had to be completed later on by radical operations. Some of the men who claimed to be the most conservative, and attracted the timid doctors and frightened patients, were actually removing more ovaries and tubes than many of their so-called radical friends. Much credit had been claimed for saving a part or the whole of one ovary and tube, when only a simple catarrhal salpingitis existed, by an operator posing before the profession and community as a conservative, when the surgeon designated a dangerous radical, to be avoided, would actually not have operated at all, and would probably have cured his patients by other means. In some instances genuine, successful conservatism was practised with lasting beneficial results, but not always from the highest and purest motives. Again, it had been charged that actual radicalism has successfully masqueraded under the name and guise of conservatism, to the injury of the trusting patient and the discredit of good surgery.

So much had been learned by accumulating experiences, and the domain of the gynecologist had undergone so much expansion, that real conservatism was gradually gaining ground over real radicalism to such an extent that he who presented ovaries and tubes or a fibroid uterus to a modern, up-to-date medical society, had to state very good reasons why he sacrificed those important organs in their entirety, to escape criticism and possibly censure. Sacrificial surgery was gradually giving way to more conservative and humane methods. He believed there was a maxim in general surgery in favor of saving every inch of the human body possible, and another that it required a higher order of skill to save a mutilated or diseased member than it does to cut it off or to cut it out. With his present experience in abdominal surgery, he was free to confess that he could now save ovaries and tubes

which he formerly thought it necessary totally to remove. The increasing skill of our abdominal surgeons and their accumulating experience in actual conservative work went to show that we were approaching nearer to that true conservatism which was the offspring of increased skill and experience. In abdominal surgery it required a higher order of skill and a greater experience to save an organ or part of an organ than it did to remove it. It was important to save a portion of one ovary, when the other had been removed on account of a tumor, an abscess, or for any other cause. The disagreeable symptoms accompanying the artificial and premature change of life were often stormy and protracted; in some rare instances threatening, if not resulting in, actual insanity. These women were happily prevented from falling into such a condition by saving one or a portion of one ovary; menstruation was then not interrupted, and the sexual and other feelings of the patient underwent none of those sudden and peculiar revulsions which unfortunately sometimes followed the total removal of both ovaries and tubes.

In conclusion, Dr. Johnson said that if growing experiences in the abdominal cavity and accumulation of evidence continued in favor of more conservative and less sacrificial operative work, he was sure that the deep debt of gratitude now felt toward abdominal surgeons by suffering women would be increased and intensified tenfold.

President's Address.—This was delivered by Dr. Richard Douglas, of Nashville, Tenn. He made a departure from the usual stereotyped form of address, and selected for his subject "Acute General Peritonitis." Before considering his subject proper he spoke of the growth of the association and the excellence of its scientific work, saying that the association owed its existence and high standing to the indefatigable efforts of Dr. W. E. B. Davis, the permanent secretary. A bacteriological classification of peritonitis was beset with many difficulties, and, while the speaker was free to admit that for all practical purposes peritonitis was of bacterial origin, yet there occurred a respectable percentage of cases in which the most rigid examination failed to disclose the presence of micro-organisms. Hartmann and Moreau recently reported in detail such a case. Of one hundred and ten cases bacteriologically classified by Flexner, there were twelve which he was obliged to consign to the idiopathic group. It is true that in all of these patients there existed conditions predisposing to peritonitis, such as cardiac, renal, or hepatic disease. In the intensely septic mycotic form of peritonitis the absence of germs might be accounted for by the fulminant type of the disease, death occurring from intoxication before the colonies of bacteria were well established. Any effort to individualize the effect of a specific bacterium, to connect its presence with a definite pathological phenomenon and characteristic symptomatology, was as yet futile. Mikulicz averred that all forms of peritonitis ran the same clinical course regardless of the bacteria that caused it. There was a law laid down by Maloz to the effect that if the peritonitis was of intestinal origin, the colon bacillus would show it; if it was of uterine origin, that is, connected with abortions or labor, we would find the streptococcus. It was asserted that the colon bacillus constituted nine-tenths of the bacteria of the digestive tract; the colon was its natural habitat, but its behavior upon gaining entrance to the peritoneal cavity depended upon many circumstances, and this bacillus had many morphological conditions, many forms and stages. The constancy of its presence in peritonitis, since the demonstrations by Welch and others of its capacity of transmigration through the bowel, had led many to attach to it great significance as an etiological factor; but its association with other forms of micro-organisms rendered the first proposition of Maloz null and void. If we interpreted Maloz's law correctly, the absence of streptococci would eliminate the possibility of peritonitis being of puerperal origin. In rebuttal of this idea, Dr. Douglas quoted from Winckel, who said: "Kroenig examined all parts of the uterus of a woman dead from infection, and found not only the superficial thrombi at the placental site thickly filled with bacteria, but also the serous lining of the peritoneum." This case showed that a woman might have a peritonitis following abortion without streptococci, and it further showed that the colon bacillus without an intestinal lesion might produce a fatal peritonitis. No doubt too much importance had been ascribed to the colon bacillus, and it was interesting to note that Taval, who was among the first to emphasize the pathogenic powers of the bacillus coli communis, thought now that the bacillus was of minor importance in the etiology of peritonitis. He held, further, that the very name of the bacillus coli should be considered merely a collective name of many varieties of bacteria. No better argument against bacteriological classification could be adduced than the words of Simon Flexner, who said: "In order that pathogenic bacteria introduced directly into the peritoneal cavity may cause a peritonitis, general or circumscribed, evanescent or fatal, the normal conditions of the peritoneum must in some way be modified." It was clear, then, that in the human being, as in experimental animals, some other condition than the mere presence of pathogenic micro-organisms in the abdominal cavity was necessary in order that peritonitis might be produced. Bacteria alone and unaided by physical conditions were comparatively innocuous.

Restricting consideration entirely to acute general peritonitis, it occurred from traumatic or consecutive causes. Under the head of traumatic peritonitis were embraced all infective inflammations arising from wounds of the peritoneum, whether accidental or operative, penetrating or non-penetrating. Consecutive, secondary, or symptomatic peritonitis might be subdivided into (1) peritonitis by continuity, and (2) perforation peritonitis.

Traumatic Peritonitis.—Under this head all forms of peritonitis must be embraced that were due primarily to a trauma. The destruction of tissue, the retention of blood clots and natural secretions, prepared a suitable soil for microbic invasion, and this essential infecting element might be introduced from without, as through penetrating gunshot, stab, or operative wounds—under which circumstances it was usually a multiple infection, the streptococcus predominating. There were also contusions of the abdomen without an external wound, which so injured and lowered the resistance of the tissue as to favor the migration of the intestinal micro-organisms and their infection of the general cavity.

Secondary Peritonitis.—The supervention of acute general peritonitis, as secondary to pre-existing disease processes, embraced in its etiology infective inflammations not only of all intraperitoneal viscera, but all organs or tissues contiguous thereto, and it did not appear to him to be too broad if there were included within its scope those peritonitides of hematogenic or metastatic origin; for it was well established that the specific germs of diphtheria, scarlet fever, pneumonia, and erysipelas have produced acute general peritonitis. Peritonitis by continuity was the uninterrupted extension of the inflammation from an infected area to the peritoneum, and was accomplished by the invading army of micro-organisms through the lymphatics, blood channels, or by direct penetration of tissues. The reactionary inflammation which determined the localization or diffusion depended upon the virulence of the bacteria, the resistance of the tissues, and, what

was too frequently overlooked, the individual resistance of the patient. Puerperal peritonitis of streptococcus origin conspicuously illustrated inflammation by continuity. Perforation peritonitis was the next subdivision of secondary peritonitis. The sudden opening of a focus of suppuration and the discharge of its contents into the peritoneal cavity, whether it was from hepatic abscess, a pus tube, or a mesenteric gland, was a true illustration of perforation peritonitis; yet the inflammation and systemic infection following were not necessarily so conspicuous. The duration of the primary disease, the virulence of the micro-organisms, the preparedness of the peritoneum by fortifications of adhesions, and the general condition of the patient were all circumstances which might modify and circumscribe the peritonitis. It was more common for perforation peritonitis to occur as a result of ulceration of the wall of some of the hollow viscera as in peptic ulcer, typhoid and dysenteric intestinal ulceration, duodenal and appendicular ulceration.

The conclusions to be drawn from an etiological study of peritonitis were thus summarized: Traumatic peritonitis, especially the post-operative variety, was essentially a grave condition, not only because there was immediate or primary inoculation of the peritoneum, but the conditions were all favorable for germ culture and dissemination. Peritonitis by continuity might become general and prove rapidly fatal, but this was not the rule except in puerperal cases. Contrary to the expressed opinion of more than one writer, there was nothing peculiar about the peritoneum, or the cæcum, or appendix, or the true pelvis, which accounts for the more frequent localization of inflammation in these regions than in other areas of the abdomen. The method of invasion, the activity of the process, and the resistance of the patient alone determined the local or general type of peritonitis. Visceral perforation, whether traumatic or pathological, was an ideal condition for germ culture and the elaboration of toxins. Their rapid absorption and general diffusion throughout the peritoneum sufficiently explained the grave state into which the patient was precipitated. It might be asserted that the clinical course and pathological expression depended largely upon the nature of the exciting cause, the character of the pre-existing disease or injury, and the mode of invasion. Without attempting to formulate any definite pathological classification of general peritonitis, and to adapt each to its special cause, he preferred to direct his efforts to simplifying and dispelling the confusion that existed. He accepted with slight reservation the now almost universally conceded idea that acute general peritonitis was and must be septic—that is, of bacterial origin. But he maintained that surgeons did not understand each other, nor had they all a clear conception of what was meant by septic peritonitis. It had been a race for life between the practical surgeon and bacteriologist as to who should claim the honor of naming the pathological phenomena in this great serous bursa. He maintained that the surgeon was alone competent to define, classify, and prognosticate the protean types of this disease. That men were honest, painstaking, and accurate, went without saying; yet how could surgeons reconcile the report of McCosh's last series of eight cases of general septic peritonitis and six operative recoveries with the experience of Senn "of many cases of diffuse septic peritonitis without a single successful result"? The answer certainly was not in the superior skill or special technique of the operator, but it was to be found in an analytical study of McCosh's cases, six of which were purulent peritonitis and two serous peritonitis—not at all the class of cases referred to by Senn. Tietze defined diffuse septic peritonitis to be "that form of peritonitis in which there is little or no exudate, severe symptoms of intoxication, and terminating rapidly fatally." Some four years ago, Dr. Douglas reported eight cases of general peritonitis subjected to operation, with four recoveries and four deaths. He dealt with them all as cases of general septic peritonitis, from a misconception of the term. Only two of them properly belonged to this class, and they terminated fatally. The others were cases of general purulent peritonitis, with two deaths and four recoveries. He was very well pleased with his percentage of recoveries, but disgusted with his classification. He did not discriminate between diffuse septic peritonitis, the patients dying in twelve hours with profound toxæmia and dry peritoneum after perforation of the appendix, and one of perforation with enormous purulent effusion, but mild symptoms of sepsis. This error of his was the common one with the profession, and it was the outcome of an attempt to classify peritonitis by the character of exudate. The etiological classification of peritonitis placed it as subsidiary to the primary lesion which produced it, and its practical import was its local origin. A painstaking investigation into the clinical history would usually determine the origin or structure primarily involved. The symptoms and physical signs, if the case was seen sufficiently early, would still further aid in incriminating the part under suspicion. This valuable diagnostic evidence did not conform to any stereotyped expression; the symptomatology of peritonitis was as varied as its causes. By the presence of any striking symptom or group of symptoms, physicians could not arrive at a decision in a doubtful case, but from the whole picture they must form conclusions.

When Should We Operate for Appendicitis?—Dr. A. M. Cartledge, of Louisville, read a paper on this subject. He drew the following conclusions: (1) Probably ninety-eight per cent. of the patients who die of acute appendicitis without operation have the fulminating variety of disease. The operation, to be of service, must be done in the first twenty-four hours—better the first twelve. (2) In view of the fact that we have no means of knowing the probable course of a given attack of appendicitis, the operation, when possible, should be performed within the first twenty-four hours after the onset of symptoms. (3) Patients seen after the third day should not be operated upon until they were over the attack, or until purulent formations, if such take place, had been walled off and the patient was practically rid of general sepsis. An exception to this rule was the rupture of an appendical abscess into the peritoneal cavity—a very rare accident, when abdominal section should be immediately performed. (4) Probably as many patients recovered from general septic peritonitis by stimulants and purgatives as did by operations. In either event, if it was a case of true general septic peritonitis, the mortality would not be far from ninety-five per cent. Contributions to medical literature would indicate that there was a sad need on the part of the profession of more definite views as to the nature of this disease. If the operation was performed at all, no attempt at general cleaning of the cavity should be practised; nature should be quickly assisted in taking care of the desperate condition of the patient, by removing the sources of the foci. To do more was to add the shock of an unbearable operation to an already nearly exhausted vitality. (5) Patients who have suffered unmistakable attacks of the disease should be subjected to interval operation. (6) Do not operate too soon after a severe attack with many adhesions; the operation would be greatly simplified by waiting a few weeks longer. In the mean time, the patient should be kept upon light diet and little exercise. Patients did not usually have a recurrence until the adhesions or splints have been removed by absorption. The mortality from interval operations should not be more than one per cent. In drawing the

above conclusions, Dr. Cartledge wished it to be distinctly and thoroughly understood that they were not to be considered in the sense of hard and fast rules, but simply as a working basis for the general practitioner.

Ureteral Anastomosis.—Dr. George H. Noble, of Atlanta, read a paper on this subject. He gave an analysis of thirty cases collected from literature, and divided them into two classes: First, ureteral anastomosis, or union of the ureter end to end or end to side; second, ureteral implantation into the bladder. On July 2, 1898, the essayist ligated the ureter with the ovarian vessels and Fallopian tubes in a case of large extraperitoneal fibroma. This was the very first ligature applied in doing the hysterectomy. The bladder end was split about three-eighths of an inch, and as much of the mucous membrane as could be drawn out was cut away; then the upper or kidney end of the ureter was invaginated into it, using a mattress suture for the purpose. The split was then closed with fine sutures, making a snugly fitting cuff around the opposing end with no mucosa intervening. Small silk was used to stitch the raw edge of the inferior segment around and to the sides of the upper section. A peritoneal cuff was thrown around the joint thus made, and the ureter buried behind the peritoneum. The entire work was conducted with the aid of a ureteral catheter, which had been introduced through the ureter into the bladder and drawn out of the urethra with a pair of forceps. The upper end was passed into the kidney end of the ureter. This served a useful purpose, the entire manipulation being greatly facilitated, and obstruction of the ureter being prevented by crowding down the cut end of the mucosa just below the line of union. This patient had suffered from absorption of pus for a number of weeks from double pyosalpinx, and was emaciated and thoroughly septic. Her temperature just before going upon the operating-table was 103° F., and had been running equally as high during the time she had been in the hospital, and perhaps longer. Her pulse was 130 per minute, weak and thready. Thus this anastomosis was done under unfavorable conditions, but was successful.

In October, 1898, he did a successful resection of the left ureter in a case of extraperitoneal extension of sarcoma of the ovary. About one and one-half inches of the duct were removed and the ends united as in the previous case. The peritoneum was stripped from the entire left half of the pelvis. The bladder was separated from the upper portion of the vagina, and also from the horizontal ramus of the pubic bone, and drawn up to the left side of the ileo-pectineal line to cover or bury the ureter, and fastened with a silk suture. In this instance the ureteral catheter was introduced on the stiletto, and, being stiffened by it, passed directly out of the urethra from the ureter; thus the use of forceps was necessary to fish it out of the bladder. Abdominal and vaginal gauze drains were used. There was no leakage.

Dr. Noble said that there were several features necessary to success in doing ureteral anastomosis aside from thorough asepsis: (1) Perfect coaptation or invagination. This must be done in such a way that no mucous membrane can slip between the two ends of the ureter. (2) The ureteral artery should be preserved in its continuity to the ends of the ureter. If this vessel was destroyed when the ureter had been dissected loose from its attachments, it will perish beyond the point where it ceased to receive its blood supply. The ends of the ureter should be cut back to the point where the artery was intact, lest under diminished blood supply and tension it should perish. (3) All strain or tension must be relieved. Should union occur by first intention, the parts would separate as soon as the sutures cut out or are released. (4) There must be no obstruction to the flow of urine.

Carcinoma of the Breast.—Dr. Willis F. Westmoreland, of Atlanta, read a paper on this subject, in which he said that carcinoma now presented even a more serious problem than formerly, on account of its rapid increase. The proportionate mortality from cancer was four and a half times greater now than half a century ago. No other disease can show anything like such an immense increase. According to statistics, two out of every five cases of carcinoma in the female were of the breast. Over three-fourths of all the tumors occurring in the breast were carcinoma. Or, to be exact, of six hundred and thirty-seven tumors over five hundred and three, or 83.2 per cent., were carcinoma, leaving only one hundred and seven, or 16.79 per cent., representing all other forms of neoplasms. The author discussed the etiology of the disease at considerable length. Speaking of the pathology, he said that there was no subject in surgery about which such divergent opinions were held. There was a wide variation in the malignancy of carcinoma, some proving fatal in less than a year, a few others taking ten or fifteen years. He divided the varieties of carcinoma into the scirrhous and medullary or encephaloid. The former had an average duration of life of about thirty months, the latter of about twelve months. When it was considered that in nearly every instance the skin and pectoral muscles were involved in this disease, the surgeon could easily see the philosophic reasoning upon which Halsted's operation was based. The speaker followed the Halsted method in carcinoma of the breast. He believed, however, that Dr. Bloodgood was the first to demonstrate the advantages of completely cleaning out the postero-internal subscapular region by the supraclavicular route. The results of the Halsted operation, in the opinion of the essayist, depended upon the ability of the individual operator, his earliness in seeing the case, and his closeness in following Halsted's technique. This operation not only required surgical skill and experience, but a proper respect for the magnitude of small things. In the opinion of Dr. Westmoreland, no surgeon did a satisfactory operation on his first few cases. He found that with each case he operated more satisfactorily. The operation did not present the seriousness that its magnitude would lead us to believe. He had operated six times before his class at a public clinic, and transferred the patients afterward, at times quite a distance, to their homes. In his first operations he had some shock from exposure, but this was easily controlled by placing hot towels over the exposed surfaces. There was practically no blood lost in a properly performed operation. It was better to complete the operation, grafting included, at one sitting. When for any reason this was not practicable, the cleaning out of the supraclavicular region and the grafting could be done at a second operation. When grafting was done at a second operation, he found it better to remove the granulations. This was best done by curetting. In two of his cases it was necessary to remove the subscapular nerves, and in another to resect the axillary vein. No unpleasant sequelæ followed in either case. He had operated upon over fifty cases of carcinoma since he began surgical work, and he always cleaned out the axilla and stripped the muscles in each case. He had been doing Halsted's operation since its introduction. He did not know the results in the majority of these cases. Two of them, however, came back to him with later recurrence—one with a carcinoma of the femur five years after the operation, no local return; the other with a local return in the cicatrix nine years afterward. This patient died in a short time from metastasis. He felt quite sure that these were not independent new growths. There was always one rule—that the more malignant the case the greater the blood changes.

The primary object of the paper was to point out the fact that a careful clinical examination of each case, a record of the local conditions, the type of tumor, the blood changes, whether or not there was marrow infection, the family history, and the length of time the tumor had existed, would not only give definite facts upon which to base a prognosis, but, if published with each case, would give all surgeons a record of infinite value for comparative purposes.

The Rarity of Ovarian Cysts in Negresses.—Dr. I. S. Stone, of Washington, D. C., contributed a paper on this subject. After several years' experience in a hospital for women, in which a large number of negresses were annually treated for gynæcological diseases, and in which cases of uterine myomata were frequent, the writer had noticed the extreme rarity of ovarian neoplasm and especially of the multilocular variety. He had addressed letters to all the members of the association and to several other prominent surgeons elsewhere, and of the large number who replied to his inquiry there was almost universal acquiescence in the position taken by him, save from one important medical centre, the city of New Orleans. According to the records from the hospitals of this city, cysts of the ovary of all classes were rather more frequent in the negro than in the white. Leaving aside this one source, the author advanced overwhelming testimony favoring the view that ovarian tumors were exceedingly rare in the negro race. The speaker made a careful distinction between multilocular and unilocular cysts, because there could be no doubt about a diagnosis at the time of operation when a multilocular cyst was found. It was otherwise with parovarian cysts or those of the broad ligament, etc., which were perhaps classified as ovarian and their removal called ovariotomy in hospital reports or operation lists, when, strictly speaking, they were not ovarian tumors. He had frequently operated for dermoid, papillomatous, parovarian, and broad-ligament cysts in negresses (although most of these were in mixed cases), but had not seen a multilocular ovarian cyst.

Resection of the Thoracic Wall for Tumor Growing from the Thoracic Skeleton.—Dr. F. W. Parham, of New Orleans, read a paper with the foregoing title. He reported two such operations of his own, with successful results. Both operations widely opened the pleural cavity, and the lung collapsed in both. In the first the collapse was relieved only when the great pectoral muscle was brought down and sutured to the rent in the pleura. In the other signal service was rendered by the Fell-O'Dwyer apparatus for maintaining regular respiration. He believed the perfection of this apparatus and its application in skilful hands would greatly aid in the developing of the surgery of the chest. He had collected all cases operated on up to date, with a mortality of twenty-five per cent. for the intrapleural operations for tumors of the chest wall.

Antistreptococcus Serum.—Dr. W. L. Robinson, of Danville, Va., presented a clinical report of the use of antistreptococcic serum in seven cases of puerperal septicæmia, four of post-operative sepsis, three of septic cellulitis, and two of erysipelas. This comprised seven cases of puerperal fever, with high fever, rapid, weak pulse, characteristic breath, chilliness, nausea, and insomnia, pelvic tenderness, with scanty, fetid lochia, treated by him. From twelve to twenty cubic centimetres were injected after the usual treatment had failed, including intra-uterine and vaginal irrigations, sealing abrasions of the cervix and perineum, saline injections, purgatives, stimulants, etc., with prompt improvement in the general condition, rapid fall of temperature, lowering of pulse rate, and complete recovery. The effect was manifest in from eight to sixteen hours in the majority of cases. In the three post-operative cases of sepsis, seemingly hopeless, all usual treatment failing, the serum in twelve hours transformed every symptom of high fever, chilliness, rapid, weak pulse, diarrhœa, etc., into a hopeful condition, resulting in rapid recovery. The pain subsided in twelve hours, the fever in eight hours, and diarrhœa in forty-eight hours. One was a vaginal hysterectomy, the second was operated on for the removal of pus tubes, and the third was a vaginal hysterectomy. Three cases of septic cellulitis consisted of suppurative cellulitis of the hand, commencing in a finger, one of injury from a rusty nail, and the other from the spur of a cock. Both had been treated by general alterative tonics and locally with improved antiseptic measures, but the disease progressed daily, involving new tissue till the serum was used, which promptly arrested the progress of the disease in both cases and saved the hands. A third case was a gunshot wound of the ankle, with marked septic prostration, chills, diarrhœa, etc., which was dissipated promptly by the use of the serum, so far as fever and general septic symptoms were concerned. There were two cases of erysipelas. One patient was sixteen years of age, with an abscess following the extraction of a tooth, discharging at two points on the neck. Redness and swelling covered one-half of the face, nose, and head. The temperature was 104.4° F.; pulse, 140. There were delirium, vomiting, chilliness, etc. Ten cubic centimetres of the serum were injected at 9 P.M., resulting in fall of temperature to 100° F. Next morning there was complete arrest of all symptoms, followed by prompt recovery. The second case was one of nephritis; the eyelids and face were puffed, and there was erysipelas of the thigh, with hard, red, shiny swelling; delirium was present. Two injections used in twenty-four hours rendered the patient convalescent in thirty-six hours.

Penetrating Wounds of the Chest.—This paper was by Dr. J. B. Murfree, of Murfreesboro, Tenn. He confined his remarks largely to wounds of this region. Such a wound was produced usually by external violence, by which the walls of the chest were penetrated and the offending substance entered the thoracic cavity. It was a wound where not only the chest walls were injured, but also the tissues and oftentimes some of the viscera within the cavity. Penetrating wounds of the chest varied in their extent, character, and severity. They ranged from a small perforation with a delicate knife-blade or small bullet, merely separating the tissues without inflicting any serious injury, to a fearful laceration with great loss of tissue or serious damage to an organ produced by a large knife or a Minié ball. Wounds penetrating the chest were dangerous from hemorrhage, from the admission of air into the pleural cavity producing collapse of the lungs, from emphysema, from empyema, from septicæmia, and exhaustion. When a large vessel was injured death quickly ensued from loss of blood, while injury to smaller vessels might endanger life and even prove fatal from continued or frequently repeated hemorrhage. The symptomatology and treatment of these wounds were dwelt upon by the essayist at considerable length.

Dr. George S. Brown, of Birmingham, Ala., reported a case of vesico-rectal fistula of eight years' standing, the result of perineal lithotomy, with a cure after ten operations.

The following officers were elected for the ensuing year: *President*, Dr. Joseph Taber Johnson, Washington, D. C.; *Vice-Presidents*, Drs. F. W. Parham, New Orleans, and W. L. Robinson, Danville, Va.; *Secretary*, Dr. W. E. B. Davis, Birmingham, Ala.; *Treasurer*, Dr. A. M. Cartledge, Louisville, Ky.; *To Fill Vacancy in the Council*, Dr. L. McLane Tiffany, Baltimore, Md. Place of meeting, New Orleans; time, to

be determined by the secretary with advice of the council.

After the presentation and adoption of resolutions of thanks, the association adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MEDICAL COUNCIL—PRESSURE IN SURGERY—A SPECIAL FORM OF HIP-JOINT DISEASE—THE PRINCE OF WALES—THE LATE SURGEON-GENERAL A. SMITH, DR. WEBB, AND PROFESSOR ALLMAN.

London, December 2, 1898.

The Medical Council has had to spend a good deal of time over the penal cases. How difficult it is for such a body to exercise judicial functions has once more been demonstrated. It was proposed to relegate this work to the branch councils, but the legal advisers said this could not be done. The penal committee only decides whether there is a *prima-facie* case. If a practitioner is to be tried at all, he must be brought before the whole council. Consequently much of Wednesday, Thursday, Friday, and a part of Saturday had to be devoted to this work. It is to be hoped that in any legislation some better tribunal may be authorized. The penal committee is in future to be elected annually.

A complaint was made that a gentleman had been refused a programme, and the president replied that it had never been the practice to supply them. In this he was quite mistaken, as I know from personal experience. Programmes could always be obtained by a visitor, and there can be no reason why they should not. I hope this is not another sign of a disposition toward obstruction by the new president.

It was decided to strike off the lowest of the preliminary examinations recognized by the council, and it is probable that this step is only the first in a series. The need of such a move has long been manifest, yet some over-cautious members managed to get the change postponed and professed a fear that there would be a danger of an inadequate supply of medical men for the public needs. Considering the notoriously overcrowded state of the profession, it is probable they were more likely afraid that fewer students meant fewer teaching fees. They should hear the remarks of general practitioners on this subject.

There was a good deal of difference of opinion on the Midwives Bill, and on this subject, too, councillors would be well advised to listen to the voice of the struggling practitioner. The talk, however, was directed chiefly to the necessity of preventing the expense of any change being thrown on the council.

The council approved the work of the committee on the subject of companies being formed to carry on professional work. This committee was reappointed, and there is hope of a law to prevent this scandal.

"Support without pressure" was a favorite phrase with the late Mr. Gamgee. The words would have been apt in the discussion on Monday at the Medical Society on a paper of Mr. Gould's entitled "The Value of Pressure in the Treatment of Wounds." The word uselessness might almost as well have been substituted for value, as the gist of the paper was to show that pressure is to a great extent ineffectual to secure apposition of the edges of wounds, to check oozing, lessen serous exudation, restrain muscular contraction, prevent cicatrices from stretching, and so forth. The author said he had given up for some time the use of pressure for such purposes, to the great comfort of his patients, while the wounds had healed as well or even better. He went so far as to say that a simple collodion dressing is all that is necessary after a laparotomy, and to this one remark the attention of subsequent speakers was too closely confined.

Mr. Alban Doran said that some years ago he tried the plan of doing without pressure after abdominal section, but he soon took it up again. He thought a bandage helped the patient to expel flatus and prevented the stagnation of fæces, so he approved of firm but not tight pressure.

Mr. Stanley Boyd rather agreed with Mr. Gould, and as to approximation of surfaces said this could often be secured by buried sutures.

Mr. Shield advocated moderate pressure, and remarked that, if not employed after colotomy, vomiting might be followed by escape of intestine.

Mr. Wallis advised operators to steer a middle course, and Mr. Beale said a certain degree of pressure was required to keep dressings in place.

In his reply Mr. Gould said he did not think a bandage could help in the expulsion of flatus, for persons troubled with that found relief by loosening all tight garments. He had never used more pressure after colotomy than sufficed to keep the pad in its place, and as to lessening serous exudation, pressure seemed to him more likely to cause it by interfering with the venous circulation.

At the last meeting of the Medico-Chirurgical Society Mr. Owen read a paper on a distinct variety of hip-joint disease in children and young persons. He thought acute suppurative cases should be carefully differentiated from tuberculous disease, and that they were caused by the micro-organism of osteomyelitis invading the loose tissue at the upper part of the diaphysis of the femur. The end of the diaphysis enters into the formation of the joint, to which fact Mr. Owen attributed the arthritis which occurs when the diaphysis is involved in osteomyelitis. This disease is characterized by its sudden onset, intensity, and rapid course. Death from septicæmia is likely to follow unless the disease is recognized and adequately treated. Mr. Owen advocates free opening of the joint, removal of the epiphysis and the affected part of the diaphysis, with thorough application of germicides to the interior of the joint, followed by drainage. He related four cases.

Mr. Barker remarked that the disease was generally recognized, and the necessity of prompt, active measures admitted. But he did not think strong germicides necessary. Thorough washing with sterile fluid was sufficient and did not give rise to destruction of tissue.

Mr. Spencer did not attach so much importance to the fact of the diaphysis entering into the formation of the joint, and could not agree with the radical proceeding of removing the head of the femur. He held that washing out the joint and drilling into the diaphysis was often enough. He preferred carbolic acid to mercurial germicide as less poisonous.

Mr. Warrington Haward supported Mr. Owen's recommendation, as a less radical treatment did not remove the seat of the disease and jeopardized the patient's life.

Mr. Wallis referred to the case he showed at the Clinical Society two years ago, in which, on opening an abdominal abscess, the head of the femur was found loose in its cavity.

Mr. Golding-Bird did not think it was always necessary to remove the head of the bone. He related a case in which the joint was washed out and the wound closed except a small gauze drain, and the patient, a boy of eight and one-half years, made an excellent recovery.

Dr. Stuart MacDonald remarked that in some cases, when the disease begins in the periosteum, recovery

may follow a simple irrigation of the joint. He mentioned a case in which an abscess was opened, and, the joint appearing normal, nothing else was done. But the next day the boy died of pyæmia, and on post-mortem the joint was found to contain two drachms of pus.

Mr. Bryant (president) could not quite indorse Mr. Owen's strong opinion, that it was necessary to use freely the gouge, scoop, and germicides; but he insisted that the bone should always be drilled.

It is announced in an official sort of way that the Prince of Wales has completely recovered, though he will continue to wear a slight splint as a precaution. This last point seems to be stated to account for the slight limp with which he walks at present.

The sudden death of Surgeon-General Alexander Smith closes a brilliant career. At an inquest on Tuesday it was shown that soon after breakfast he was seized with a feeling of sickness and fainting, and died before medical aid could be obtained. He was seventy-four years of age, and had served before Sebastopol and subsequently in India, and was P. M. O. in the Afghan War. Dr. Smith was frequently mentioned in dispatches, had received the C.B., and was honorary physician to the Queen. He retired in 1884.

A memorial to the late Miss Mabel Webb, M.B. Lond., is to take the shape of a new pathological museum at the Royal Free Hospital, where Miss Webb's work was accomplished.

Prof. G. J. Allman died on the 24th ult., aged eighty-six years. He was educated as a medical man and took a degree, but never practised the profession, having devoted his life to natural history.

THE "SURGICAL NURSES" OF THE ACADEMY OF MEDICINE—A REPLY.

To the Editor of the Medical Record.

Sir:—In your issue for November 26th appears a letter from the undersigned, written in the hope of inducing the management of the Academy of Medicine to exercise more care in selecting their surgical nurses, and specifying instances in which they have sent out "surgical" nurses who did not even know the names of the instruments, and that these should not be put into bichloride solution, and should be taken apart for cleaning.

In your issue for last Saturday the chairman of the executive committee replies. He disapproves of me and all my works; though without attempting to deny the truthfulness of the instances I gave.

I am saddened that I did not do so obvious a thing as to make my inquiry very privately, and of Miss MacHaffie of the Nurses' Bureau, since my obtuseness has resulted in the courteous if unconscious demonstration by Dr. Jacobi that a great specialist may be but a lesser logician, and one who proposes, as he states, "not to go behind the returns," but to continue supplying incompetent surgical nurses provided Dr. John Smith, of Nowhere, guarantees that they are all right and "up" in asepsis. Dr. John Smith is probably a pediatric specialist, or maybe is even a general practitioner. Hence, of course, he knows the details of that science in itself—practical asepsis—and consequently can judge of surgical nurses.

The result all may see who depend upon the Academy for surgical nurses.

I have never seen an abler instance, Mr. Editor, than Dr. Jacobi's reply, of the cuttlefish art of throwing ink to hide a main issue. Actually I am accused by him of desiring to introduce a religious test to the prejudice of certain of the nurses! He says: "But they are not asked" (at the Academy) "about their religion, as the gentleman appears to suggest, nor does the bureau care for their 'medical training.'"

Obviously the bureau does not care for their medical training: that I promptly admit. But why be proud of it?

After some puzzled reflection and a careful reperusal of my letter to the Medical Record, I have come across the only word in it which by any possibility of distortion could give Dr. Jacobi a handle for this remark upon religion. It is as follows: "I do not doubt that each of these nurses [criticised] was a true Christian, and was possessed of a fair amount of medical training; but it is calculated to shake one's confidence in the Academy's bureau to find them selected as exponents of surgery—and of asepsis" (of course, as applied to nursing).

Now, if Dr. Jacobi meant anything whatever by his remark, it must have been a chivalrous, if uncalled-for, defence of the Christianity of these ladies; his plain inference being that I prefer those of a different faith. The paradox presented by this bit of Quixotism is delicious—the nominal Christian being put on his defence! I am irresistibly reminded of the converse of the proposition, in that book of epigrams, "Without Prejudice": "'A pretty Christian thou art!' exclaimed a voice, in unthinking vituperation"—of the author, Israel Zangwill.

Perhaps in no other respect is a reply called for, unless it be to the triumphant inference that because one of the "surgical" nurses I complained of in my letter was retained by the family several weeks, she must have been satisfactory. The fact was, that after the first day there was no operating. She ceased to be needed for her asepsis, and was kept for different work, "because of her good heart," as the patient explained to me.

Whether the instances I have named were recent or old is entirely immaterial. One is quite old, another quite recent. Not by a word did I intend to "eulogize the good old days before MacHaffie's clerkship." That is a remark without any basis of truth.

I would beg to repeat that I have no axe to grind, and am far from being alone in my views upon this matter of the nursing.

The writer is a fellow of the Academy of a good many years' standing, and is an admirer of that great institution of which Dr. Jacobi is an ornament. But when one of its departments falls short of our reasonable needs in any particular, and when—as now—that particular can easily be remedied, it behooves the management not to quibble over words, but to "go behind the returns," if need be, for the honor of the Academy.

Robert H. M. Dawbarn, M.D.

105 West Seventy-Fourth Street, New York City.

THE TREATMENT OF LEPROSY IN HAWAII.

To the Editor of the Medical Record.

Sir: I see in November 5th of the Medical Record a letter from Dr. J. C. Bowker, of Lawrence, Mass., in which he gives me entirely too much prominence in the treatment of leprosy. The board of health created, in November, 1894, "a committee on the treatment of leprosy," consisting of Drs. C. B. Wood, F. R. Day, N. B. Emerson, George Herbert, R. P. Myers, and W. H. Howard—Dr. Wood, chairman, and myself secretary; Dr. L. F. Alvarez, microscopist and bacteriologist. The experimental station is situated at Kalihi, a few miles from the city (Honolulu), and is under the control of the board of health. I wish you would make a simple statement of the facts, as I do not wish to have the credit and prominence given me through the good intentions of my friend, Dr. Bowker. Dr. Alvarez is doing good work, and the committee all in its power to promote the allevia-

tion of the disease and what it can for its cure. In passing, I would also call attention to a statement in a recent editorial, which quotes a writer who credits us with lepers to the extent of ten per cent. of the population. As a fact proved by government statistics, there is not more than one per cent.

By making such a statement of facts you will much oblige ROBERT P. MYERS, M.D.

HONOLULU, November 23, 1898.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 17, 1898:

	Cases.	Deaths.
Tuberculosis	199	174
Typhoid fever	45	12
Scarlet fever	131	13
Measles	112	7
Diphtheria	171	19
Laryngeal diphtheria (croup)	20	7
Cerebro-spinal meningitis	0	3
Chicken-pox	32	0

To Remove Ink Stains.—Use a solution of chlorinated soda. Wet the stain with the solution and wash thoroughly after a few moments.

The Study of Leprosy in Breslau.—Arrangements are being made for the careful study and treatment of leprosy in the Breslau University clinic for skin diseases, the patients being brought from Eastern Prussia with great precautions as to isolation and disinfection of the railway carriages.—*London Lancet.*

Drinking in La Vendée.—The Paris correspondent of the *British Medical Journal* says that the inhabitants of La Vendée drink on an average four to eight litres of wine a day. They are rarely in a condition of alcoholism, and quite exceptionally have delirium tremens. Dr. Terrien believes that this immunity is due to the fact that white wine made from the grape grown in the district is almost exclusively drunk in La Vendée. The few sufferers from delirium tremens whom he met with had been in the habit of drinking bad red wine.

Color of Black Babes at Birth.—The negro baby, when it comes into the world, presents a delicate pink color; the second day it is lilac; ten days afterward it is the color of tanned leather; and at fifteen days it is chocolate color. The coloring matter which lies between the layers of the epidermis is semi-fluid, or in the form of fine granulations; in the Indian it is red, and in the Mongolian yellow. It is influenced not only by sun and by climate, but by certain maladies, and the negro changes in tint just as the white person does.—FARABERY.

Degeneracy in the Negro.—Dr. Johnson, of Brunswick, Ga., believes that the liberty granted the negro by the war of the rebellion brought with it a license to indulge in vice which has served to enervate and degrade him. Physical degeneration has been brought about by dissipation and want of care and forethought; and consumption, which before the war was almost unknown among the slaves, is now very prevalent. Dr. Johnson belongs to the race of which he speaks.

Accidental Lesions of the Aortic Valve.—Linemen and those engaged in heavy manual labor, especially heavy lifting and athletics, are among the victims of this accident. Also, in rare instances, soprano singers, when engaged in prolonged and exhaustive feats on the higher notes, are liable to this lesion, which may vary from a mere strain or slight yielding to the complete rupture of a valve. And the immediate symptoms may also vary from a slight faintness and enervation to complete syncope and collapse.—DR. J. C. SPOHN, *Tri-State Medical Journal*, November, 1898.

A Backslider.—A convict in the Trenton prison, who was a Christian scientist, was sent into the hospital one day last week, suffering from asthma. Dr. Brewer, knowing the patient's tendencies to look upon all ills as merely "mortal thoughts," susceptible to cure by belief in their non-existence, suggested that the cell would be a more appropriate place for undisturbed self-communion. To this the sufferer agreed. In the middle of the night, however, the doctor was called and begged to prescribe. The patient was lost to the "science," but not by it, as so many have been of late.

Sale of Horse-Flesh in Paris.—The annual statistics published by the French Ministry of Agriculture indicate that the consumption of horses, mules, and donkeys is steadily increasing in Paris. The number of stalls at which it is offered for sale now reaches 193. The number of horses brought to the shambles for slaughter was 21,667, of mules 52, and of donkeys 310; but 734 horses, 1 mule, and 7 donkeys were condemned as unfit for human food, so that the total killed and consumed was 20,933 horses, 51 mules, and 303 donkeys. The prime cuts fetched about a franc a pound, some of the inferior parts costing little more than ten centimes per pound.—*London Times.*

Heredity a Contrast.—In the *Revue Scientifique* for April last, Dr. Cesare Lombroso, in an able discussion of the relative influence of heredity and environment, announced the conclusion that "the influence of environment is potent enough to annihilate all ethnic traits." At the meeting of the German Anthropological Society in August of this year, Professor Kollmann, of Basle, in an address on the same subject, stated the dictum of science to be that "the influence of heredity is stronger than that of environment. The ethnic traits are immortal, and persist, though the people who bear them may disappear from history" (*Globus*, August 27, 1898). When two of the most distinguished anthropologists in Europe differ in opinion so widely, what is the ordinary searcher after knowledge to think, or whither shall he go for guidance?

Effect of Tea Cigarettes.—Tea cigarettes are of a grade of green tea which has but little dust, and is composed of unbroken leaf. This is dampened to make the leaves pliable and capable of being stuffed in the paper cylinder, while the dampness is not sufficient to affect the paper. The cigarettes are laid aside for a few days, and are then ready to be smoked. The feeling of a tea cigarette in the mouth is peculiar. The taste is not so disagreeable as might be supposed, but the effect on the tyro is a sense of thickening of the head and a disposition to take hold of something or sit down. If the beginner stops then, he will not try tea cigarettes again. If, however, the smoker sits down and tries a second cigarette, inhaling it deeply, then the thickening feeling passes and is succeeded by one of intense exhilaration. The stage lasts as long as the smoke continues. The agony of the opium fiend is a shadow to that of the nauseated victim of the tea cigarettes. Food cannot be looked at for hours, yet the first step toward a cure is a cup of tea. An hour afterward comes the craving for a cigarette.—*Medical Progress.*

MIDWIVES AS ILLEGAL PRACTITIONERS.[1]

BY ELBRIDGE T. GERRY,

PRESIDENT OF THE NEW YORK SOCIETY FOR THE PREVENTION OF CRUELTY TO CHILDREN.

THE office of midwife, which dates back to the days of ancient Egypt (Exodus i. 15–21), exists in this country more universally among foreigners than among natives. Abroad its functions are regulated by statute, or are under the control of the regular medical profession, excepting in those countries where the latter has no organized legal existence; and it is therefore quite natural that with the tide of immigration which has been pouring into America for the last fifty years, every variety of the human race from the other side of the Atlantic should bring with it the practices and the prejudices existing among the lower classes, which attach to this office. Among the lower classes of the larger nations of Europe, such as Russia, Germany, and Italy, the midwife is something more than a monthly nurse. She is permitted not simply to assist but to control the functions of parturition at their close, and rarely is the medical attendant called in, excepting in the event of some complication, or to relieve her from personal responsibility in case of error or carelessness.

In this country, however, the functions of the midwife are of a limited character. Among our own American people they existed previous to the institution of trained nurses, as the old familiar monthly nurses, but were even then merely an adjunct of the regular medical attendant in charge of the case. But with the influx of foreigners midwives came into the country, unobstructed by any specific legislation and not requiring the license or sanction of any medical or public board; and it was not until the boards of health and the medical profession in our large cities were aroused by the ignorance, want of cleanliness, and general incapacity, and frequent criminal practices of these women that legislation on the subject was attempted.

In 1893 the attention of the New York Society for the Prevention of Cruelty to Children was called to open violations of law by certain notorious keepers of so-called "lying-in asylums," who advertised ostensibly for that purpose in the daily papers, but whose places were more frequently resorted to for the purpose of criminal abortion. The society vigorously prosecuted and secured the conviction of these offenders: Frieda Karsch, Wilhelmina Schmitt, Bertha Schroeder, Annie Buckholz, Emily Winkelman, Helen Hoppe, Elizabeth Geyer, Edward Conrad, Christina Rothkran.

Finding their business thus seriously interfered with, many of the midwives upon legal advice proceeded to form a "Midwives' Association," and quite a number of them obtained articles of incorporation under the Hospital Act (Laws of 1889, chap. 95). The incorporators were usually the immediate relatives or friends of the chief figure, whose name appeared in the corporate title and without any direct or apparent connection with the "institution" run by her. One of these will appear later in this address as an illustration, as they are all substantially in the same form. After this "incorporation," when again arrested, they claimed that they were "institutions" within the meaning of the provisions of section 288, subdivision 2, of the Penal Code, as it then read. At that time a hospital association could be created without even the fiat of a justice of the supreme court; and to show the extent of this ingenious attempt to evade the law, the following is a partial list of the so-called "lying-in asylums" which were thus incorporated:

CORPORATE TITLE.	DATE OF INCORPORATION.
The Brown Home and Hospital for Females	October 20, 1893.
The Frieda Karsch Home and Lying-in Asylum	October 27, 1893.
The Schmitt Home and Hospital for Females	October 26, 1893.
The Hoppe Home and Hospital for Females	October 12, 1893.
Alma Landgraf Home and Hospital	October 18, 1893.
The Rothkranz Home and Female Hospital	October 11, 1893.
Becker's Home and Ladies' Hospital	October 27, 1893.
Schroeder's Home and Hospital for Females	August 24, 1893.
The Winkelman Home and Lying-in Asylum	August 17, 1893.
The Nagel Home and Hospital for Females	April 7, 1894.
Godarsky Home and Hospital for Women	January 17, 1894.
The Schott Home and Hospital for Females	January 17, 1894.

The society immediately conferred with the State board of charities, with a view to having the laws amended so as to cover the evil. The result was a bill, introduced in 1894 in the Legislature at the society's request by the late Senator O'Connor (being Senate Bill No. 89), which amended Penal Code, section 288, subdivision 5, by requiring the certificate of the State board of charities, approving the organization and incorporation of institutions of the character in question, and authorizing that board to apply to the supreme court for the cancellation of any certificates of incorporation previously filed without its approval. This bill became Laws of 1894, chap. 171. Another bill (Senate Bill No. 271) in the same year, amended the Laws of 1889, chap. 95 (being the Hospital Act), by forbidding the filing of a certificate of incorporation of such an institution without the approval of the State board of charities. This became Laws of 1894, chap. 256, and has continued to be the law to the present time. The attention of the State board was at the same time called to the existence of the so-called "institutions," and a request made that certificates previously filed by them should be revoked and cancelled by the action of that board under the provisions of the act referred to.

Unfortunately, no definite action appears to have been taken by the State board under the statute to cancel these certificates, and it is to be feared that many still exist. As late as October, 1898, the case of Christina Rothkranz, who had been previously convicted and "incorporated," as above stated, was brought to the attention of the society, and her arrest took place under the following circumstances: The officers of the society visited the rooms, No. 219 Seventh Avenue, where a sign appeared in the window, "Drs. Rothkranz," and an entrance bell marked "Drs.' bell" indicated the character of the dwelling. They inquired for Mrs. Rothkranz. She came in and accompanied the officers through the house, which is an old-fashioned three-story-and-basement structure. On the first floor were the dining-room and parlor of Mrs. Rothkranz. One flight up were her private apart-

[1] An address delivered before the New York Medical League, December 16, 1898.

ments, and the top floor was utilized for her servants and business. On the top floor in the front room an officer found a woman in bed, who stated that she had been confined five days previous of a male child, who was then in a crib in the room. This birth had not then been reported to the board of health. The officer inquired of Mrs. Rothkranz what doctor, if any, had attended the woman in her confinement, and she replied, "There was no doctor; I confined her myself, and she had just as good care at my hands as could be given by a doctor. I have brought many of them into the world and never had any mishap." A second visit to the house for the execution of a warrant against Mrs. Rothkranz, issued at the instance of the society, for keeping a lying-in asylum without a permit under section 288 of the Penal Code, disclosed the presence of a young woman, aged twenty years, in bed on the same floor and in the same room, then suffering from gonorrhœa and under medical treatment. Upon the arrest of Mrs. Rothkranz an examination was demanded before Magistrate Pool. The evidence in the case showed very clearly that Mrs. Rothkranz had only a certificate as midwife from a so-called "Columbia College of Midwifery," which speaks for itself. Here is a copy of it:

"Columbia College of Midwifery. Be it known that Christina Maria Rothkranz has attended the several courses of lectures delivered at the College and has passed a satisfactory examination in anatomy, physiology, obstetrics, parturition, and infancy. In testimony whereof, we, the Board of Directors, have granted this diploma of Graduate in Midwifery, given at our College in the City of New York this 16th day of June, in the year eighteen hundred and eighty-eight. Witnessed the signature of the President and Secretary (censors) and our corporate seal.

(Seal) "Columbia College of Midwifery, incorporated 1883. Max Feller, President; C. P. Kreizer, M.D., Secretary; E. S. Bates, M.D., J. Manion, M.D. (censors). Press of E. Scott, 463 Hudson Street, New York City."

Its name is presumed to have been selected in order to connect it in the minds of the ignorant with Columbia University, then Columbia College. It was located in West Forty-seventh or Forty-ninth Street in this city, and managed apparently for the financial benefit of the persons connected with it. Another institution similar thereto and possibly connected with it is believed to have been managed by another doctor. This so-styled "college of midwifery," although incorporated, had no more authority than any private individual to confer a diploma, and in the opinion of the County Medical Society its diplomas carried no more weight than a similar paper issued by any job printer. The teaching at this "college" was said to consist of the reading of some work on obstetrics a couple of hours a day, for a few weeks or a few months, when a diploma was issued, the "graduate" paying from $25 to $50 therefor. "It does not necessarily follow," wrote the counsel for the County Medical Society some time since, "that a woman is unworthy because she has the diploma of this rotten affair; but the college is not capable of giving a midwife any legal status that she cannot have without it."

It fully appeared upon the examination of Mrs. Rothkranz that she affixed the letters "Drs." to her sign to indicate "doctress," because, as she said, "it sounds better to have a fictitious name. People in general call a midwife in plain a doctress." Upon the examination, she admitted the insertion of an advertisement in the daily prints, reading as follows:

"Drs. Rothkranz; Incorporated Sanitarium for Females; thirty years' experience; treats female diseases; irregularities; positively painless; success guaranteed every case; confinements; strictly private; motherly care. 219 Seventh Avenue; one door below Twenty-third Street."

And then she claimed that she was duly incorporated as a hospital pursuant to the following certificate:

"Certificate of Incorporation of 'The Rothkranz Home and Female Hospital,' verified October 10, 1893, recorded in the county clerk's office, October 11, 1893. The certificate is verified before H. W. Leonard, notary public, New York County. Duplicate filed with the Secretary of State at Albany, October 11, 1893.

"State of New York, City and County of New York, ss.

"We, the undersigned, desiring to form a corporation as provided for under the statute regulating the incorporation of hospitals, do hereby in conformity therewith organize themselves for the purpose of establishing, maintaining, and operating a hospital or home, for the reception, care, maintenance, and the giving of medical and surgical advice, aid and treatment to females who are desirous of placing themselves under the care of the manager or medical attendant thereof.

"That the Hospital or Home of said corporation shall be located in the city of New York, and be known as 'The Rothkranz Home and Female Hospital.'

"That the business, object, and the purpose of said incorporation is as follows:

"To provide a home or hospital for the reception, care, and maintenance, and the giving of medical and surgical advice, aid, and treatment to females who are afflicted with physical injuries, weaknesses or deformities or infirmities or maladies, and who are about to be confined with childbirth, or in need of medical treatment in general.

"The affairs of this corporation shall be conducted, managed, and administered by a board of managers, to consist of nine persons, who shall hold office for one year after the filing of this certificate, and annually thereafter an election of the members of the board of managers shall be had which shall be by ballot by all the members of said corporation in accordance with the rules and by-laws hereafter to be adopted by said corporation.

"The officers and board of managers shall consist of a president, vice-president, secretary, and treasurer and medical examiner, and who shall with four others constitute a board of managers, and who shall have and possess full power of the general management of the said home or hospital, as provided by the rules and by-laws of the corporation.

"The following members shall constitute the board of managers: 1, Mrs. Christina Rothkranz; 2, Arnold Rothkranz; 3, Arnoldine Rothkranz; 4, Louis Rothkranz; 5, Louise Hansen; 6, H. J. Schiff, M.D.; 7, Anna McEvoy; 8, Alice Haffenan; 9, Bertha Hartman.

"In witness whereof we have hereunto set our hands and seals this 9th day of October, in the year one thousand eight hundred and ninety-three. In presence of H. W. Leonard.

"Mrs. Christina Rothkranz, Arnold Rothkranz, Arnoldine Rothkranz, Louis Rothkranz, H. J. Schiff, M.D., G. G. Gaertner, Louisa Hansen, Anna McEvoy, George Brown, B. G. Jenne, A. C. Clark.

"State of New York, City and County of New York. On this 10th day of October, in the year one thousand eight hundred and ninety-three, before me personally came Mrs. Christina Rothkranz, Arnold Rothkranz, Arnoldine Rothkranz, Louis Rothkranz, Louise Hansen, H. J. Schiff, M.D., G. G. Gaertner, Louise Hansen, Anna McEvoy, George Brown, B. J. Jenne, A. B. Clark, to me known and known to me to be the individuals described in, and who executed the foregoing instrument, and they thereupon acknowledged to me that they executed the same. (L. S.) H. W.

Leonard, notary public, New York County. Endorsed, filed, and recorded 11th October, 1893. M. J. D.

"No. 229, State of New York, City and County of New York, ss.

"I, Henry D. Purroy, clerk of the said city and county, and clerk of the supreme court of said State for said county, do certify that I have compared the preceding with the original certificate of incorporation of The Rothkranz Home and Female Hospital, on file in my office, and that the same is a correct transcript therefrom, and of the whole of such original. Endorsed, filed, and recorded 11th Oct., 1893, 9h, 40m.

"In witness whereof I have hereunto subscribed my name and affixed my official seal, this 20th day of Nov., 1893. Henry D. Purroy, clerk."

She was held to answer by the magistrate notwithstanding, upon the charge of keeping a lying-in asylum without a license, and also for violation of the State medical law in practising as a physician, not being licensed. The case has not yet been disposed of in the trial court. The opinion of Magistrate Pool is instructive:

"The testimony in this case goes to show that the defendant is the sole representative and manager of the alleged corporation, purporting to be organized for the purpose of establishing and maintaining a hospital or home for the reception, care, maintenance, medical and surgical advice and treatment of females who may place themselves under the care of the manager or the medical attendant thereof. The purported managers of this corporation are mostly the relatives of the defendant, residing out of the State, and not in any way conducting and carrying on the purposes for which the corporation purports to have been organized.

"I find from the evidence that the defendant uses and controls the corporation for her own personal use and benefit, and to do so attracts persons to the same by fictitious advertisements, so that she may treat female diseases 'positively painless: success guaranteed every case; confinements; strictly private'; and that in such or any cases of persons attracted to said advertised place the defendant receives pay in her own right for any services she may have given them, whatever they may be; that the services by the defendant given by her are in most cases outside and in another place out of the alleged advertised home of the corporation.

"It further appears to me from the evidence that the defendant is not lawfully authorized to practise medicine within this State; and that from the evidence the defendant assumes and advertises herself as a doctress and holds herself out as such doctress, and by her conduct, advertisement, and solicitation conveys the impression to the unsuspecting persons who are seeking and needing medical and obstetric attention, that the said defendant is a legal practitioner of medicine; and I find that she is conducting business under cover of said corporation charter.

"It is apparent to my mind from the evidence that the defendant is using the alleged corporation name to further her business and practice of midwifery; that the corporation is not carried on there for legitimate purposes nor for the purpose which it is alleged the same was organized for; and the attorney-general should be notified of the fact, that he may take the necessary steps to annul the charter.

"I therefore hold that there is probable cause to believe that the defendant has committed the offense charged in the case of Thomas R. Agnew on behalf of the people and also the case of the Medical Society of the County of New York against this defendant, and I fix the bail in each case for trial at five hundred dollars."

Now this case has been cited as an illustration of the difficulties which arise in dealing with offenses of this description. In the first place, there is no registration of midwives by competent authority. True, they claim that they are "registered" by the board of health. But this amounts to nothing, as the officials of that board admit that they register anything but do not examine as to qualifications. In other words, this registry simply consists in taking whatever name and address the woman may give; it does not decide or affect her qualifications or right to practise. Anybody can register as a midwife who desires to do so. This class of women practise midwifery principally in the thickly settled districts of the city, charging for their services at times as low as from five dollars to one dollar. No physician attends. The woman is left afterward in a very improper condition, with the result frequently that she is an invalid for the rest of her life and a burden upon some poor laboring man, or at least unable ever again to bear children. Not only this; but the child, from the inattention and negligence of the midwife to report to some medical authority the condition of its eyes, becomes a subject for the care of some hospital or eye infirmary for a long period; or worse still, in many cases, not receiving such care, becomes partially or totally blind. Even when the case is cared for by the eye infirmary, and when the most skilful treatment is given the child by the physicians attached thereto, the child at times is afflicted with partial and perhaps total blindness. The society is frequently called upon by the hospitals to prosecute the midwife who occasioned the trouble. Any of the physicians attached to the infirmaries for the treatment of the eye in this city will testify to the truth of this statement. The society has successfully prosecuted many of these cases.

Another class of these women embraces those who advertise in the daily papers to take women in confinement. To them resort those who desire to conceal their unfortunate condition; the great majority of whom, it is found, reside outside the city of New York, and sometimes come from other States. In one of these establishments recently an officer found five women, all of whom were residents of other places. After being delivered of the child, unless an abortion is effected, which is many times the case, thereby risking the life of the woman and frequently resulting in her death, the child is disposed of by being left in the street, through the assistance of the midwife, or is "adopted" out, after passing through the hands of two or three confederates of the midwife, the person "adopting" paying a certain sum of money for the child, and later being subjected to a species of blackmail for a considerable time, or to threats of exposure, by bringing the mother to take the child away, after the foster parents, perhaps very reputable people, have become attached to it. This was recently illustrated in the case of The People *v.* Louisa Wagner, now undergoing imprisonment for keeping one of these establishments. It was shown in her case that she "adopted," or sold, a child to a gentleman and his wife for ten dollars, and later, after the gentleman's wife had become very much attached to the child, she demanded a present of one hundred dollars, threatening that otherwise she would bring the mother of the child to claim it. He fortunately called the society's attention to the matter, and through its assistance the "midwife" was thwarted in her attempt at blackmail and extortion.

Very few of these so-called "midwives" have any knowledge of anatomy, or of the proper care of a woman in confinement.

It should be borne in mind that there are plenty of legitimate maternity hospitals located in the borough of Manhattan, to attend to the care of women in confinement. Here is a list of some of them:

Maternity Hospital of Department of Public Charities, Blackwell's Island; Emergency Hospital for Wo-

men (branch of above), 223 East Twenty-sixth Street; The New York Foundling Hospital, 130 East Sixty-ninth Street; New York Infant Asylum, Amsterdam Avenue and Sixty-first Street; New York Mothers' Home of the Sisters of Misericorde, 523–537 East Eighty-sixth Street; Nursery and Child's Hospital, 571 Lexington Avenue; The Old Marion Street Maternity Hospital, 139 Second Avenue; Sloane Maternity Hospital, Fifty-ninth Street and Tenth Avenue; Society of the Lying-in Hospital of the City of New York, Seventeenth Street and Second Avenue; New York Medical College and Hospital for Women, 213 West Fifty-fourth Street; The Mothers and Babies' Hospital, Lexington Avenue and Fifty-second Street; The New York Infirmary for Women and Children, 5 Livingston Place; Ladies' Hebrew Lying-in Society, 128 Second Avenue; Metropolitan Dispensary and Hospital for Women and Children, etc., 1307 Lexington Avenue; Colored Home and Hospital, Sixty-fifth Street and First Avenue; New York Post-Graduate Medical School and Hospital, Twentieth Street and Second Avenue.

The remedy for the evil is very simple. If the attention of the State Medical Society was called to the matter, with a bill properly drawn, requiring the registration of midwives either generally, or at least in all cities, making it a penal offence for any woman to practise as a midwife without being so registered; and placing the control of the matter in the hands of the local County Medical Society, the evil would to a great degree be suppressed. The act should provide that all women permitted to practise as midwives should be compelled to serve a definite prescribed course in some duly incorporated maternity hospital, and receive therefrom a diploma similar to that now issued to trained nurses by training schools. They should then be required to duly register in some proper public office (that of the county clerk, for instance), under proper provisions and safeguards defined by the county medical societies, which should have the right to apply for the removal of their names from the list at any time, for cause shown; and, in addition to this, there should be a further proviso, forbidding any incorporation of such midwives with other persons for any purpose incidental to, or connected with, their business. With these safeguards the illegal practice of these midwives might be restrained; and, while it may not be possible to suppress them as a body, so long as their functions are controlled by the legitimate medical profession an additional security will be afforded against the unlawful practices which are now the cause of frightful infant mortality in this city.

A CASE OF ANEURISM OF THE UTERINE ARTERY, CURED BY LIGATION OF THE INTERNAL ILIAC ARTERY.

By PAUL F. MUNDÉ, M.D.,

GYNECOLOGIST TO MOUNT SINAI HOSPITAL, NEW YORK.

THE reason for reporting this case is its rarity. In an experience of over thirty years not only have I never before met with such an accident, but a careful search through the surgical and gynæcological literature at my disposal has failed to discover a mention of its occurrence. In the most comprehensive work on general surgery in my library—Ashhurst's "International Encyclopædia of Surgery," 1883—there is no mention of aneurism of the uterine artery, although aneurisms of various abdominal arteries are recorded, apparently including all known instances of the lesion in that locality. And none of the surgeons or gynæcologists of my acquaintance of whom I have made inquiry has a recollection of seeing any condition in the female pelvis which might be looked upon as an arterial enlargement resembling an aneurism, with the sole exception of Dr. E. Pierre Mallett, of this city, who remembers meeting with a strongly pulsating swelling in the vaginal vault of a woman whom he examined within the past year in his service at the Vanderbilt clinic. He was unable, however, to confirm his suspicion as to the character of the swelling, as the patient did not return.

Considering the liability of the uterine artery and its branches to frequent prolonged dilatation during the physiological hyperæmia of pregnancy and the pathological changes incident to the development of fibroid tumors and ectopic pregnancy, and also the common injuries to which this vessel is subjected at the time of labor and by surgical measures, it is strange that the uterine artery should have remained free from a lesion which occurs so readily in nearly all the more important arteries of the body.

The danger common to all aneurismal enlargements, that of rupture, applies equally to aneurism of the uterine artery, although the course of that vessel in the pelvic cellular tissue lessens the risk in a measure, owing to the comparatively limited space in which the effusion of blood can occur. Still, as is well known to take place in intraligamentous rupture of an ectopic gestation sac or in a pelvic hæmatoma due to the bursting of a varicose vein in the pelvic cellular tissue, the escaped blood may be sufficient in amount to dissect up the peritoneum as high as the renal region and produce alarming and dangerous collapse. Hence an aneurism of the uterine artery cannot be considered a trifling lesion, and must be treated and cured as soon as discovered, on the principle applied to all other aneurisms, by shutting off as much as possible the blood supply to the diseased vessel, and thus producing a coagulation and shrinking of the aneurismal contents and sac. And it was on this principle that I treated the present case.

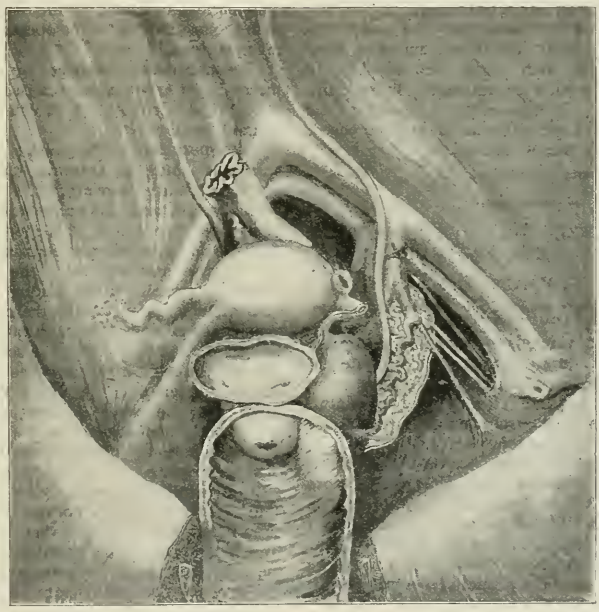
On September 28, 1898, Mrs. N——, thirty-two years old, mother of one child, eight years of age, called on me at my office for an examination, complaining of a "burning, throbbing" sensation in the left inguinal region. She reminded me that I had seen her two years previously at her home, in consultation with Dr. E. C. Savidge, who had operated on her for a lacerated cervix, after which operation an abscess had developed. I remembered the case perfectly. I found pus issuing from the external os when pressure was made with the finger on a boggy, soft swelling in the left vaginal vault, and I judged therefrom that there was a fistulous communication between the cavity of the abscess and the cervical canal. Hence I advised slitting out the cervix from the sinus down to and through the external os and into the abscess, so as to lay the cavity of the latter freely open. This Dr. Savidge informed me later was done, and the abscess closed rapidly. A severe venous (so Dr. Savidge distinctly told me) hemorrhage took place at the time, which was controlled by tamponade.

The patient stated that she had been perfectly well and under no medical care until three months previously, when, while on a visit in the West, she felt an uncomfortable feeling in the left lower part of the abdomen, and consulted a physician in Milwaukee, who examined her and told her that she had a "swelling" in the left side of the pelvis, for which she should consult a specialist on her return home. He gave no opinion, she says, as to the nature of the "swelling."

I expected to find a chronic salpingitis or some chronic inflammatory condition of the appendages or cellular tissue, but was more than surprised to find a softly elastic, strongly pulsating, and thrilling tumor, of about the size of a hen's egg, projecting into the left vaginal vault, close to the cervix and extending

slightly down on the left vaginal wall. At one point next to the cervix there was a "purr," so pronounced and distinct as to make me apprehensive that the aneurism, as it clearly was, might burst at any time. The accompanying illustration, made for me by Dr. W. H. Luckett, former house surgeon to Mt. Sinai Hospital, gives an excellent representation of the site of the aneurism as well as of its vascular relations. It was evidently an enlargement of the uterine artery, that being the only arterial vessel in that locality which was sufficiently large to admit of such a dilatation.

The dangerous character of the lesion was evident, and the remedy seemed equally clear, namely, the ligation of the arterial trunk, from which spring the uterine artery as well as several other smaller vessels supplying the female pelvic organs. That trunk is the internal iliac artery. It occurred to me that I might be able to reach and ligate the undilated portions of the uterine artery at either end of the aneurism through an incision in the vaginal vault; but the uncertainty as to the exact origin and extent of the aneurism, and the danger of wounding a vessel, vein or artery, the ligation of which through the vagina would prove difficult or impossible, as well as of injuring the ureter, deterred me from adopting this method. To apply clamps to the artery at either side of the dilatation, and thus bring about the coagulation of its contents, seemed too uncertain and risky.



There remained for me, therefore, only one safe and sure way of cutting off the blood supply to the diseased vessel, namely, by opening the abdomen and ligating the internal iliac artery midway between its separation from the common iliac and its division into the hemorrhoidal and uterine arteries. The direct blood supply of the aneurism would thus be checked, with the exception of the probably trifling amount received by anastomosis with the ovarian artery.

As regards the etiology of the aneurism, it occurred to me that it might be traumatic, the artery having been injured at the time the abscess was opened. I communicated with Dr. Savidge at once by telephone, and he informed me of the violent venous hemorrhage at that time, but could throw no light on the causation of the aneurism.

Fearing the risk of delay, I sent the patient at once to a private room in Mt. Sinai Hospital, and operated on October 1st, with the kind assistance of Dr. Howard Lilienthal, adjunct surgeon to the hospital. Through a four-inch incision in the left semilunar line I opened the abdomen in Trendelenburg's position, and after some difficulty in isolating the artery, especially from the ureter which crosses it and lies close to the inside of it at that point, I succeeded in passing a Deschamp's pedicle needle under it and ligating it gently but firmly, so as not to injure its coats, with chromicized catgut. Before doing so, the finger of an assistant on the aneurism in the vagina informed me when pressure on a certain part of the artery arrested pulsation in the aneurism, and it was at the spot thus indicated that the ligature was applied. When tightened, pulsation in the aneurism ceased entirely. The wound in the peritoneal covering of the vessels was closed by fine uninterrupted catgut suture, and the abdominal incision by buried catgut and deep silkworm-gut sutures. Recovery was uneventful.

Immediately after the operation there was a faint, apparently transmitted pulsation in the aneurism, which at the end of a week had increased somewhat, probably owing to the establishment of collateral circulation. The purr and thrill had, however, entirely disappeared, and never returned, and the outer portion of the aneurismal swelling had become hard and solid, and had evidently contracted. Wishing to make as perfect a cure as possible before discharging the patient, I decided to try the effects of galvano-puncture of the aneurism, and twice at intervals of three days passed a current of twenty milliamperes from a chloride-of-silver battery through the sac for half an hour, a carefully insulated platinum needle being thrust deeply into the centre of the aneurism and connected with the positive pole, the negative pole being a large wet sponge under the left natis. The effect of these two galvanic sittings in hardening and shrinking the aneurism was very apparent, but I am confident that this method would have proved utterly inadequate and probably dangerous through the possible detachment of particles from the thrombus and distant embolism, if the chief arterial supply had not been previously shut off by ligation.

When last examined, six weeks after the operation, the aneurism had shrunken to one-half its original size, was hard and painless (at no time, indeed, had it caused any particular pain), and pulsated no more than the normal uterine artery.

I should add that the cervix was normal, the incision at the time of the abscess having healed with scarcely a trace.

While exploring the abdominal cavity during the operation, I could reach the upper border of the aneurism with the tip of my finger, but could not trace out its limits with sufficient clearness to feel justified in attempting to ligate its immediate afferent and efferent vessels; neither did I attempt to ligate the ovarian artery, which I could easily have done at the upper margin of the left broad ligament close to the uterus. I did not estimate its relation to the aneurism by anastomosis with the ascending branch of the uterine ar-

tery as of sufficient importance to call for a prolongation of the operation. However, should I meet with another similar case, I would take this additional precaution. To endeavor to dissect out the whole aneurismal sac after ligating or clamping its vessels, as has been suggested to me, would, I think, be too hazardous and uncertain, and anatomically too difficult, however tempting and theoretically practicable it might appear.

As regards the ligation of the internal iliac artery, it may be permissible to say that it is by no means an easy operation, even with the vessel exposed as it is in Trendelenburg's position. The difficulty is chiefly the isolation of the artery from the vein and the ureter, and, this accomplished, the passing underneath and around it of the ligature needle. I found the ordinary aneurism needle and a bent silver probe insufficient to force their way through the subjacent areolar tissue, but the slightly sharp tip of the Deschamps ovarian pedicle needle answered admirably, the point being carefully watched by the left index finger.

The operation is a comparatively rare one; Ashhurst says that up to 1883 "the whole number of cases is about twenty-seven, with eight recoveries." No doubt, since the perfection of antiseptic surgery and the introduction of Trendelenburg's position, the number of cases of this operation has greatly increased, with a corresponding rate of recoveries.[1]

20 West Forty-Fifth Street, November 21, 1889.

A NEW OPERATION FOR THE RADICAL CURE OF HEMORRHOIDS.[2]

By H. J. SCHIFF, M.D.,

ATTENDING SURGEON, ST. MARK'S HOSPITAL, AND OUT-DOOR DEPARTMENT, MT. SINAI HOSPITAL.

I know of no disease which is so amenable to surgical treatment as hemorrhoids, whether they are internal or external. There are in practice at present many operations for the cure and relief of this complaint, but they all have the same disadvantage, namely, that the time of convalescence is too long.

I have nothing to criticise as regards the effectualness of the operations now in use. They are all more or less curative. "The knife and ligature," "the clamp and cautery," "Whitehead's partial excision of the lower bowel," etc., etc., are all good in their proper place; but one and all have objections, and these objections are the cause of my placing before you, for your careful consideration, a new operation.

The clamp and cautery operation is undoubtedly very rapid in its execution. Not more than five to fifteen minutes is consumed in its performance, but after the slough separates it leaves a large granulating surface or surfaces which usually take from two to three weeks to cicatrize.

The incision and ligature operation (Allingham's method) is also rapidly done, but it takes six to ten days for the ligatures to separate, and about ten days longer before the wound is perfectly healed and the patient pronounced cured.

"Whitehead's" operation also has its objections, although it is an ideal one in certain cases. It is very bloody in its performance, and in quite a few instances it has been followed by anal stricture.

The operation I am about to describe is very simple, easy of performance, rapidly done, and is followed by a quick convalescence.

The patient is prepared as for all hemorrhoid operations. The bowels are thoroughly cleansed with frequent enemata and cathartics for from twenty-four to forty-eight hours before the time of operation. The perineum is shaved and rendered thoroughly aseptic. The patient is placed in the lithotomy position after being anæsthetized. The operative field is once more made surgically clean.

The instruments required are very few and simple: three or four artery clamps, scissors, scalpel, and small needles; either fine silk or catgut as suits the fancy of the operator.

The Operation.—Thoroughly stretch the sphincter and pass a plug of iodoform gauze into the bowel as a precautionary measure, as I have frequently seen much trouble and annoyance when this was neglected.

If there is a circle of hemorrhoids divide it into quarters and operate on one quarter or one hemorrhoid, as the case may be; seize the mass or hemorrhoid with a clamp, and while making traction make an elliptical incision encircling the mass, and carefully cut from the cutaneous surface inward and upward leaving the vessels the last part to be severed, and as soon as the vessels come into view grasp them with an artery clamp and separate the entire mass from its connections with the bowel. Now ligate the vessels and suture the mucous membrane and cutaneous wounds, as you would any other wound in which you sought primary healing. This completes the operation.

A few words in regard to the method of suturing I employ. If I have a normal bowel to deal with, I suture from side to side—that is, I suture so that the line of union shall be parallel with the bowel; when there is prolapse or a tendency to prolapse, or a very lax bowel, I also suture parallel with the bowel. In cases, however, in which there might be a tendency to stricture or in which the lower bowel is narrow, I suture at right angles to the bowel, so that my cicatrix will be parallel to the sphincter, and in some cases I should even advise that the anterior and posterior wounds be sutured parallel with the bowel, while the lateral wounds are sutured at right angles to the bowel.

In all cases the old rule of leaving mucous membrane between the masses removed must be adhered to, otherwise you have nothing to suture. After suture is completed withdraw the iodoform plug.

The claims which I make for this operation are:

I. The patient is well in from three to five days; there is no lengthy convalescence.

II. There is less pain during convalescence than follows any of the other operations.

III. By the fourth or fifth day the patient is able to attend to his business, which is a desideratum in these cases.

IV. The only difference in time of performing this operation and the clamp and cautery operation is the time consumed in suturing.

V. There is less danger of secondary hemorrhage in this operation than in Allingham's or the cautery operation.

[1] After this case was reported to the section on obstetrics and gynæcology of the Academy of Medicine, on November 25th, the proceedings of which appeared in the MEDICAL RECORD for December 10th, and after this article had been sent to the MEDICAL RECORD, I received a note from Dr. A. Jacobi, informing me that a case of aneurism of the uterine artery was recorded in the Wiener medizinische Wochenschrift, No. 37, 1891. I looked up the article and found that at the meeting of the physicians and naturalists of Poland, held in Cracow, on July 17 to [illegible]01, Prof. Anton Mars reported "a hitherto unknown and undescribed case of aneurism of the uterine artery" in a woman forty-four years of age; the tumor in the vagina was as large as a hazelnut, and the chief symptom and sensation were violent throbbing. He suggested the danger of rupture during a future confinement. Bylicki, of Lemberg, had seen a similar case, which burst during labor, and the patient died. He advised galvano-puncture rather than operation. Possibly it had been caused by compression by forceps. Braun, of Cracow, recommended ligature of the afferent vessel. While this case deprives my observation of its unique character, the aneurism in my case was not only three times as large, but also more dangerous in possessing thinner walls and being liable to burst at any time, irrespective of pregnancy and labor; and, finally, it was cured by two of the methods suggested—ligation and galvano-puncture.

[2] Read before the Metropolitan Medical Society, November 22, 1898.

I have now performed this operation seven times and have had more satisfaction than from any of the others.

The after-treatment and dressing do not materially differ from those we have been accustomed to in other cases. I insert an opium suppository and a tube wrapped about with iodoform gauze, and on the third day I give repeated small doses of sulphate of soda or magnesium until the bowels act.

In looking over the literature of this subject I find no mention of anything at all similar to this operation, although for the past ten years I have given the preference to that of Allingham, except in addition to what he recommends I sutured the entire wound save at the place of ligature. In this operation I also cover the site of the ligature.[2]

117 East Seventy-Ninth Street.

DIAGNOSIS AND TREATMENT OF SUPPURATIONS OF THE MIDDLE EAR.[1]

By MAX TOPLITZ, M.D.,

NEW YORK.

Exhaustive papers upon otological subjects are but rarely read before general medical societies. This is simply due to the slight interest of the general practitioner in this subject. Otology has always been considered as the stepchild of medicine. In this country it is an appendix of ophthalmology, with which it is but very loosely connected. It is not as yet admitted in Germany as subject of the state medical examination.

The extent of otology, it is true, was formerly quite limited, and the general opinion prevailed among physicians that the treatment of aural diseases was, on the whole, of little value, which holds good as well of extreme cases of deafness as of atrophies of the optic nerve. In this province, however, of late an extreme transformation has taken place. The knowledge of affections of the ear and their treatment has so progressed as to place otology on the same level with the other branches of medicine. If I, therefore, dare to read an otological paper, I do it with the firm belief that otology, althought a strict specialty, has preserved its intimate connection with general medicine, particularly in the province of suppuration of the middle ear.

The tympanic cavity is very small. It measures in its largest diameter sixteen millimetres, is thirteen millimetres long, and the distance of the drum membrane from the promontory is but two millimetres. Anteriorly it communicates directly with the Eustachian tube, posteriorly with the mastoid antrum. The Fallopian canal lies freely exposed at the inner wall. The cavity is divided into an upper space, the attic, and into a lower one, the tympanum proper. Shrapnell's membrane limits the attic outwardly.

Three pathological processes claim our interest in considering aural suppuration: Acute simple otitis media, acute perforative otitis media, and chronic suppurative otitis media. In the description of these affections I limit myself to the conditions important for diagnosis.

Otoscopy, in acute simple otitis media, offers the picture of inflammation of the membrana tympani, which is frequently bulged out by the pressure of secretion, particularly in the postero-superior quadrant. The subjective symptoms consist in pain, occurring in attacks increasing at night and extending into the neighboring parts. In many cases headache and toothache are the only complaints. Fever, increasing in the evening, is not unfrequent, and is in children in some instances so high as to be associated with vertigo, headaches, dulness, vomiting, deliria, and convulsions, occasionally with temporary facial paralysis and clonic convulsions. Violent cerebral symptoms have also been observed in infants. In some cases the temperature is but slightly increased, and there is also deafness in the diseased ear. In suspected cerebral disease or meningitis of children, otoscopy will frequently exclude these affections. Acute otitis media is often mistaken for dental convulsions. Infants during an attack of otitis media are extremely restless, particularly at night, cry incessantly, grasp the head, are feverish, and become emaciated.

Simple acute otitis media, if rationally treated, is usually perfectly cured or becomes perforative. The latter offers the same otoscopic picture as the simple acute form, enhanced by greater distinctness of serous imbibition and bulging in a yellow spot. Perforation takes place through a small opening, but in infectious diseases frequently from the onset through a large hole. The secretions are seen at the bottom of the external auditory meatus, more or less profuse, of serous, sanguinolent, purulent, or muco-purulent character.

The symptoms are the same as in the acute simple form, more violent however, with temperature above 40° C., frequently beginning with chills, occasionally associated with the severest cerebral symptoms, which may entirely disappear after the establishment of perforation. The acute perforative form cannot be distinguished before perforation from the acute suppurative form.

Chronic purulent otitis media develops from the acute perforative form in scrofulous, tuberculous, syphilitic, diabetic, and cachetic individuals; in scarlet fever, diphtheria, typhoid fever, and after severe puerperia; in chronic affections of the nasal mucous membrane, in complications with otitis externa and mastoiditis, in persistent granulations and caries, and finally through irrational treatment.

The external auditory meatus and the tympanic cavity contain secretions mixed with blood if granulations are present. The offensive odor of the pus is due to saprophytes. Sparse secretions frequently dry up as crusts, which cover the pus, promote the proliferation of granulations, and occlude small perforations. The membrana tympani, apart from perforations in the pars tensa, presents in some instances those of Shrapnell's membrane, behind which secretions stagnate in the attic, attacking the ossicles, the lateral wall of the tympanic cavity, and the mastoid antrum. The stagnating pus is creamy, viscid, offensive, and fills occasionally the attic and mastoid portion with cholesteatomatous masses and granulations. The changes of the membrana tympani, manubrium mallei, and mucous membrane of the tympanum are manifold. The acuteness of hearing is more or less decreased. In chronic suppurations pain exists in affections of the mastoid portions, in retention of pus, in caries of the middle ear, and exacerbating inflammations. Facial paralysis renders the diagnosis of caries almost a certainty, which is still further substantiated by vertigo and vomiting. Chronic suppurative otitis media is entirely cured under favorable conditions of the patient's constitution, and with rational treatment by the formation of a cicatrix of the membrana tympani, and in persistent perforations by epidermisation of the tympanic mucous membrane. On the other hand, the suppuration may last throughout life, or, more frequently, lead to death by the development of meningitis, brain abscess, sinus phlebitis, pyæmia, and sep-

[1] Since writing the above I have ascertained that Dr. J. Coplin Stinson, of San Francisco, has reported an operation in many respects similar to the above. We both seem to arrive at the same conclusion, that excision and suture is the best method; but my mode of excision and suture is not exactly like his.

[2] A paper read on May 2, 1898, before the German Medical Society of New York.

ticæmia; rarely by erosion of the carotis interna, sinus transversus, and bulbus venæ jugularis. Exacerbations of chronic suppurations constitute a greater danger. The sequelæ often occur quite suddenly, and more frequently in chronic than in acute suppurations. Every suppuration, no matter how small, is a menace, and perforation of Shrapnell's membrane is severer owing to the difficulties of treatment and to cholesteatoma resulting therefrom.

The treatment of aural suppurations comprises the acute and chronic otorrhœa.

The *general* treatment consists in the prevention of injuries to the ear and head respectively. Congestions of the head due to faulty ventilation, overfilling of the stomach, use of alcohol, constipation, etc., should be avoided. Absolute rest is to be strictly enforced. The diet should be fluid. As long as absorption of the secretions is expected, abstraction of blood with Heurteloup's instrument or leeches applied to the tragus or mastoid are adequate measures. Before the spontaneous or artificial evacuation of the pus, instillation of water, as hot as it can be borne, or introduction of vapors should be ordered against the pain. Opium and cocaine are locally of little value. Cold solutions should never be used in the ear. Ice applications around the auricle are very efficient. If ice cannot be borne, hot poultices should be substituted (not to be placed upon the auricle). The pain is principally caused by the extreme tension of the pus inclosed by the membrana tympani and bony walls. The incision, relieving the tension, often removes the pain instantly. The paracentesis should be aseptic and as deep and long as possible. Any small-bellied scalpel can be used. The opening made by a slender blade is too small, since the entire cutting edge cannot fully act. The lancet-shaped knives formerly in use should be rejected. The knife used by myself differs from others in its minute point and its extremely curved edge. One incision into the postero-inferior quadrant of the membrana tympani usually suffices. Beginners, puzzled by the shortening of the shaft of the knife in the perspective, either do not reach the membrane or cut too far beyond it. In suppurations of the attic, Shrapnell's membrane and the posterior fold ought to be severed. Dench devised the formation of a flap. Neither before nor immediately after the perforation should air be driven through the catheter or Politzer bag into the middle ear, since micro-organisms are thus introduced into the ear, and secretions forced through the aditus and antrum into the mastoid or through defects in the tegmen tympani into the middle cerebral fossa. After perforation, catarrhal secretions should not become purulent, and aerial inflations are also to be avoided. It suffices to introduce in these cases, and in ruptures of the membrana tympani, aseptic plugs to the drum membrane, which are to be changed as soon as they are saturated. In purulent discharge, above all, proper drainage ought to be established. If the perforation is too small or closes, it should be enlarged or reopened. Permanent openings are produced by the galvano-cautery. In well-drained cases with moderate discharge, dressing with sterilized gauze in the external meatus and absorbent cotton above it, attached with roller bandage, the patient lying upon the affected ear, is of advantage. The dressing is changed every twelve hours. This treatment can be carried out only in hospitals and private practice. Syringing of the ear is generally practised in Europe and in this country. It should be carefully and exactly executed, and cannot be spared at all in profuse discharges. Only piston syringes should be used. The syringes of American make are not so good as the English ones, since the pistons, not fitting hermetically, advance by jerks, and thus drive a good deal of air into the ear. Fountain, soft balloon, alpha syringes, etc., are to be rejected, principally on account of their frequent dirty conditions due to their applications to other purposes and of their uneven and sudden action. Forced syringing produces vertiginous attacks. The air should be removed before syringing, by turning the syringe. The temperature of the water ought not to exceed 104–108° F., and generally blood temperature suffices. Sterilized water is best suited for syringing. The lowest capacity of the syringes should be two ounces. One or two syringefuls suffice for each application. Boric acid (1:30), carbolic acid (1–2:100), and sublimate (1:6,000–8,000) may be used. After syringing the auditory meatus is dried by the aid of the mirror with sterilized cotton and closed with sterilized gauze. Irrigations are made according to the amount of discharge, viz., every first, second, or third hour, according to the saturation of the gauze.

Ten to twelve years ago astringents were frequently used in acute suppurations, viz., zinc sulphate, zinc sulpho-carbolate, alum, tannic acid, etc. Such remedies are to be absolutely avoided. For the introduction of boric acid into otological therapeutics, Bezold deserves credit. Powder treatment cannot be dispensed with in many cases. Dangers, it is true, may arise from its careless application, which caused the Schwartze school to object to it. For, if the powder is blown upon a small perforation, the pus may be readily retained. Packing the meatus completely with boric-acid powder, as it was formerly practised, is irrational; owing to the insolubility of the powder in the discharges it is rendered lumpy and stony, and thereby injurious. The powder treatment as a rule should never be left to the patient.

Boric acid, with or without iodoform and aristol, after cleansing the meatus, applied by means of Urbantschitsch's powder-blower in a fine layer, has a good effect. For the first days of suppuration during the extremely acute stage this treatment is not suitable.

In chronic suppurations, irrigations and insufflations cannot be dispensed with. Irrigations must be warm, since the middle ear cannot bear cold temperatures. Bathing, particularly surf bathing, should be strictly prohibited.

Irrigations several times a day, strictly carried out, frequently cure even the most persistent suppuration. Irrigations through the Eustachian tube by means of the nasal catheter as devised by Politzer are rarely used in this country. I am almost convinced of their injurious influence, since the entrance into the mastoid cavity lies in a continuous line with the Eustachian tube, and injected solutions directly enter it, together with the bacteria of the naso-pharynx.

In Gruber's method, which is of the same character, both ears are simultaneously irrigated by syringing through the nose while the cheeks are blown out. Irrigation with Hartmann's tympanic cannula directly introduced into the tympanum and connected by a soft-rubber tube with the syringe is much more rational.

Alderton, who recently proposed to bend the end of this cannula at such an angle as to introduce it through the perforation directly into the mastoid antrum, goes decidedly too far. Gruening's method of removing secretions from the middle ear by hermetically closing the external meatus with an attachment connected by means of a rubber tube with the syringe, and then withdrawing the piston of the syringe, is of great advantage in cases with tenacious discharge.

In the treatment with drugs, alcohol, as recommended by Politzer, takes the lead. This treatment was also objected to by Schwartze and his followers. However, in selected cases, particularly those associated with swelling of the mucous membrane, it is of great advantage if used with care. It is proper to begin with instillation of a saturated solution of boric acid in twenty-five per cent. alcohol, and gradually increase,

if well borne, to sixty-six and two-thirds per cent., and even absolute alcohol.

Peroxide of hydrogen is frequently used in this country; when instilled into suppurating ears, it forms bubbles by generating oxygen. The gas creeps into the tympanic cavity and its deepest recesses, whereby they are thoroughly cleaned. The disadvantages are, that deposits of detritus remain, which have to be removed by irrigation; furthermore, that the original solution, which ought to contain sixteen volumes by percentage, cannot be borne, and, therefore, has to be diluted and warmed; finally, that when the bottle is repeatedly opened some of the gas escapes and the expected effect is not realized.

If despite all these remedies the suppuration persists, pathological conditions not reached thereby are at fault and operative procedures are in order. Small granulations are to be cauterized with chromic acid in substance, fused in pearls to a caustic holder, the excess being neutralized by saturated solutions of chloride of sodium. Large granulations and polypi are removed, after due cocainization, with the cold snare, Urbantschitsch's forceps, and, above all, with the sharp spoon and ring knife, which I prefer.

The removal of adenoid vegetations from the nasopharynx, of enlarged tonsils, and of nasal obstructions and swellings, in conjunction with aural treatment is of the greatest importance.

If with these interferences the suppuration does not cease, it should be ascertained, if possible before the beginning of the treatment, to what extent the middle ear is affected. The suppuration often attacks the ossicles, of which the incus more frequently presents isolated caries than the malleus. Mallear caries is diagnosed by the presence of a tiny fistulous opening above the short process. Isolated incudal caries is recognized by fistulæ behind the short process, granulations in the postero-superior portion of the drum-membrane, and by perforations reaching upward above Shrapnell's membrane and forward to the handle of the malleus. If isolated caries of ossicles is ascertained, their removal is indicated.

It is doubtful whether, when the affection is limited to the middle ear, the ossicles should also be removed. For ossiculectomy, at any rate, is the "less interfering and more sparing procedure and offers under all circumstances the advantage of decreasing thereby the dangers of retention of pus in the attic, though it does not always lead to recovery." Ossiculectomy is by no means an easy operation, since the field of operation is obscured by continuous hemorrhage, and the upper wall of the meatus occludes the attic inferiorly in such a way as to permit the removal of the ossicles by tactile sensation alone. Injuries of the facial, jugular, and carotid are not out of the range of possibility. My own ossiculectomies have all been successful. I never promise improvement of the hearing, since I have observed even impairment of hearing after the operation, owing to ankylosis of the stapes, and advise the operation only for suppression of suppuration. If this aim is not reached by ossiculectomy, or there is good ground for the belief that deeper processes, such as cholesteatoma or mastoid caries, are present, the radical operation is indicated.

During a score of years and longer the aurists had been desirous of removing persistent suppurations by operations from without. The mastoid process was opened, as in operations for acute mastoid empyema, and irrigations through its antrum were believed to accomplish this end, as it were, through a *vis a tergo*. These attempts, however, were not successful. Küster, a general surgeon, in 1889, published a whole series of operations on the mastoid process, in which the bone was extensively and deeply opened by removal of the outer plate up to the upper wall of the external meatus, and the removal of the posterior wall of the meatus was also recommended. He condemned the former methods as non-surgical. In cavities with bony walls empyemata should be opened early, the incision to be at the lowest place, and irrigations limited to the smallest extent. Küster's operation, it is true, is surgical, but not otological, since injuries of the facial nerve and of the semicircular canals are much more frequent in his operation, and the function of the ear is entirely left out of the consideration. His operation at any rate marks a decided progress and incited at once to bold procedures. Zaufal was the first aurist to follow in his footsteps. He operated more cautiously than Küster, by trying to preserve as much as possible. He formed a triangular flap extending from the apex of the mastoid process to the anterior margin of the auricle, detached the periosteum and the posterior wall of the meatus, removed as much bone as possible with Luer's forceps, and attached the flap by stitches. Stacke goes still further, by detaching the auricle, as in former operations for the removal of foreign bodies from the middle ear, partially shelling out the membranous external meatus, chiselling off the upper wall of the meatus, opening, if necessary, the mastoid antrum and process, removing the bone between the two cavities, and transplanting the membranous lining of the meatus into this opening. The only essential modification of Stacke's operation, as suggested by other surgeons, consists in beginning every radical operation from the mastoid antrum. Other not very essential modifications consist in the variability of flap formation for transplantation. All cases in which I operated according to this method are cured. Among these cases are two of tuberculosis of the mastoid process, one case in which the dura mater was exposed, one case with facial paralysis, which had entirely disappeared after ten weeks. The suppuration had lasted in one case thirty-five, in another twenty-five, and in two others fifteen years.

I use the sharp spoon, after the opening, as little as possible, owing to the frequency of injuries caused thereby. Furthermore, I remove the posterior wall of the meatus but superficially, in order to avoid injuries to the facial nerve, and chisel as close as possible to the upper wall, whereby a sufficiently large communication between the mastoid antrum and the tympanic cavity is established.

With the aid of all these methods, we now succeed under favorable conditions, if the process remains local and the general conditions are satisfactory, in curing every aural suppuration and thus eliminate a danger from the organism which may destroy it at any time.

Accordingly, you will agree that the assertion made in the beginning of this discourse holds true, namely, that otology has attained a well-esteemed position in medicine, principally owing to the successful treatment of suppurations of the middle ear.

123 East Sixty-Second Street.

Thrush in the Bladder.—Pneumaturia was discovered in an anæmic woman sixty-four years old, by Dr. V. Frisch (*Wiener klinische Wochenschrift*, No. 39, 1898), and the urine, which contained sugar and albumin, showed a number of white granular bodies, some of which floated to the surface with the gas bubbles. By means of a cystoscope the bladder wall was seen to have attached to it a number of similar bodies. The microscope showed mycelial threads, which on cultivation proved to be the same as those found in thrush. A cure was effected in a month's time by washing with silver solution (1 : 1,000). This would seem to be the first recorded instance of thrush fungus being located within the bladder.

A PRACTICAL VIEW OF ANTITOXIN AND DIPHTHERIA IN PRIVATE PRACTICE.

By ADOLPH RUPP, M.D.,

FORMERLY AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

ANTITOXIN is the name given to a laboratory product, the essential nature of which is pathological. Its measurements of therapeutical values or units are of an arbitrary character, uncertain, and unequal. These units of therapeutical valuation are not exact, but approximate biological appreciations, translated from zoological probabilities into anthropomorphic possibilities. And the unit of value is as variable as the element of individual resistance at both ends of the animal scale where the tests apply. There can be no absolute or fixed standard of measurement. It is a question of more or less. Its chemical composition is unknown, and its physiological action is yet to be determined. We know that it is a poison from its effects on the animal economy. Many experimenters and clinicians claim that it inhibits, counteracts, or neutralizes the action of the poison of diphtheria which develops in the animal and human body. Antitoxin is a word that scientists may well claim as their own. It had its birth in the laboratory. Diphtheria, however, is a word that is not the sole property of scientists. Clinicians have used the word diphtheria in an empirical sort of way for years and years, to designate a condition characterized by more or less constitutional disturbance and an inflamed sore throat, accompanied at the same time by depositions of pseudo-membrane. "No membrane, no diphtheria," was the keynote.

In 1861 Alonzo Clark wrote: "There is some vagueness in the use of the term diphtheria. . . . While diphtheria prevails, it is usual to have at the same time a sore throat prevailing epidemically, which has but little tendency to the production of membrane. And as these two forms of disease are apt to go together, physicians have been somewhat in the habit of grouping them under one head and considering them both diphtheria." The habit, it should not be forgotten, was not general; it was only somewhat so, not generally so. Not only Clark, but many physicians besides, thought it necessary to separate these synchronous affections, because "the form of sore throat which is not attended by the production of membrane is a mild disease, and is almost never fatal."[1] "The very term diphtheria," he continued, "implies the existence of a false membrane; and we must limit the signification of the word to such inflammations as terminate in or have in their course this membrane as a sign." Clark goes on to say, "To make this membrane the basis of classification may not be scientific, but it is practical. And," he said correctly, "science requires us to make distinctions where there are differences. And here [between the benign sore throat and the diphtheria, as defined] we have the broad difference that one disease is ephemeral, with a tendency to recovery; and the other is often [not uniformly so] terribly fatal, and is liable to a long train of symptoms of a serious if not of an alarming character."

Clinically and historically we have a true diphtheria varying much in severity as individual cases come and go; and clinically and historically a false or pseudo-diphtheria, which is a mild disease and very rarely fatal. These terms in their historical and clinical senses are unlike the same terms used by scientific physicians and bacteriologists of our day—the terms in their historical meanings stand for different things, and are conceived of in different ways. And yet in our day the terms and their meanings are very often confounded, and discussions consequently often result in confusion, and fallacies and misunderstandings are disseminated.

[1] American Medical Times, March 23, 1861, p. 187.

Scientists have given us the facts of the Klebs-Loeffler bacilli and other cocci to think of, and these low forms of life have dislocated our ideas of diphtheria, true and false. But scientists are not a unit as to the significance of the Klebs-Loeffler bacilli for diphtheria and its relationships to the other bacteria which are granted an active participation in the local processes of this clinical disease. Concerning their diagnosis of this disease as defined by themselves, scientists do not base their diagnosis on the number of Klebs-Loeffler bacilli that may be present, absolutely or comparatively, over against the number of other cocci and bacilli that may be present in clinically true or false diphtheria. The mere presence of the Klebs-Loeffler bacilli demonstrably qualifies their diagnosis. Incongruities of quantitative facts are readily explained away by such terms as mixed infections. When an apparently bad case of clinical diphtheria is met with and no Klebs-Loeffler bacilli are detected, we are assured that the case is false diphtheria. And if a case of clinical diphtheria develops a membrane that persists longer than one or two or three weeks, even though antitoxin has been given *lege artis*, and even though the Klebs-Loeffler bacilli are detected, the scientific diagnostician tells us that the case is one of mixed infection, and that the persistence of the membrane is due to various cocci and other bacteria than the Klebs-Loeffler form. To the scientist neither of these forms is true diphtheria.

We are assured by the scientific physician that "false diphtheria is a very dangerous disease, though its mortality is not as high as that due to the Klebs-Loeffler bacillus."[1] This is given us as a bare assertion. We must accept it on faith and as a scientific definition. Notice the difference and the distinction made by practical physicians, as voiced by Clark about thirty-five years ago. It is a new revelation! Bacteria are ubiquitous. If we are to accept as fact the reports of all bacteriologists collectively that we can find time to read, we shall be obliged to conclude that no single kind of bacilli or cocci is found alone doing mischief. And if we accept the teachings of any one particular bacteriologist as telling the truth, the whole truth, and nothing but the truth, we shall find it easy enough to be logical, but we shall find ourselves differing much from the conclusions arrived at by others who pin their faith to the finds and teachings of some other one particular bacteriologist. For instance, Baumgarten claimed that streptococci are the true primary cause of diphtheria, they being always present in cases of clinical true diphtheria; and that the Klebs-Loeffler bacilli are only of secondary or accidental importance in this disease, because they are not invariably present. Baumgarten is no novice. He strengthened his contention by saying that streptococci are not found in healthy mouths and throats, but that Klebs-Loeffler bacilli are. And now comes Dr. Paul Hilbert, who tells us that although everybody must admit that Baumgarten is one of Germany's most eminent pathologists, yet he is wrong in what he has seen and in his contentions. Hilbert was successful in finding, in all cases examined by him, the specially reputed pathogenetic long streptococci in the crypts of tonsils of healthy people.[2] Streptococci are very convenient things to deal with. Nothing so obliging! They explain rheumatism for some scientists. In the estimation of others they generate acute suppurative tonsillitis, and skip away quickly for the benefit of the patient when staphylococci make up to push them out of sight.

[1] "The Modern Treatment of Diphtheria, etc.," by Aug. Caillé. Reprint from the Post-Graduate, October, 1897, p. 3.

[2] "Die Rolle der Streptocokken bei der Diphtherie." Dr. Paul Hilbert, Verhandlungen des Congresses für innere Medicin, Sixteenth Congress, 1898.

When suppuration of any kind or anywhere takes place, then they are there, active, obstreperous busybodies, to help the scientific logician. It is not at once easy to see how Caillé or any clinician can be sure that streptococcic diphtheria (or, rather, his and others' non-Klebs-Loeffler bacillary or false diphtheria) is less frequent in occurrence than Klebs-Loeffler diphtheria. Hilbert affirms that streptococci are usually around, and, if not immediately so, they are always close at the heels of Klebs-Loeffler bacilli in cases of scientific diphtheria anyhow.

Some things in this connection that a New York physician can be sure of, thanks to health-board bacteriologists, are:

1. Some, not by any means many, of his cases that run a course of true clinical diphtheria from start to finish are false diphtheria in the scientific sense, despite the presence of the pseudo-membrane.

2. Some of his cases, only occurring now and then at longer or shorter intervals, develop or show up the presence of the Klebs-Loeffler bacillus when all active local processes have become clinically a thing of the past.

3. In the great majority of his cases of clinically true diphtheria the Klebs-Loeffler bacillus is found. The health board gives only qualitative information. Other information than the Klebs-Loeffler presence is not furnished the practitioner, except when the Klebs-Loeffler bacillus is not found. Now if Hilbert is right in his contention, and Baumgarten in his, all these cases of true clinical diphtheria are cases of mixed infection—streptococcic, etc., and Klebs-Loeffler bacilli. Baumgarten's testimony in a large measure neutralizes Hilbert's. But it may be interesting to state here that one of the lessons that Hilbert tries to enforce is this: Streptococci alone are not so bad, but when Klebs-Loeffler bacilli fall in with them, why then a bitter fight ensues, which can be checked by the early administration of antitoxin. After Klebs-Loeffler bacilli and streptococci have been damning and damaging the patient for a longer or shorter while, they create such havoc that antitoxin given late can do no good. Antitoxin early administered paralyzes the Klebs-Loeffler bacillus, and then streptococci give up the fight. They don't seem to be enamoured of a fight single-handed, as it were. Hilbert thus introduces a new element into the antitoxin controversy without clearing up the befogged questions.

The reader will please excuse the Hilbertian digression. New York physicians know from experience that few clinically true diphtherias are not also true scientific diphtherias. And according to my experience and practice, and according to the practice of many of the New York physicians known to me, very, very few cases of clinically false diphtherias are reported to the health board. The presence of a pseudo-membrane in the throat that is sore determines almost invariably the report of diphtheria to the health board. And this is so because the practitioner thinks clinically, and is obliged to do so, no matter how well informed he may be concerning science and statistics this way and that way.

From a clinical standpoint I have collected notes from over one hundred practitioners in and outside of this city on antitoxin and its value as a remedy in the treatment of diphtheria. My correspondents and acquaintances, like those who have written and parleyed on this subject, can be divided into three classes:

1. Those who positively affirm superlative results.

2. Those who are doubtful and undecided, but who use antitoxin.

3. Those who are sceptical and condemn its use theoretically, if not always practically.

1. Six physicians in a hundred with whom I have compared notes, one of them a homœopath, have not used antitoxin. These men may be prejudiced, but they are not cowards—they have the courage of their opinions. And in most of the practical concerns of life they prove to be as wise and able as the enthusiasts or doubters. All of them have seen antitoxin used, and observed the cases afterward. One of them affirms that in a case that he had treated the Klebs-Loeffler bacillus was not discovered until after antitoxin had been injected, and then the pseudo-membrane that had been undergoing dissolution became actively formative and spread. My homœopathic friend is sure that in a case of his which he refused to treat with antitoxin, but in which another physician administered the remedy on the third day of the disease—this patient died a few days afterward of "suppression of urine." And prior to the administration of antitoxin, he claims there were no evidences that the child would die of such a complication. Another of these sceptics says that a patient, in which he had no power to prevent antitoxin from being used, died soon after of endocarditis.

2. My friends who doubt and are not sure one way or the other are as numerous, almost, as the enthusiasts. Statistical tables influence them only very little. One of these physicians, who had used this remedy faithfully in every case that came into his hands, summarized his view thus: "Either the whole theory is false, or else the best antitoxin we can get is worthless." This man is no fool. Neither is he in a hurry to reach conclusions. His perceptions are quick, and he is a good diagnostician. Another of this class says he uses antitoxin when he may, and that he had seen patients die in which antitoxin was used, as though so much water had been injected. He, however, believes that antitoxin acts on the heart in an unpleasant way, accelerates the pulse, and increases the temperature for a time. In some cases he thought antitoxin acted decidedly like a poison. He had one case of "fatal syncope and convulsions" follow a few hours after antitoxin had been injected. He gives antitoxin because public opinion obliges him to be up-to-date and scientific. On the whole, none of these men can see that antitoxin does any good in those cases where they would most wish to get beneficial effects. They have seen croup develop under its use. So far as their own experience goes, they are not able to see that other complications are rarer than before they used antitoxin.

3. If the enthusiasm of a good many honest men could settle the high reputation of any therapeutical remedy, then there would long since have ceased to be any question concerning the superlative value of antitoxin for diphtheria. My enthusiastic friends are enthusiasts! One of these friends wrote to me: "The evidence is so overwhelmingly in favor of antitoxin, and the advantages of the treatment are so well known and so frankly acknowledged, that any one who should attempt to write it down would stultify himself, unless he could produce evidence not yet known to literature and subversive of what we know, which is rather impossible." Such talk is typical. One hears the like rather often in New York. This distant friend had a syncopal case—made so, he admits, by a dose of antitoxin—which he came near losing. He also had an adult case of diphtheria in which the membrane persisted in the throat for weeks, although repeated doses of antitoxin had been given. Klebs-Loeffler bacilli were present in this case, but he says they were few and that the persistence of the membrane must have been due to streptococci. Streptococci act as an apology for the inefficiency of antitoxin under other circumstances and varying instances of mixed infection.

Another friend and enthusiast, practising in a Western country town, had used antitoxin for over one year when it first came out. Thinking that his results were no better than before, he gave up using it. Then his

losses of croup cases disheartened him, and he again used antitoxin. He now became more hopeful. He thought he was preventing croup, and that cases of croup that came his way were being saved, as was not the case before. But by the end of the year he was not satisfied with the totality of successes recorded, and he this time concluded that the antitoxin was not so good as it ought to have been. He wrote to the makers of the antitoxin that he had been using, giving them his views and experience. The firm replied, suggesting that his cases may have become worse, etc., and that their antitoxin was as good as could be obtained. He now tried another make. Again he was jubilant over his results. But strange are the workings of facts and fate! This last make, that was filling his heart with joy and thanksgiving, was doing worse in a distant city hospital than the antitoxin he had discarded. To this friend antitoxin is the greatest discovery of the century. He has not found it necessary to tracheotomize or intubate any of his croup cases since he has changed the make of antitoxin—that is, when used early enough, which in his experience is not the third, but the fifth day of the disease (diphtheria). It is not an uncommon thing for this class of men to excuse their lack of success with the plea that this or that brand or make of antitoxin was or is below the standard. One of my enthusiastic friends told me that in his experience any make or brand of antitoxin becomes less and less efficient after the fourth week of its making. It is not like good wine!

Another enthusiastic acquaintance, who has a large general practice and who holds both a homœopathic and a regular diploma, claims to have had cases of all sorts of diphtheria which he treated with antitoxin, and in upward of eighty of them with success; there were no deaths. And these successes he claims resulted from doses varying from six hundred to one thousand units. Sometimes he had given larger doses. But he only rarely found it necessary to repeat the dose. Soon after this communication he had several deaths in rapid succession. On these I have had no comment from him.

Another of my enthusiastic friends, commenting to me on his fatal cases that had been treated with antitoxin, gave me to understand that they died, not of diphtheria, but of incidental complications—pneumonia, Schluck-pneumonia, and nervous troubles; never of croup *per se*.

So much from my friends: and now for my own personal experiences.

I have treated twenty-four of my diphtheria cases with antitoxin, and, I have the good fortune to be able and say, without a death or any very serious casualty resulting. Of course, other remedies and medicines formed part of the general treatment of these cases. The ages of these patients ranged between the second to the eighth year of life. I have given as large a single dose as twenty-five hundred units, and as small a one as six hundred units. No sign of any particularly marked character made itself evident to signify the difference of dosage in the different cases. Opinion, among my antitoxin acquaintances, differs as to the size or quantity of serum dosage necessary to obtain desirable and striking results. Some gave six hundred units and were satisfied. Others have been advancing the dose quantities, thus keeping abreast of advancing scientific recommendations. When smaller doses were given, the results were as favorable as they are now, in so far as can be gathered from their reports. These men have followed the recommendations of authorities and literature.

In most of my cases one injection of one thousand units was given on two successive days. In several, two injections were given on the same day. In a half-dozen cases one injection was given on three successive days; and in several others one injection on four successive days. In none of my cases were the immediate or after results such as to impress on my senses any of the reported magnificent effects vaunted by Baginsky and other enthusiasts.

Of these twenty-four cases, one, a boy, four years old, had to be tracheotomized; another, a girl of five, was intubated; and another, a girl of six, was also intubated. The tracheotomized boy was croupous when first seen, and was reported to have been sick only a few days. Fifteen hundred units of the health-board antitoxin was immediately injected, and six hours later another one thousand units. There was membrane in the nose and pharynx, not abundant; and the boy had a temperature of only 102° F., and was not very bad otherwise. But in spite of the antitoxin the croup progressed, and, intubation failing to give relief, he was tracheotomized, the membrane having extended into the trachea; the canula was removed eight days after operation. The membrane in the pharynx disappeared slowly and was gone five days after the operation had been done. This boy also received about eight hundred units the day after the operation. The relief obtained by tracheotomizing was marked and evident; but not so were the antitoxin effects.

The six-year-old girl when first seen was but slightly croupal, and was reported to have been sick but a day. I thought her illness of longer duration. I offered to administer antitoxin. The parents would not consent. Next morning she seemed better. The deposits on the tonsils had become less, but a thin streak of membrane was seen stretching downward behind the posterior pillar of the fauces on the left side. Again—the fifth day of illness according to my view—the antitoxin was spoken of. The parents now consented to have this new remedy given. Accordingly twelve hundred units was administered in the afternoon. No change had taken place, except that the membrane on the tonsils seemed less, but that behind the faucial pillar had enlarged. Next morning—the sixth of the disease—the child was much more croupous, somewhat cyanotic, but not markedly so; the temperature had gone up from 100° to 102° F., and I had to speak of the possibilities of an operation—intubation. The father of the child then turned on me and said: "The child was much better before antitoxin was given." We parleyed much, and operation was finally consented to. Operation became necessary on the evening of this, the sixth day of the disease. At my 10 P.M. call I noticed a hissing sound now and then when the child cried. I inferred that this sound was caused by air pressing up along the outside of the tube, and I put the child's watchers on guard. I told them the tube might be coughed up. At the time the tube seemed effective and firmly in place. At 1 A.M. of the seventh day of illness I was called, and found that the tube had been coughed up. When I saw the child she was sleeping calmly. Her respiration was hissing, occasionally, but not obstructed; nor was there marked cyanosis. I let her alone, but watched her for several hours, and then went home. This girl developed an irregular and intermittent pulse. She finally recovered, but with a slight paralysis of the palate, which lasted several weeks.

The other five-year-old girl had one thousand units injected on the afternoon of the first day's attendance. She had bronchitis. It was reported that no membrane was present in the morning. In the evening when I saw her her temperature was 103° F., and there were thin deposits on the tonsils. I gave her another injection—a little more than twelve hundred units—and then she was intubated next morning. At a later visit she was given one thousand units more of antitoxin. The membrane disappeared for the most part

on the third day after intubation. This child could gargle. But here and there little flecks of membrane persisted for two days longer. Thus in this case membrane persisted in the throat for five days after it was first noticed. The tube was removed on the seventh day after emplacement. This child had an intercurrent catarrhal pneumonia. Here, too, the heart condition that developed after the injection of antitoxin necessitated strychnine injections and alcoholic stimulation.

In none of these cases did antitoxin seem to have any inhibitory influence on the progressive croupal process; and in the three cases the membranous deposition was rapid, and in none of them did the antitoxin have any effect apparently in checking it or rendering its disappearance more rapid than ordinarily when antitoxin is not given. Indeed, in the one case the father of the child thought her condition became aggravated after antitoxin was given.

In none of the twenty-four cases could any beneficial influence on the membrane be observed, in such a way as to be beyond doubt. In all of them the temperature was sent up a degree or two; the pulse was accelerated, and in some cases became irregular. In some cases the patient became exhilarated or irritable, in most cases depressed, and in others there followed no general phenomena. Several cases developed a slight diarrhœa after the injections had been given. A few complained of vague joint pains. Only one boy, three years of age, developed red, painful, and swollen knee- and elbow-joints, which lasted less than a week, and which followed the injection of the antitoxin. In this case, simultaneously with the joint affection, a papular eruption appeared over the body generally, but particularly abundant on the legs, where it finally became purulent and crusty. This eruption was preceded and accompanied by an annoying pruritus. This boy finally recovered, and without the development of any paretic condition anywhere. There was no marked albuminuria in any of the cases, either before or after the injection of antitoxin. In some cases it was thought to have become increased after the injection, but of this I am not sure. In many of the cases the amount of urine became increased after the injection. None of these patients was rendered sickly and ailing for any great length of time after antitoxin had been injected.

Although none of these patients died, no conclusion in my opinion bespeaking the beneficent powers of antitoxin is justifiable. Patients treated without antitoxin did just as well and were not afflicted with the minor inconveniences that may be attributed to antitoxin.

Conclusions.—1. Whatever thousands of antitoxin-ated cases of diphtheria may seem to prove to hundreds of other physicians, my twenty-four cases teach me clearly enough that the remedy has no well-marked favorable effect on the general or clinical course of the disease—it neither shortens nor lessens its severity.

2. In the croupous cases it exerted no beneficial or inhibitory influence on the progress of the croup. The operations in these cases, and not the antitoxin, saved the children.

3. In none of my twenty-four cases, nor in those seen in the practice of some of my acquaintances, did the antitoxin seem (beyond a reasonable doubt) to cause the pseudo-membranes in the throat to disappear sooner than would have been the case had no antitoxin been given.

4. In all of my cases the initial dose of antitoxin was given not earlier than the third day, and not later than the fourth day. None of the cases was markedly "septic" or "mixed," nor were they severe cases in any sense.

Consequently, in view of the above conclusions, which are based on practice and not on speculation, and what has just been said of the time of injection and the character of the cases—consequently, I say, antitoxin is not a specific in the treatment of diphtheria.

One more word in conclusion. Drs. Biggs and Guerard, in their very lengthy summary of "Antitoxin Serum in the Treatment of Diphtheria," [1] quoted with apparent unction and much applause the following rhymes:

> "The best critics in the world are they
> Who along with that which they gainsay
> Suggest another and a better way."

The sense of the rhymes, and the unctuous applause the gentlemen quoted allow them, are based on a misapprehension of what practical criticism should be. All through life we are critics, and not from choice. Criticism is judgment forced into action. As practitioners we are obliged to be critics for the benefit of our clients. And as practitioners we cease to be academic disputants, and always are judges and executors, and often expositors as well! It was not a poet in the sense of a rhymester, nor a great philosopher in the sense of a drawing-room hero, who said: "Be sure you are right, then go ahead." In this antitoxin business we practitioners have not been granted the privilege of thinking that we are right. We were treated as though we could not think and need not think. We had to accept what scientists and the public clamor they set in motion forced into our hands. We were more or less regimented: forced to do, and not to question why! And that, too, by men who it now seems really did not know, but only imagined or thought they knew.

In a subsequent essay I shall try to prove by means of statistics, constructed by others, all that my own experience has taught me and all that the above conclusions imply.

406 West Thirty-Fourth Street.

Clinical Department.

WAS IT A CASE OF PHLEGMONOUS GASTRITIS?

By VIDA Z. BAERECKE, M.D.,

DE LAND, FLA.

The patient was Mary L——, aged fifteen and one-half years, a bright pupil of the public high school, born in Wisconsin of Swedish parentage but for the last five years living in Florida. She came under my care on June 24, 1898, for chronic pharyngitis. She complained of not having felt well for some time. On examination I found that her appetite and digestion were good; the bowels were somewhat irregular; she slept well; had no headache or dizziness; menstruation, which began a year ago, had been regular for the last three times, and without pain. The girl appeared stout for her age and well proportioned; the expression of the face was fairly healthy; the heart was normal; the left lung was sound; over the middle of the right lung was a dull and tender spot, where the patient felt soreness after running or after taking cold. She had no cough, no expectoration, no night sweats, no elevation of temperature, no family history of tuberculosis; the urine was normal. The feeling of malaise might be accounted for by the continuous hot weather at this time of the year.

On June 29th the girl reported that the constipation had been readily corrected. She still felt tired and weak, but the use of Blaud's pills, three grains, combined with arsenious acid, one-sixtieth of a grain, three times a day, made her feel somewhat better.

On July 13th, at 3 A.M., she had a severe attack of

[1] The Medical News, December, 1896.

pain in the stomach and abdomen, not localized and not extending to the back; the tongue was slightly coated. The patient vomited, an hour before I saw her, the remnants of the supper taken a few hours before. I ordered bismuth, creosote, and morphine, and put the patient on a milk diet. This caused some improvement.

On July 14th the patient vomited some curdled milk; she had pain in the epigastrium, though not severe; "a kind of numb feeling in the hands." I made a careful examination of the abdomen. No tumor was to be felt anywhere; there were no painful or sensitive spots, no tympanites, no eruption; in fact, no alarming symptom of any kind.

On July 16th, at 9 A.M., the temperature was 101° F.; pulse, 100 and less strong than usual, which was attributed to the exclusive milk diet; there was pain in the lower abdomen; micturition was somewhat painful; the urine was said to be slightly darker colored than before; there was no irritability of the bladder.

On July 18th there was much belching, the gas producing a sour taste in the mouth; the tongue was clean and of normal color; there was neither pain nor tenderness nor distention of the abdomen; headache, nausea, and diarrhœa were also absent. At breakfast the patient took the white of an egg in milk, which was promptly vomited, and she then returned to milk alone, which agreed well with her.

In the evening I was called and found the patient much changed. Temperature, 103.2° F.; pulse, 120, weak. The face looked pinched; there were dark rings around the eyes; profuse sweating; abdomen slightly tender all over, without any especially tender spots, and slightly tympanitic. The patient complained of difficult breathing; the tongue was dry and there was great thirst. Her mind was clear. There was no preference as to position; generally she lay flat on her back, sometimes with the thighs flexed, but often not. She was restless. I gave her a hypodermic injection of morphine to relieve the pain in the epigastrium, and put turpentine stupes on the abdomen. After some time she expressed herself as being comfortable, and fell asleep.

I took the vomit home for analysis. It was of liquid consistence, with a thin layer of solid matter floating upon it; the liquid part was light reddish, the solid part was dark reddish-brown. It was moderately acid in reaction, and without smell; filtrate clear. No hydrochloric acid (Günzburg test); very small amount of lactic acid (Uffelmann's test after treatment with ether); amount of mucus not excessive; no biliary matter. The microscope showed many oval-round cells of the size of a leucocyte, few larger epithelial cells, some blood corpuscles, a fair amount of fat drops of all sizes, probably from the milk, and for the rest dark-colored granular matter (necrotic ?). There were no sarcinæ, no yeast cells; no pus, no streptococci; only a few isolated cocci; and in seven cover-glass preparations only two long and slender bacilli, slightly motile in the fresh preparations (not the Oppler-Boas form).

I considered the case as one of very severe acute gastritis; the absence of pus in the vomit seemed to indicate, however, that there was no immediate danger, although the temperature was approaching 104° F.

Between twelve and one o'clock the following morning the patient vomited "some fluid of the same nature as before;" afterward she became slightly delirious, and ten minutes before I arrived she died. I found the fingers and toes cold; eyes open, pupils dilated; temperature under the arm, 107.4° F. Permission to make an autopsy was refused.

How did I arrive at a diagnosis? Vomiting was one of the principal symptoms throughout the disease. The absence of headache excluded a cerebral and the temperament of the patient a hysterical origin of the vomiting; the cause of vomiting, therefore, was sought in some local irritation of the alimentary canal. The history and absence of characteristic symptoms excluded poisoning, cholera morbus, typhoid fever, appendicitis, and intestinal obstruction. Up to a few hours before death peritonitis did not manifest itself if it existed. The principal seat of pain, viz., the upper abdomen, the nature and frequency of the bowel evacuations, the belching and the relief by vomiting, the composition of the vomit, and the presence of a moderate fever pointed to acute febrile gastritis; and this I thought was the disease, till the sudden fatal end proved that there was something else. What else could there be? The apparent suddenness of the attack, the seat of pain, the nausea and vomiting, the moderate fever, the final abdominal tympanites, the short duration of only six days, might suggest acute pancreatitis; but this disease is accompanied by symptoms of collapse and by tendency to constipation, often by hiccough, while my patient did not show collapse at any time, was never troubled with hiccough, and instead of constipation diarrhœa was present. And although the character of the vomit was in some respects in favor of the diagnosis of cancer, the short duration and other symptoms were opposed to it. So I came back to acute gastritis, and from this point went again over the whole ground.

Before July 13th there existed for some time an indistinct feeling of not being well, accompanied by irregularity of the bowels; at last there was a decided feeling of weakness, masked for a short time by the tonics; no fever. In the light of later events I am inclined to attribute this condition to the presence of an ulcer in the stomach, not at all an uncommon condition in the female sex and in persons of sedentary habits. Even the lack of prominent symptoms is in this disease well known to occur; the absence of hydrochloric acid in the vomit is no objection to the existence of a stomachic ulcer, as was formerly thought. The presence of the dull spot in the right lung and of chronic pharyngitis go far to prove that the patient's constitution was less good than it appeared to be, and would provide an etiological factor in the origin of the ulcer. At two o'clock in the morning of that day the presence of the ulcer made itself for the first time manifest by severe pain and vomiting; the vomit contained remnants of the supper taken some hours ago, and this fact locates the ulcer at the pylorus, one of the most favored spots. The attack was, however, different from those that generally accompany pyloric ulcer; fever at once followed it, and the attack itself was not renewed; vomiting no longer occurred some hours after the taking of food, but at once. The ulcer had broken—not into the stomach, and therefore no pus appeared in the vomit; nor into the peritoneum—but at the boundary of the submucosa and muscularis probably, where the difference of resistance in the tissues often modifies the shape of the ulcer (Ziegler's "Pathologische Anatomie," 7 Aufl., ii., S. 516). A diffuse process of suppuration was set up in the submucous coat, causing moderate infiltration of small round cells in the mucosa, and on the other side a rapid extension into the muscularis. The outward signs were those of acute gastritis, accompanied by fever and perhaps the premature return of menstruation. For some reason the mucosa withstood the strain a second time; hence no pus showed itself, and only a small amount of blood, caused by hyperæmia, mixed at last with the vomit. The muscularis, the seat of severe suppuration, gradually affected the serosa, and on the evening of July 18th the pus entered the peritoneal cavity over a relatively large area. A rapidly spreading peritonitis with extremely high temperature closed the scene.

Considering the ulcer, the formation of which was hardly noticed and not recognized, as the inciting cause, I diagnosed the real disease, lasting for exactly six days, as phlegmonous gastritis, although, to my regret, direct proof by means of section was not obtainable.

RENAL CALCULUS; NEPHROLITHOTOMY; RECOVERY.

By WILLIAM D. HAMILTON, M.D.,

COLUMBUS, OHIO.

The case to be described shows that a small kidney stone embedded in healthy renal tissue may require removal. Pain and hemorrhage were the prominent and urgent symptoms. Recurrent renal colic, hemorrhage, and the passage of tubulous matter, small calculi, or fragments of stone with the urine, form a symptom complex which is characteristic of this condition. The presence of pus and albumin in the urine usually attends it. It is a disease, however, in which some of these salient features may be absent, as is shown by the appended history.

The patient, Mrs. J——, aged thirty, a resident of Newark, Ohio, was seen by the writer in consultation with Drs. C. H. Stimson and W. H. Knauss, on June 7, 1898. She had enjoyed good health until six years ago, with the exception of periodical headaches, to which she had been subject. At that time she began to have dull pain in the right loin. The duration, intensity, and frequency of these attacks increased for three years, when she sought medical advice. The pains recurred at irregular intervals, sometimes with the menses. For the last two years the suffering had been at times very severe. One paroxysm, three hours in duration, had occurred a week prior to the operation. The pain was most intense. It originated in the right loin and followed the course of the ureter of that side. Profuse hæmaturia followed most of these seizures.

Examination of the urine showed the presence of albumin, some pus cells, high specific gravity, an alkaline reaction, and the deposit of large quantities of urates. She was at the time taking alkaline medication. By means of the Harris instrument the urine from each kidney was separately examined. A specimen from the left one was normal, but that excreted from the right kidney was cloudy and contained albumin, pus, and blood. On palpation of the right loin, what seemed to be the kidney, somewhat enlarged and tender, could be readily felt, although the patient was rather stout. Examination of the left side yielded negative results. A diagnosis of stone in the kidney was made by the attending physicians, and operation was advised by them.

The patient, having been etherized, was put upon the left side, under which a compress was placed. This made more prominent the right costo-iliac space. An oblique six-inch incision was made, from opposite the outer border of the quadrate lumbar muscle downward and inward toward the right groin. A hard place was felt about the centre of the kidney, nearer to the hilum than to the outer border. A bistoury passed into the outer border of the organ near its middle struck the stone at a depth of about two inches. The opening was enlarged by the finger, and the stone was easily dislodged. To insure permanent hæmostasis, two silk sutures were carried through the kidney in front and tied on its posterior surface. These were located in the track of the kidney wound. After irrigation of the parietal incision, sterilized gauze was packed about the kidney for hæmostasis and drainage. The wound was closed and dressed in the usual way. Convalescence was uneventful. The patient now enjoys perfect health. The calculus, which was small and rough, was of the uric-acid variety and weighed twelve grains. Its shape was like that of an olive seed.

Mr. Morris, of Middlesex Hospital, emphasizes the distinctive effects of calculi upon the kidney itself and the health of the patient as well. Numerous lumbar explorations have been made, the symptoms of stone being present, with negative results. Mr. Jacobson, of Guy's, has published a list of his cases, about twenty-five in number, in which no calculus could be found and some other pathological conditions were observed. When, however, symptoms such as those described in the history above given afford strong presumptive evidence of disease of one kidney, the propriety of exploration is evident. A circumscribed focus of tuberculous disease, calling for resection, may be found; or a neoplasm may be discovered, requiring the removal of the organ. We may add—and this is a fact with which surgeons are familiar—that in some instances a subsidence of pain and hæmaturia has followed a merely negative exploration.

Progress of Medical Science.

Hæmatemesis as a Symptom of Ileus. — Hæmatemesis is such a rare symptom in intestinal obstruction that text-books and monographs on this subject neglect to make mention of it, yet Dr. A. Tietze (*Deutsche Zeitschrift für Chirurgie*, Bd. xlv., Hefte 1 and 2) records two cases, one of which came under his own observation. The first was due to a deeply seated stenosis of the small intestine, with hemorrhagic infarction of the proximal gut, the result of compression by bands of adhesions from an old perityphlitis. There was considerable vomiting of blood and the patient died within a few hours. The second case, as shown by operation, resulted from a high-seated strangulation of the entire small intestine by the free edge of the omentum, which was retracted downward and backward. There existed only "mouthful" vomiting of black, discolored blood. The patient died twelve hours after operation. The author explains the hæmatemesis of ileus as the result of structural changes in the afferent intestine, such as submucous hemorrhage, disintegration of the same, deeper ulceration involving the muscular coat, hemorrhagic infarctions, and, finally, necrosis of the entire intestinal wall. These changes are most marked in the immediate vicinity of the incarceration, becoming less so as the distance increases. Submucous hemorrhages may even exist in the stomach. Hæmatemesis occurring in ileus is more suggestive of strangulation than obturation, especially when bleeding is profuse. Hæmatemesis is not to be expected in obstruction in the large intestine, because, on account of the long distance to the stomach, and the resistance of the valve of Bauhin, blood would not be macroscopically detected in the vomited matter. There is one exception to this, and that is when a severe and fatal peritonitis develops before the occurrence of hemorrhage. The symptom is of prognostic value as an indication of severe destruction of the intestinal wall.

The Action of Atropine and Pilocarpine on Peristalsis.—Traversa, being struck by the fact that injections of atropine caused constipation rather than increased emission of fæces in horses, has investigated the action of this drug and also of pilocarpine. It was found that pilocarpine accelerated and strengthened peristalsis, while atropine lessened and finally abolished the movements of the intestine. In each case the result is obtained through paralysis or stimulation

of the ganglia and nerve endings in the intestine. From this it follows that belladonna is not likely to be of value in constipation from atony of the bowel muscle; but in lead colic where it is not improbable that the intestinal ganglia are irritated belladonna may prove a useful remedy, and indeed in all cases when painful intestinal spasm, due to irritability of the intestinal ganglia, is present, the drug in question may be used with advantage.—*British Medical Journal.*

Pseudo-Membranous Angina in Pneumonia.—Drs. A. and V. Vedel (*Montpellier Médical*, No. 29, 1898) have observed five cases of severe angina in children, due to the pneumococcus. In three cases the erythematous type existed; these children recovered in from seven to eight days. The other two cases were of the pseudo-membranous type; the children from the outset gave evidence of severe infection. All therapeutic efforts were without effect; the injection of diphtheria antitoxin produced no result, and the children died.

Treatment by Colored Light.—In the recent congress at Nantes, France, Dr. Raffegeau made a report upon the influence of colored light in the treatment of nerve diseases. In a series of twenty patients he had been enabled to determine that a stay of several hours in a room in which a violet light was diffused produced a quieting effect upon the nervous system. If, on the other hand, a prolonged sojourn was made in a room lighted only by red rays, a pronounced excitation would be produced.—*Bull. Méd.*, No. 64, 1898.

Treatment of Inebriates in Germany.—The sixth paragraph of the new code which will come into operation in Germany in 1900 enacts compulsory treatment of habitual drunkards. Among the persons liable to be interdicted, the interdiction involving being placed under a curator, who will be empowered to place the individual anywhere for treatment until discharged from curatorship by the court, inebriates are specifically mentioned. The exact description is, "He who, in consequence of inebriety, cannot provide for his affairs, or brings himself or his family into the danger of need, or endangers the safety of others." This measure was first advocated in 1863, at a meeting at Hanover, presided over by Judge Naumann, of Hamelin.—*British Medical Journal.*

Posterior Urethritis.—Dr. A. Ravogli, of Cincinnati, states his disappointment in the use of bichloride solutions, and considers the Janet method by permanganate solutions a progressive step in the treatment of gonorrhœa. His conclusions are as follows: (1) Irrigations by the Janet method in a recent case of gonorrhœa will in many cases prevent posterior urethritis. (2) Irrigations with the recurrent catheter, with permanganate of potassium, followed by injections of protargol, will cure in a relatively short time a case of subacute posterior urethritis without complications. (3) When chronic posterior urethritis, lasting for a long time, has caused infiltration of the submucous tissues, the application of a sound with ichthyol salve gives the desired results.—"Mississippi Valley Medical Association Report."

Smegma Bacilli in the Lungs.—Pappenheim (*Berlin. klin. Woch.*, 1898, No. 37) has demonstrated smegma bacilli in the sputum, and the same case, coming to autopsy, showed identical bacilli in smears taken from the lungs as well as in sections of diseased areas. To distinguish them from tubercle bacilli the following procedure is recommended: The covers are to be first stained in boiling carbolfuchsin; second, the surplus stain is allowed to drain away; third, the covers are decolored and counter-stained by dipping them from three to five times in the following solution: one part of corallin (aurin, rosolsäure) is dissolved in a hundred parts of absolute alcohol, the whole completely saturated with methylene blue, and to this twenty parts of glycerin are added; and, fourth, they are washed in water, dried, and mounted. Dr. Nicholls pointed out in a paper read at the Lister Laboratory Club of Montreal, November 11, 1898, that in gangrene of the lung the smegma bacillus seems often to be present. It is more likely to be found in clusters and within cells. Still he has known experts to be deceived. He has also seen the tubercle bacillus within cells in the sputum. Cultures are unsatisfactory. The only way to differentiate is by the staining reaction. The smegma bacillus is decolorized by absolute alcohol in from two to five minutes, while the tubercle bacillus is not. The best staining-solution is that of Pappenheim.

Parasites of the Blood.—The claim is made by Dr. Löwit (*Centralblatt für Bakteriologie*, p. 206, 1898) that a protozoon has been found by him in the white corpuscles of leukæmia, and Grassit is reported to have demonstrated an amœba very similar to the malarial parasite in no less than eight cases of goitre. This parasite, it is stated, contains a red instead of black pigment.

Pharyngo-Mycosis.—Dr. Lubet-Barbon, in the *Annales de Médecine et Chirurgie Infantiles*, draws attention to this interesting condition affecting the closed glands of the tonsils, pharynx, tongue, and occasionally pillars of the fauces and velum, in young children. It is distinguished from lacunar tonsillitis, which it closely resembles, by the firm attachment of the patches by means of peg-like prolongations into the tissues, and by marked indolence. When irritation has occurred some instances are said to be distinguished with difficulty from diphtheria. The microscope, however, shows the hardened cheese-like plugs to be made up of a somewhat conical sheath of epithelium containing tubules of leptothrix. The treatment recommended includes gargling with potassium chlorate if the child be old enough, applications of iodine, or mechanical removal of the plugs and cauterization of the base with chromic acid.

Radioscopy of the Lungs.—In a paper by Dr. Albert Abrams, of San Francisco, on the danger of misinterpretation by those who employ this method of diagnosis (*Philadelphia Medical Journal*, November 26, 1898), formulates the following conclusions: (1) Atelectatic zones may be demonstrated in a large number of individuals. (2) These zones throw circumscribed shadows on the fluoroscope, which will vary according to the degree and area of the pulmonary atelectasis. (3) The shadows cast by the atelectatic zones can be made to disappear by continuous forced breathing, and they will reappear after a variable period when quiet breathing is resumed. (4) Before deciding whether the shadow cast on the fluoroscope is really due to pulmonary consolidation, the subject should be instructed to make forced inspirations; if the shadow disappears and is supplanted by a bright reflex, it is due to atelectasis; if the shadow persists, pulmonary consolidation may safely be concluded to exist, excluding, of course, other anatomic conditions that would interfere with the transmission of the Roentgen rays to the fluoroscope. (5) Radioscopy of the lungs demonstrates that the opacities on the fluoroscope corresponding to the atelectatic zones greatly exceed the percussional areas of the latter; and, furthermore, that in individuals in whom no zones can be demonstrated opacities are sometimes present which disappear after forced inspiration. (6) Before and during a radioscopic examination of the lungs, it is always imperative to instruct the patient to practise forced breathing.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, December 31, 1898.

THE LATEST REPORTS ON THYROID THERAPY.

WITH the treatment of myxœdema, cretinism, Basedow's disease, lipomatosis universalis, cachexia strumipriva, and insanity, it would seem as if the use of thyroid had reached its limitations. The successful administration and beneficial results obtained in some of the above diseases, however, have stimulated many observers and experimenters to make a wider trial of this form of medication, with the result that hardly a week passes by without an attempt being recorded to extend its field of usefulness. Thus we find Hertoghe advocating the use of thyroid as a galactagogue, and his good results have been corroborated by Stawell. Apart from this, the *Klinische therapeutische Wochenschrift*, No. 24, 1898, mentions spastic torticollis, tetany, acromegalia, Parkinson's disease combined with struma and scleroderma, as conditions in which the administration of thyroid gland has proved beneficial. Delace reports the case of a woman suffering from hæmophilia with bleeding gums, excessive menstruation, and purpura, in whom thyroid effected a complete cure. In gynæcology good results have been reported from the administration of the extract in fibroid tumors, the growth having decreased in size and the general health improved. In dermatological practice the remedy has found its principal application in psoriasis and ichthyosis, although premature grayness has responded to its use.

The dosage, method of administration, and danger signals are no less important than the indications for its use. The hypodermatic administration of the liquid extract and the grafting of the fresh gland have long fallen into disuse, and the tendency of the present day is to administer the powder or to give tablets or capsules prepared from the desiccated fresh gland. The dose varies with the individual, and for this reason it is advisable to begin with small doses, which should be gradually increased until the desired effect is produced. Beginning with one or two grains a day, as much as fifteen grains may be administered, the prescriber always being on the *qui vive* for poisonous symptoms. During the course of administration, especial attention should be given to the respiratory and cardiac apparatus, and at the first appearance of rapid pulse, embarrassed respiration, rise of temperature, vertigo, or gastric disturbance, its use should be abandoned.

Thyroid was the pioneer of the animal extracts, and thus far may be said to hold the first rank. Its field of application has been so varied that it is to be hoped that physiologists and pathologists will study its *modus operandi* more thoroughly, so that its administration in all conditions may be based upon strictly scientific grounds.

GONORRHŒAL ARTHRITIS.

THE inflammation of joints in the course of and at times after specific urethritis assumes an importance not only from the side of exact etiology, but likewise from the interesting questions of diagnosis and treatment. Views have changed in many respects during the past decade, and the discovery of gonococci in the fluids of joints as well as in the blood has opened the way to a better understanding of the whole subject. To be sure, the gonococcus cannot always be found in the effusion about the joint, but it is sufficiently often to be detected to make it of great etiological importance. In general gonorrhœal infection, in which the cocci are found in the blood, as in a recent demonstration by Ahmin and in a case reported by Rendu and Hallé (*Annales de Dermatologie et de Syphiligraphie*, February), not only may we have multiple arthritis, but lesions of the endocardium and pericardium, in which gonococci are abundantly present.

In the instance last mentioned, fluid drawn from a phlegmonous œdema of the elbow is reported to have given an almost pure culture of gonococci, and the latter were found also after death in aortic vegetations and in the pericardium. The rule, therefore, that gonorrhœal arthritis is a mono-articular affection is by no means an absolute one, and, as pointed out by Dr. Still (*The Clinical Journal*, March), it is often found that in infants and young girls with purulent vaginal discharge a number of joints and the peri-articular structures as well may become inflamed and simulate rheumatism, when gonorrhœa is the true cause.

One of the most recent contributions on this subject is that of Mühsam (*Centralblatt fur Chirurgie*, July 30th). In a series of forty cases one joint only was affected in thirty instances, and in ten more than one. Gonococci were found in the joint effusion in only four of the patients, while in the remainder they could not be identified. The results are of no little interest, and show how guarded must be the prognosis as to final results. Fifteen, or less than half, recovered with full motion in the affected limb; twelve were improved, but readily suffered relapse; in seven there was ankylosis, and no less than three had to undergo resection of the joint, while one thigh amputation became necessary, and one patient died from sepsis six weeks from the date of gonorrhœal infection. The most successful treatment was found to be complete immobilization of the joint, but when effusion has taken place the joint may, according to this author, be punctured and irrigated.

THE "TRANSACTIONS" OF THE SOCIETY OF ANÆSTHETISTS OF ENGLAND.

From a perusal of the published "Transactions" of the Society of Anæsthetists of Great Britain, one will, of course, gather much highly instructive and practical information; but at the same time one can hardly forbear to notice the difference of opinion that exists between skilled anæsthetists, both as regards the anæsthetics to be used and the manner of administering the same. Owing to the large number of fatal results following the giving of chloroform, that drug has undoubtedly, even in Great Britain, fallen into a certain degree of disrepute as an anæsthetic, and ether has correspondingly risen in the estimation of medical men as a safer means of producing unconsciousness. Nevertheless the upholders of chloroform still contend —and probably rightly enough—that the danger is not so much in the chloroform itself as in the manner of its administration. Mr. Tyrrel, when reading a paper before the society, and commenting on the many writers to medical journals nowadays who conclude their communications by saying that they have never had any difficulties with ether, appositely remarks: "When I read these letters I feel like Mr. Underwood, who was instructing a student at the Dental Hospital of London how not to break a tooth in extracting it, when the student said that he never had broken a tooth, and Mr. Underwood said: 'I am sorry for you; your experience hitherto must have been extremely small.' And this is what I feel when a man rushes into print to say that he has never had any difficulty with ether." Mr. Tyrrel is also not in favor of the A.C.E. mixture, but uses an adaptation of his own of the "double-bottle method," by which chloroform can be administered and ether added as required for the particular case under treatment. This method is said to act very well in the hands of a skilful administrator, although it has yet to be proved that ether increases the action of the chloroform. We should be rather of the opinion that its action is that of a stimulant to the patient.

The paper read by Mr. Alexander Wilson, on resuscitation in emergencies under anæsthetics, is a clear exposition of the subject, but is much too lengthy to be more than briefly noticed. To one point we would, however, draw attention—to the habit of injecting strychnine to counteract the ill-effects of chloroform. For some time past Dr. Silk has been accustomed to give strychnine in all cases in which he contemplated a severe operation, injecting a small quantity (one-twentieth grain) immediately after the induction of anæsthesia, and repeating the dose once or twice if necessary. Recently, in the *British Medical Journal*, it was reported that as much as half a grain of strychnine had been given in a case of chloroform poisoning; and in the same journal a writer stated that when he used strychnine as an antidote to chloroform overnarcosis, he gave at least fifteen minims of liquor strychninæ. This would seem to show the importance of giving fairly sized doses, in order to get any counteracting effects. Dr. Dudley Buxton, the president of the Society of Anæsthetists (speaking on the question of the methods to be used in administering anæsthetics, and in answer to questions by Dr. Cook inquiring whether the pouring of chloroform on lint or A.C.E. mixture in Rendle's inhaler, which allowed the ordinary air to be mixed with it, was not an unjustifiable method in the light of recent exact experiments and the results obtained from them), said that he, the president, could not sit in judgment upon methods which others had seen fit to employ, nor could he go so far as to say whether or not any methods were unjustifiable. His own personal feeling was that any method which did not admit of exact or nearly exact dosage was faulty, and that faultiness would sooner or later appeal to those who used it in a most unpleasant way. One had also to remember that no less an authority than Lord Lister had stated that an exact dosage could not be guaranteed by the employment of lint or a towel on which chloroform was dropped, believing as he [Lord Lister] did that, knowing the temperature of the air and therefore the rate of evaporation, no one could tell at what rate the anæsthetic was inhaled. Personally he thought the experiments from which the dictum was made were open to grave criticism.

It will be seen from the foregoing that the feeling in Great Britain leans toward the use of ether; that it is now generally recognized as a safer anæsthetic than chloroform; and also that medical men are gradually but surely becoming conscious that methods whereby exact dosage can be guaranteed are far safer than the old haphazard modes of administering anæsthetics.

News of the Week.

Uncleaned Streets in Chicago.—One of the results of a political quarrel in the city government of Chicago, whereby the annual appropriation bill is held up, is that there is almost no money left for street cleaning, and consequently the streets will have to remain dirty. Misery loves company, and we sympathize with our sister sufferer.

A Gift to Science.—Baron Iveagh, formerly Sir Edward Cecil Guinness and head of the well-known brewing firm in Dublin, has presented $1,250,000 to the Jenner Institute of Preventive Medicine in Great Britain. The purpose of the gift is to promote research in bacteriology and other forms of biology as bearing on the causes, nature, prevention, and treatment of disease. Lord Lister says that the gift will enable the Jenner Institute to compare favorably with any similar establishment in the world, and will remove from the British Isles the reproach that their opportunities for research directed toward prevention of disease are not equal to those of other nations.

The Fever at Key West.—Dr. R. D. Murray writes from Mobile: "In your editorial on the Navy Medical Department in the Medical Record for December 17th you state this: 'Yellow fever broke out at Key West,' etc. Permit me to state that there was no yellow fever in Key West in 1898; there was no isolation of the sick, and no persons were removed beyond the

danger of infection, if yellow fever had been in existence. Dengue attacked every class, naval men, tenderfeet, strangers, natives, and immunes, and in over one thousand cases not a death was recorded or considered attributable to the United States army or the United States navy 'yellow fever.' I know whereof I write, for I saw many of the cases and suffered with the disease myself."

The Disinfection of Schools.—The board of health of this city recently published the announcement that during the holidays all the public school buildings in every borough would be subjected to a thorough fumigation and disinfection. The neglected streets having been washed clean by a beneficent Providence, which sends its rain upon the just and the unjust, we may hope for an improvement in the health conditions of the city.

The Plague.—A British steamer from Calcutta arrived at Plymouth, England, on December 24th with a case of bubonic plague on board. The patient was an officer of the India Company who showed symptoms of the disease when the ship was in the Mediterranean. From St. Petersburg it is reported that the outbreak of the plague in Turkestan is now completely under control, the hygienic measures energetically applied by the military authorities having proved amply successful. In some cases whole villages were burned by order of the authorities, together with all the clothing and furniture of the inhabitants.

Leprosy in Ohio.—According to a recent despatch from Columbus, Ohio, Dr. Charles O. Probst, secretary of the State board of health, has investigated two reported cases of leprosy at New Lexington, Ohio, and has found them to be fully developed leprosy. The lepers are a young woman, aged twenty-two, and her little sister, twelve years old. For many years the mother had managed to conceal from her neighbors her children's affliction. Finally, forced by straitened circumstances, she told the story to the county authorities. The two leper girls will be isolated in a cabin to be built among the hills outside the town limits. In this cabin, which will be Ohio's leper settlement, the mother will care for her daughters, while food and clothing will be furnished by the county.

Southern Medical College Association.—This association met at Memphis, Tenn., December 5th, prior to the meeting of the Southern Surgical and Gynæcological Association, and after considerable discussion, it was decided to increase the course of study from three to four years. It is well known that the question of making the course four years instead of three has been before the association for two years, but it has been passed from time to time, in order that so radical a move might be fully discussed by all the faculties that are to be affected. Dr. Sinclair, of Memphis, presented the matter first at the meeting of the association in Atlanta, and since then from time to time it has been discussed frequently among each of the faculties in the association. At the meeting only two of the thirteen colleges in the association failed to send representatives to the conference. On account of the change to the four-year course, it was necessary to introduce a number of amendments to the constitution and by-laws of the association, but none of them was passed, because it is the rule that such amendments shall lie over for one year. This is for the purpose of giving the delegates an opportunity to present plans for whatever changes are contemplated in their respective faculties before final action is taken.—*Journal of the American Medical Association.*

The Quarrel in the Kentucky School of Medicine.—We learn from a Louisville paper that the suit between the contesting factions in this school has come to an end, at least temporarily, the court having dismissed the petition of Drs. Woody and Kelly and dissolved the injunction against Drs. Cochran, Boyd, and Wathen. This decision reinstates Dr. Wathen as dean of the school, and entitles Drs. Cochran and Boyd to professorships. Judge Miller's opinion, in effect, is that the board of regents, and not the professors, have control of the school. It is said, however, that the defeated side will carry the case up to the court of appeals, and in the mean time the court is asked to continue the injunction temporarily pending the appeal.

Education and Diphtheria.—The public health department of the London County Council has issued a report upon diphtheria and elementary schools, in which Dr. Shirley F. Murphy repeats his opinion that the increase of diphtheria in London is largely due to the aggregation of children in schools. Dr. Murphy closes his report with this very grave warning: "I am satisfied that the full recognition of the effect of compulsory school attendance in this connection is absolutely necessary if efficient measures are to be adopted for the prevention of diphtheria caused in this way. The system of notification supplies but a very inconsiderable record of the total number of persons actually suffering from the disease, its principal use being to give indications as to where inquiry should be made. The circumstance that schools contribute largely to the prevalence of this disease not only justifies but necessitates the medical officer of health having free access to schools where school children can be most readily examined for the prosecution of his inquiries. I am led to make these observations, because the medical officer of health of a London district reports that the London school board has addressed to his authority a letter 'severely censuring' him for examining in school certain children during scarlet-fever prevalence among the pupils of the school, where, in fact, he found children he had grounds for regarding as possibly infective. The board stated that they would not allow him or any other medical officer to examine children in their schools. The authorities in London should look to this, and would act wisely if they followed the example of New York in this respect."

The Value of a Medical Diploma in Missouri.—The court of appeals of Kansas City has recently decided that it is not necessary for one to attend a medical college in order to secure a diploma from it, and if the officers of a college believe that any one is

qualified to practise medicine or surgery, they may give a diploma to him. In so doing they might be guilty of a technical violation of the law, the court decided, yet they cannot be prosecuted for the illegal act. The decision was rendered in a suit brought to annul the charter of the "National School of Osteopathy" for having sold a certificate (price, one hundred and fifty dollars) that the bearer had completed a full course of study at the institution, whereas he had simply entered the building twice. The curious person exercising judicial functions at the time wrote a most learned and logical opinion, maintaining that "the violation of the law was that the diploma was issued when there had been no personal attendance for the time specified by the Missouri laws. This was a legal wrong, but not sufficient to warrant the forfeiture of the school's franchise. It was not a wilful abuse of the law, nor an improper neglect of the duties prescribed for such colleges."

The New York State Medical Society.—Dr. W. G. Macdonald, of Albany, announces, on behalf of the business committee of the New York State Medical Society, that the programme is already overflowing with contributions and that no more can be received. The preliminary programme will be issued within a few days, and promises to be an interesting one.

The Bombay Medical Union on Preventive Inoculation in Plague.—The following resolution was adopted on November 8th, by the Bombay Medical Union, at the close of a discussion on the plague, which had occupied several successive meetings. "This meeting is of opinion that, considering the data now available and the satisfactory results of the observations collected regarding the protective effect of Professor Haffkine's plague prophylactic, the time has now arrived for the profession to utter a definite pronouncement on the subject and to invite the public to resort freely to protective treatment as the only safeguard against plague. The immunity derived from inoculation when done with a full dose appears to last for at least six months; but there is a possibility of its lasting much longer. From observations collected lately it appears that a second inoculation, done ten days or so after the first, further reduces the incidence of plague in those who resort to inoculation, and a third if such be practicable would increase the immunity still further. The public are therefore to be invited to resort to at least two inoculations, and even to a third if practicable. The duration of protection is also likely to be enhanced by such a repetition. This meeting of medical men, who have had a wide experience of inoculation on persons of all positions, ages, and conditions, declares emphatically that rumors of inoculation originating different diseases are devoid of any foundation; that considering the nature of the prophylactic, which does not contain any living germs, such an eventuality is absolutely impossible, and that there are no facts to show that inoculation aggravates any existing ailments, despite rare and isolated instances which may at first suggest such an idea." Four native physicians opposed the resolution.

Obituary.

JOHN B. HAMILTON, M.D., LL.D.

CHICAGO, ILL.

Dr. Hamilton died at Elgin, Ill., on December 24, 1898, of acute peritonitis. He was born in Jersey County, Ill., on December 1, 1847. He was graduated from the Rush Medical College, Chicago, in the class of 1869. He at first engaged in general practice, but in 1874 entered the medical department of the United States army, with the appointment of assistant surgeon. Two years later he resigned and entered the Marine Hospital service as assistant surgeon. The following year he was promoted to the rank of a full surgeon, and in 1879 was appointed supervising surgeon-general on the death of the then incumbent. In 1891, having failed in an endeavor to induce Congress to raise the Marine Hospital service to an equal rank, including salaries of the officers, with that of the medical corps of the army and navy, he resigned his position as supervising surgeon-general, and re-entered the ranks of the service as surgeon. After serving as surgeon in charge of the Marine Hospital at Chicago for a number of years, he finally resigned from the service and resumed private practice.

While resident in Washington, Dr. Hamilton was professor of surgery in the medical department of the University of Georgetown and surgeon to the Providence Hospital in Washington. In Chicago he was professor of surgery and clinical surgery at the Rush Medical College, professor of surgery in the Chicago Polyclinic, attending surgeon to the Presbyterian Hospital, and consulting surgeon to St. Joseph's Hospital and the Central Free Dispensary. Two years ago he was appointed superintendent of the Insane Asylum at Elgin, near Chicago.

While on a visit to the East two weeks since, Dr. Hamilton was attacked by a severe cold, and in a few days peritonitis developed. In spite of everything that could be done, he grew worse rapidly, and on December 18th it was decided, by Dr. Nicholas Senn, that an operation was necessary to save his life. The operation was performed, and at its conclusion Dr. Senn said that in his opinion Dr. Hamilton had no chance of recovery. He rallied slightly after the operation, however, and for a few days there seemed to be a probability that he would pull through. For the last two days he had, however, been sinking slowly, and death came at 6:30 P.M., December 24th.

Dr. Hamilton was pre-eminently a man of executive talents. He was a good surgeon, but his best work was done as head of the Marine Hospital service, when he had to contend with two serious epidemics of yellow fever in the South, and also as editor of the *Journal of the American Medical Association*, to which position he was elected in 1893. For his excellent work during the Florida epidemic of yellow fever in 1889, he received the thanks of the legislature of that State. In 1892, at the time of the threatened invasion of this port by cholera, he was instrumental in establishing "Camp Low," a retention camp at Sandy Hook. It was through his influence that the national quarantine acts were passed by Congress. A favorite study of his was the history of medicine.

Dr. Hamilton was a man of strong personality, and impressed the stamp of his individuality upon everything he undertook. In him many men have lost a firm friend and most genial companion, some few an implacable but fair-fighting enemy, and the American Medical Association an excellent editor and a member who has done more than any other one person to promote the usefulness of the organization.

Reviews and Notices.

Wie ist die Fürsorge für Gemüthskranke von Aerzten und Laien zu fördern? Von Prof. Dr. C. Fürstner. Berlin: S. Karger. 1899.

This small monograph is intended to increase the knowledge of physicians and laymen in caring for the insane.

Die Störungen des Verdauungsapparates, als Ursache und Folge anderer Erkrankungen. Von Dr. Hans Herz, in Breslau. Berlin: S. Karger. 1898.

The present book treats of the digestive disturbances which accompany diseases of other organs than the digestive tract. It is quite interestingly written and can be warmly recommended.

Transactions of the Medical Society of the State of New York. 1898.

This publication by the society is issued in the usual good style and contains five hundred and twelve gilt-edged pages, bound in green. This represents forty-four papers and discussions. Handsome illustrations accompany the paper by Williams and Fink on the *x*-rays. Hypertrophy of the prostate is discussed by Keyes, Bangs, Pilcher, and others. Altogether this *résumé* of the society's work is creditable.

Diet and Food. Considered in Relation to Strength and Power of Endurance, Training, and Athletics. By Alexander Haig, M.A. and M.D. Oxon., F.R.C.P. London: J. and A. Churchill. Philadelphia: P. Blakiston's Son & Co. 1898.

The present monograph by the well-known English writer is quite interesting but somewhat one-sided. Haig, as a whole, champions a strictly vegetarian diet, going one step further in excluding also eggs, on account of the uric acid they contain. He is also a strict believer in temperance, and forbids all beverages containing alcohol, tea and coffee, and smoking.

Fatty Ills and their Masquerades. By Ephraim Cutter, LL.D., M.D. Harvard 1856, and University of Pennsylvania, 1857, and John Ashburton Cutler, B.Sc., M.D. Albany Medical College, 1886, Corroborator.

In this curious book, with its peculiar title, the authors attempt to prove that fatty degeneration is the cause of many common diseases known under other names. They establish their claims upon false premises, however, in assuming that Bright's disease, alcoholism, etc., are fatty ills, the result of fatty degeneration, whereas such a degeneration is merely an outward or physical manifestation, the result of a known or unknown etiological factor.

Laboratory Work in Physiological Chemistry. By F. G. Novy, Sc.D., M.D., Junior Professor of Hygiene and Physiological Chemistry, Ann Arbor University. Second edition. Ann Arbor: George Wahr. 1898.

The present edition, while not yet bringing Professor Novy's work up to a point of completeness or exhausting the subjects discussed, is a decided improvement on the first, and the brief explanatory descriptions added will be found of value to the student. In several parts more detail still and points of technique might have been added. In a work of this kind it is not safe to assume that the student has any previous knowledge, and each step must be fully explained. The pages have been wholly rewritten, and the author must be complimented upon a painstaking work which will be a safe guide to students, and one which teachers of medicine as well as those who work in the laboratory will find almost a necessity.

The Treatment of Skin Cancers. By W. S. Gottheil, M.D., Professor of Dermatology at the New York School of Clinical Medicine; Dermatologist to the Lebanon Hospital, the Northwestern and West-side German Dispensaries, etc. New York: Published by the International Journal of Surgery Company.

No more praiseworthy motive could be found than that which the author tells us in his preface actuated him, in putting forth this little volume of sixty-seven pages. He says: "It is my hope that what I have written may do something toward taking this most eligible method of treating cutaneous carcinomata out of the hands of unauthorized practitioners, and placing it where it belongs, at the disposal of the profession at large." Physicians are not sufficiently careful about warning their patients to avoid the many different kinds of quacks, who, by their advertisements of cure without the knife, etc., attract sufferers from cancer, and from many other diseases as well, away from their own and other reputable physicians. There are a number of illustrations of skin cancer and formulæ of arsenical pastes, etc. Other methods are discussed briefly.

A Laboratory Guide in Urinalysis and Toxicology. By R. A. Witthaus, A.M., M.D. Fourth Edition. New York: William Wood and Company. 1898.

The fact that this little book has passed through four editions is proof in itself of the approval which it has met with at the hands of students and general practitioners. The first half deals with inorganic chemistry and is admirably arranged to suit the needs of the student during his laboratory hours. The second part is devoted to the qualitative and quantitative analysis of the urine, to urinary deposits, and to the detection of the volatile, metallic, and vegetable poisons. The same care, precision, and conciseness which characterized the earlier editions are evident now. The print is limited to one side of the paper, thus giving the student ample room for additional notes. The illustrations are well selected and convey an excellent idea of the conditions under discussion. The binding is neat and attractive, the price moderate, and the entire book is of such a size as to enable it to be carried in one's pocket.

The Practitioner's Manual. A Condensed System of Medical Diagnosis and Treatment. By Charles Warrenne Allen, M.D., Consulting Genito-Urinary Surgeon to the City (Charity) Hospital; Consulting Dermatologist to the Randall's Island Hospital; to the Hackensack Hospital, to the Bayonne Hospital, to the Infant Asylum of the Holy Rosary; attending Surgeon to the Good Samaritan Dispensary (Department of the Skin), etc. Pages 851. New York: William Wood and Company. 1899.

This volume, as the title suggests, is a compilation of many practical points which are of decided use to the active general practitioner who wishes a book of ready reference. The author has wisely arranged his work alphabetically in order thus to facilitate its consultation. Under each heading he gives the definition of the disease, the main clinical features which would lead to its detection, with the special points of its differential diagnosis concisely but fully described.

The main portion of the book, however, consists in the collection of therapeutic measures, which are apt to be but too often hurriedly dismissed in the modern systems of medicine and students' text-books. He has taken the pains to forward circular letters to those eminent in the profession asking for their views and favorite formulæ, thus enabling him to publish the most recent ideas which are extant, many of which have heretofore not found their way into print. In the difficult task of selecting the best prescriptions he has certainly shown admirable discrimination and a spirit of fairness, thus making his work extremely valuable to a large group of readers who wish to learn the various and often conflicting views of the leaders of medicine. In so doing he makes it possible to afford a latitude of choice so essential in treating complex conditions where certain drugs may be contraindicated, or where the selected medicine fails to act as expected. A useful feature is the rather full consideration which he gives to the minor ailments, to the simpler symptomatic complaints which often tax the therapeutic ability of the physician, and about which the ordinary text-book is oftentimes too silent. When powerful drugs are advised in the various prescriptions he has appropriately added a "caution," naming the special danger or contraindication which must be considered lest harm result.

The volume does not pretend to supplant the use of the usual works on medicine, but rather to supplement them, and the author is certainly to be congratulated on the success which has met his efforts. In fact it is a book which every man in general practice will find handy and useful, and will serve as a means of introducing to him many ideas and hints which would otherwise have been inaccessible, and of enabling him to procure at a minimum of exertion that which ordinarily would require much time and delay to find in the scattered volumes and journals of his library.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 15, 1898.

E. G. Janeway, M.D., President.

The meeting was in charge of the Section on Genito-Urinary Diseases.

Observations upon the Pathological Anatomy of Chronic Enlargement of the Prostate, with Special Reference to the Causes of Muscular Insufficiency of the Bladder.—Dr. Samuel Alexander presented a communication with this title, and illustrated it freely with lantern slides. He said that when there was a distinct and more or less pedunculated nodule, one might be sure that the trouble began in the accessory glands at the internal urethral orifice. The cause of the prostatic pouch was to be found in the fact that the muscle covering the trigone was very rigid and compact, while the muscle lying behind the bladder was loose and easily dilated. When, therefore, pressure was brought to bear behind the trigone, as occurred in cases of obstruction, this portion behind the trigone gave way and sank down behind the trigone, thus forming a post-trigonal pouch, often improperly called a "post-prostatic pouch." There might be very marked enlargement of the posterior isthmus without interference with urination. Obstructive disease of the prostate when due to the lateral lobes was purely mechanical at the beginning, the bladder being simply called upon to overcome the obstruction which the pressure downward of the lateral lobes had produced on the urethra. When the lateral lobes projected into the bladder, and deformed and narrowed the urethra, the same thing occurred. When, however, the obstruction occurred on the floor of the canal only in one place—*i.e.*, above the veru montanum, and between that and the internal urethral orifice—it might be due to one of three causes. When there was enlargement of the anatomical median lobe itself, there was simply hypertrophy of the muscle covering the trigone, owing to its attempt to overcome the obstruction by elevating the lower end of the internal urethral orifice. A second cause was to be found in the cases in which the accessory glands which lay along the course of the urethra in many normal prostates grew out into the urethra, forming an intra-urethral tumor arising from the floor of the canal. This was usually connected also with enlargement of the so-called anatomical median lobe. A third cause was to be found in those cases in which the median enlargement and enlargement of the floor of the canal occurred as a result of hypertrophy of the accessory glands at the internal urethral orifice and the formation of a separate tumor. This was separated at first from the anatomical median lobe by the muscle of the trigone, but later on, as the disease advanced, it became continuous with the third lobe. In all of these three classes of cases, and especially in the last two, the cause of the loss of power was the destruction of the insertion of the vesical muscle into the prostate and the consequent inability of the bladder to empty its posterior fold.

Dr. Willy Meyer said that the treatment of prostatic hypertrophy could not fail to be greatly benefited by such studies as that just presented. He had been especially impressed with the manner in which the lateral lobes press down upon the urethra in such a remarkable way. In his recent paper on the Bottini operation he had referred to a case in which catheterism had been extremely easy, and yet there was a considerable quantity of residual urine. In this case with the cystoscope he was able to demonstrate the existence of a small growth within the urethra, which evidently caused the obstruction. It was a counterpart of what had been presented on the screen this evening. The accessory glands, about which so much had been said in the paper, could be well seen by means of the cystoscope. The part played by the lateral lobes in the production of obstruction, as demonstrated in the specimens just exhibited, brought out the fact that, in the Bottini operation, instead of raising the handle of the instrument it should be depressed.

Dr. Alexander, in closing, said that he desired to express his great obligation to the members of the pathological staff of the Carnegie Laboratory for their kindness in connection with this work, and also to Mr. O. Mason, the distinguished photographer of Bellevue Hospital who had spared no pains in the production of the lantern slides.

A Very Rare Book.—Dr. A. Jacobi announced that a very rare and valuable book had just been presented to the library of the Academy by Lothar Voss, one of its honorary fellows. Dr. Voss returned to Germany thirty years ago, being at the time a surgeon of note. He was the second person in New York to introduce tracheotomy as a part of the systematic treatment of croup. He had been collecting rare and valuable books all his life, but the one just given by him to the Academy was the best "find" of them all. The book is on the lymph vessels, and is by Gaspar Asellii, who discovered these vessels on July 23, 1623. He also discovered the valves, and noted that they ran in the opposite direction to those of the veins. Asellii was born in 1581, and died in 1626. The book was printed in 1627, and was the first one giving colored anatomical plates. The book was reprinted twice, the third edition appearing in 1640, but these two later editions were decidedly inferior to the first one. The work had been considered almost extinct. There was one copy in the University of Leipsic, and a defective copy in the library of the University of Breslau. The book just given to the Academy was one of the two copies now known to be in existence, and was one of the first edition. The Surgeon-General's Library, Washington, D. C., contained a copy from the inferior third edition of 1640.

Dr. Lewis A. Sayre, in moving that the Academy of Medicine should express, though Dr. Jacobi, its thanks for this generous donation, took occasion to speak of the circumstances in which he had first become acquainted with Dr. Voss, who, he said, was a bold, practical, and brilliant surgeon.

SECTION ON SURGERY.

Stated Meeting, December 12, 1898.

W. W. Van Arsdale, M.D., Chairman.

Almost Complete Excursion of Scapula due to Paralysis of the Trapezius.—Dr. V. P. Gibney, on behalf of Dr. C. Tranchida, presented this interesting case. The patient, a man twenty-three years of age, an Italian by birth, had been apprenticed when ten years old to a maccaroni factory, where the work was said to be exceedingly severe, requiring extraordinary muscular development of the upper extremities. After a number of years at this occupation he attempted at the age of eighteen to enter the Italian army. He was excluded by the surgeons because of a weakness of the muscles controlling the scapulæ. Shortly after this he received electrical treatment and massage at a hospital in Palermo, and, on leaving there, came to this country. Examination showed that the scapulæ projected like "angel wings." A few months ago he began to have weakness of the muscles of the right hand. Since then his walk had been peculiar. The

case was apparently one of well-marked progressive muscular atrophy. The erector spinæ muscles were not as yet very much involved. Owing to the paralysis of the trapezius, the scapulæ, and particularly the right one, made a remarkable excursion. There was a peculiar falling forward of the shoulders owing to the fact that only a few muscular bands of the pectoral muscles still remained. That the disease was progressive was well shown by the history, and there was but little prospect that he would improve. A careful investigation had failed to show any such disorder in other members of his family.

Multiple Exostosis.—Dr. J. F. Erdmann presented a case of this kind occurring in the person of a physician, about thirty years of age, whose family and personal history were negative except that the patient himself had had an attack of typhoid fever about fourteen years ago. The first tumor discovered, that on the right femur, was not noticed until convalescence from this illness. Examination showed an exostosis in each vastus externus muscle, in the right radius, on the outer aspect of the right femur, and on the right internal malleolus. Radiographs of the case were also exhibited.

Dr. B. Farquhar Curtis said that about five years ago he had seen at the Vanderbilt Clinic a somewhat similar condition of the muscle to that observed in Dr. Gibney's case. The scapulæ stood out just as in the present case, but they were very much smaller than normal. The disease in this case did not appear to be progressive, but rather a congenital condition.

Dr. Reginald H. Sayre said that he had seen only two cases of this kind, one unilateral and the other bilateral. There had been a good deal of discussion as to whether this condition was due to slipping off of the serratus magnus or to paralysis of the subscapularis. In the cases that he had seen, it seemed evident that the paralysis of the subscapularis was the cause of the tipping out of the scapulæ from the body, rather than a dislocation. This also seemed to be the condition present in the patient under discussion. The cases he had seen had not exhibited, during the few months they had been under observation, any tendency to progress.

Dr. W. W. Van Arsdale said that there seemed to be so many muscles affected and the grouping of them was so peculiar that he was reminded of those paralyses described by neurologists as "systemic paralyses." Although they did not seem to correspond exactly to any of these groups, they did not correspond to the grouping laid down by neurologists as ordinarily observed in progressive muscular atrophy.

Dr. Gibney said that he had seen a number of these cases of multiple exostosis, and had reported about sixteen years ago a series of five or six cases occurring in one family. The grandfather was a musician, and his exostosis developed first in the arm with which he was accustomed to hold his musical instrument. The father had a great many exostoses, and several of his children also presented similar conditions. He had followed these cases for a number of years, but had learned nothing further in regard to them. The muscles gradually became accustomed to the presence of these growths, and they then gave little trouble, so that very few of them came to operation.

Dr. John B. Walker said that he had seen three cases in the last eighteen months. In the first case there was an exostosis over the internal condyle in a young girl. Recently it had grown rather rapidly and had caused some pain. It had accordingly been excised. He had also seen an exostosis over the internal condyle in a boy and in a male adult. Only yesterday he had seen still another case in a dissecting-room subject.

Dr. Van Arsdale remarked that it was an easy matter to remove these growths by operation, and the results were entirely satisfactory.

Dr. Erdmann said that these growths were often seen near the internal condyle, but the case presented was interesting because of the exostosis on the outer aspect. The patient desired to have them removed because of the inconvenience which they occasioned.

Elephantiasis of the Vulva, with Report of a Case.—Dr. W. Duff Bullard read a paper on this subject which will appear in a future issue.

Dr. W. B. Coley said that the case was a most remarkable one. The question of etiology seemed to him especially important and interesting. He did not think the causation by the filaria sanguinis could be ruled out here. The fact that the disease developed shortly after bathing would seem to be very strong evidence that the cause might have been the filaria, as bathing was one of the modes by which the filaria was introduced into the system.

Dr. B. F. Curtis said that one or two cases of filaria associated with elephantiasis of the lower extremities in males had been at St. Luke's Hospital. The presence of the filaria had been demonstrated in these cases only after repeated and most careful examination. In many cases in this country elephantiasis developed in connection with chronic inflammatory conditions. He recalled one case of chronic ulcer of the leg and necrosis of the tibia, in which a typical elephantiasis of the skin was engrafted upon the first condition. At the urgent request of the patient he had amputated the limb above the knee. In such cases the elephantiasis was evidently due to chronic inflammation and obstruction of the lymphatics. In cases of filaria observed in this country, the persons had at some previous time lived in the tropics.

Dr. Carl E. Pfister said that he had seen a good deal of elephantiasis in India, Japan, and China. There is very little elephantiasis in South America. He recalled a very interesting case of elephantiasis of the penis in an English soldier, following the removal of a chain of infected inguinal glands. That was the only case of elephantiasis that he had seen in India among the white population. He had seen elephantiasis of the scrotum in two white persons.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE BRADSHAW LECTURE—PERFORATION OF STOMACH BY ULCERS—MEDICAL COUNCIL—MR. HORSLEY'S REPORT—SCHOOL OF TROPICAL MEDICINE; COMMITTEE AND STAFF DISPUTE—SIR W. BROADBENT'S VERDICT—THE "CHRISTIAN SCIENCE" CASE—DEATH OF DR. CLEVELAND.

London, December 9, 1898.

The Bradshaw lecture was delivered at the Royal College of Surgeons on Wednesday by Mr. Pickering Pick, who took for his subject "The Union of Wounds." He remarked that, while many hold that repair is incompatible with inflammation, others regard that process as essential to healing. No doubt Hunter believed that wounds may heal without inflammation, and at the present day this view is expressed by Roser. But so many surgeons and pathologists oppose this notion that it seems clear that the word is differently interpreted. There will be no agreement until the previous question of a definition is settled.

Mr. Pick divides the several modes of union into only two classes, those without and those with suppuration; and the latter he regards as merely a modification of the other. Primary adhesion as taught in

some text-books he discards as untenable, the cases so described being merely those in which the inflammatory process is at a minimum. He pointed out the close analogy between the processes of union by first and second intention. In both there are inflammation and exudation; in both the material exuded, though differing in amount, forms the bond of union. In the second class of cases there is the same process with the conversion of the exudation into granulations and in the superficial layers. The cells degenerate into pus cells. This is due to prolonged or excessive irritation produced by micro-organisms. Those who hold that such organisms are present in every inflammation will not admit Mr. Pick's arguments. But those who admit that we may have inflammation without the concurrence of organisms may readily accept the evidence he brought forward that union of wounds is, after all, an inflammatory process. If not, what is it?

The necessity for immediate operation when perforation occurs from gastric ulcer was discussed at the Clinical Society's meeting last week. The subject was introduced by Mr. J. C. Wallis, who read notes of two cases on which he had operated. In one the abdomen was opened ten and one-half hours after perforation, and the patient did well for eleven days, but then developed phlebitis. On the seventeenth day pneumonia set in and lasted to the twenty-ninth day, when the temperature fell and improvement began. But on the thirty-first day the patient suddenly vomited six ounces of blood and died in an hour. As no post-mortem could be obtained the cause of this late hemorrhage can only be conjectured.

In the other case a married lady, who had suffered from gastric symptoms since 1882, was seized with signs of perforation, in November, 1895. She recovered, but still had so much pain that she could take no exercise and only fluid food in small quantities. An exploratory operation revealed a strong cord a quarter of an inch broad and one and a quarter inches long uniting the pyloric end of the stomach to the abdominal wall. This was removed, and after long convalescence the patient quite recovered, after fourteen years of suffering, and is now (two years after operation) well. Mr. Wallis therefore hopes the benefit will be permanent. At a later period of the discussion he admitted that some cases of recovery without operation had occurred after perforation, but the great majority had been fatal—in fact, the patients died for want of laparotomy, which he did not consider a very terrible ordeal. He therefore agreed with most surgeons that operation is imperative.

Dr. Hawkins, of Reading, described a couple of cases in which it was believed perforation had occurred, but recovery took place although no operation was performed, and he raised the question whether this measure is always necessary.

Dr. Kingston Fowler said no to this, and related a case to show that after perforation with escape of gas into the peritoneum recovery may take place.

Dr. S. Phillips also mentioned two cases of recovery after the usual signs of perforation.

Dr. Lucas Benham observed that posterior ulcer is not so dangerous as one on the anterior surface, and outlined a case of the kind, which, however, was fatal, the ulcer at the post-mortem being found to be the size of a shilling and freely permitting the contents of the stomach to pass in and out of the posterior cavity of the peritoneum.

Mr. Spencer observed that disappearance of liver dulness is sometimes due to distention of the colon, and to be of value must be accompanied with rapid pulse—rarely below 120 to 130 in perforation. He mentioned cases to illustrate this.

Dr. Toogood told of a case of acute pain, disappearance of liver dulness, and pulse of 130 to 140. On abdominal section he found the stomach normal, but the patient died the next day, and at the post-mortem a very small ruptured aneurism of the aorta was found.

Mr. Symonds described the case of a lady sixty years old on whom an exploratory operation revealed a thickened mass springing from the posterior wall, dividing the stomach into two cavities. He united the cardial end to the small intestine, thinking the case malignant. Death occurred on the sixth day suddenly. At the post-mortem the stomach was found full of blood from an old ulcer of which the thick mass had been the border. On the posterior wall was an enormous ulcer with the edges fixed to the parts in front of the spine. Another case was that of a gentleman who has undergone seven laparotomies but is now well. He remembered a man forty-three years of age on whom it was intended to operate the next day, but in the morning acute pneumonia was found. In another case a girl was operated on and the stomach found healthy. She recovered, and her case was recorded as acute hysterical vomiting. The pulse was not invariably rapid—he had seen it as low as 60, and a lower figure has been recorded. It is obvious that diagnosis is not so clear as is often stated, and the mistakes that have been made may well give pause. Nevertheless, most surgeons would prefer to operate early, and in a clear case this is the most hopeful practice.

Mr. Horsley in the Medical Council endeavored to raise the question of the appeal of the late Mr. Hunter. This gentleman was the qualified practitioner who was prosecuted by the council last May for styling himself "physician and surgeon." I mentioned the matter at the time. Mr. Hunter died soon after, and there are not wanting those who declare that his death was brought about by the council. The council by a vote of 21 to 6 declined to give Mr. Horsley the opportunity to discuss the case, and resolved to digest their shame in secret. Accordingly Mr. Brown and Mr. Horsley have sent to the journals a protest against the legal advisers of the council appearing in support of their appeal now pending. The blundering of the council and their advisers on this case accentuates the disgust felt at their carelessness as to the doings of notorious quacks.

Mr. Horsley has issued his fifth report to the Registered Practitioners, in which he deals effectively with this case. The council has not discussed the case, and the unconstitutional procedure adopted is akin to the obstruction offered to the production of the documents of the council for inspection by councillors. Mr. Horsley is doing splendid work in maintaining the equal rights of all the members and in forcing the council into more constitutional proceedings.

The proposed School for Tropical Diseases has begun badly. Sir H. Burdett, who has a fancy that he knows everything about hospitals, wrote to *The Times* in July that the teachers would be the senior officers of the Dreadnought Hospital together with others specially selected. It now appears that these senior members were never consulted about the matter and have since been asking why, but have extracted no explanation of the discourtesy from Sir H. Burdett and the committee. This is the requital the three senior medical officers receive for their service of eighteen, ten, and seventeen years respectively. The matter has provoked such unfavorable comment in the newspapers that the committee has issued its defence in a "memorandum" which it was silly enough to submit to Sir W. Broadbent. He has replied in a letter showing that the committee presented a one-sided statement to the Secretary of State and in its own memorandum is guilty of a *suggestio falsi*.

Sir William concludes that "a committee capable of such a suppression of truth material to the issue and

of such a suggestion of what is calculated to mislead is, in my opinion, totally unworthy of confidence." After such a distinct condemnation by the authority they selected the committee has no honorable course but to retire. Sir William Broadbent's verdict will be indorsed by the whole profession.

The magistrates have dismissed the charge of manslaughter against the "Christian Science" women in the case of the late Harold Frederic, remarking that they were partly influenced by the fact that it is still open to the treasury to prosecute on the finding of the coroner's jury.

The Queen has paid another visit to the sick and wounded soldiers in Netley Hospital.

The death of Dr. Cleveland was very sudden. On the 24th ult. he was as well as usual, and about the time he was expecting a couple of friends to dinner he walked from one room to another, fell down, and expired immediately. He was seventy-five years old, and a post-mortem showed fatty degeneration of the heart. Dr. Cleveland had for many years been a familiar figure in the medical world and an active member on the council of the British Medical Association. He had been president of the Metropolitan Branch.

THE PERPLEXITIES OF MEDICAL VISITORS IN NEW YORK.

To the Editor of the Medical Record.

Sir: It has been often repeated in editorials and addresses that it is no longer necessary to go to Europe to obtain all that is latest and best in medical science. It is true that some of the most brilliant surgeons of the world are operating in New York City. Moreover, if one would see surgery, it is unpatriotic not to learn what advantages our own metropolis offers before going to Vienna.

All this has been earnestly promulgated and is generally admitted. If some surgeon should, however, for inspiration leave his practice to spend two weeks in the city, he would soon discover one reason why those who can afford to do so continue to go abroad. This reason is the impossibility of knowing when and where the operations take place which he desires to see.

His hotel will inform him that there are hospitals in abundance for two or three miles in every direction; but unless he is especially acute, his stay will be nearing its close before he finds out how and when he can see anything at them. It would seem to be the most natural thing in the world that of somebody or in some place, for love or for money, there could be obtained information of the operations and operators on a given afternoon. But if this be possible to exceptionally brilliant people, it certainly is not so to the ordinary visitor. Of course he does not expect to see anything in the forenoon, for then every one is busy in his own office. Evenings are dedicated to amusements; the only hope of accomplishing anything is at three o'clock in the afternoon. Certain hospitals, he learns at last, have operations every Saturday afternoon. At others there are operations by different surgeons at irregular intervals. Sometimes postal cards are printed announcing them, but no one knows where to go to see these postals. One may telephone to each hospital every morning for information, but the chances of getting any from the boy who answers the telephone are meagre. A lively fancy might harbor the supposition that the bulletin board at the Academy of Medicine would contain such notices, but on applying the test of experiment to this flight of the scientific imagination he would find there only advertisements of practices for sale, examinations for house surgeons, and the like.

There remains to him the method of travelling about from Fifteenth to One Hundred and Fourteenth Street and surprising people in the offices by inquiring if any operations take place in their hospital on that day; but as for seeing the special operations that he needs, or many of the men of national reputation that he came to see, the prospect soon grows doubtful.

By perseverance—and chance—if his time is not too limited, or he does not begin to feel that it could be better spent at home, he does witness some surgery, and very good surgery it is likely to be. The surgeons themselves treat him so kindly, and are so obliging in answer and demonstration, that he cannot think that it is from any unwillingness on their part that their hospital work cannot be better seen. It might well be that the eminent surgeons would feel that too many were dabbling in surgery, and that the little knowledge they could impart by too public clinics would be a dangerous thing for the country practitioner as well as for themselves. This idea, however, is not the general one. That giving doth not impoverish, and withholding doth not enrich, is, I think, the belief most generally held by our profession in regard to scientific truth or its adaptation to the healing art.

It is because this waste of time to the visitor does seem so needless that I have ventured to call attention to it in this letter. A practical remedy is not so easy to suggest. If each hospital should send a list of operations for the next day to the Academy of Medicine—furthermore if the Academy should endeavor to keep this list complete, charging those who consult it a fee if thought best, or posting it publicly if they could afford to do so—it would certainly be a very great convenience. Any other location might be selected and an item to the effect published in our city medical journals. Two or three years ago such a list was daily posted in the College of Physicians and Surgeons in Philadelphia, which must have proved an accommodation to others besides the writer.

I am quite sure that if this statement of the troubles of the visitor from outside shall fall under the eyes of certain of the energetic physicians of New York City, they will add to our present obligations to them by putting in operation some remedy similar to or better than the one here proposed.

F. N. Higgins.

Cortland, N. Y.

[If the writer had consulted the bulletin board at the left of the entrance in the Academy he would have seen cards announcing operations in many, if not most, of the hospitals in the city. He evidently looked only at the bulletin at the library door.—Ed.]

THE CARE OF THE TROOPS IN HAWAII.

(From our Special Correspondent.)

To the Editor of the Medical Record.

Hawaian Islands, November 30, 1898.

Sir: Of numerous sanitary questions arising from a new colonial departure of the United States in tropical countries, the health condition of our troops requires immediate attention. Since the beginning of the war to this day Honolulu is crowded with troops, partly as a local garrison but principally as a transport and coaling station on the way to the Philippines. Ever since, an epidemic of typhoid fever, with a percentage of mortality far above the usual for this place, has continued to ravage in their midst. The mischief is due to several causes. Upon inquiries we learn that a considerable part of the volunteers are clerks, merchants, and others untrained for any active physical life and privations connected with an extemporized campaign. Owing to the hardships of camp life, forced

marches, and poor diet, they embark at San Francisco with their constitutions already undermined. During the voyage of seven to twelve days to Honolulu their condition becomes still worse; upon the transports they are crowded, and the food is poor and insufficient. Complaints in this regard upon landing are general. As a rule, several cases of typhoid fever develop on board every transport already on the way. Thus all conditions for an epidemic are present; burning matches are lying close to the powder, germs of disease close to a good medium for their quick and extensive propagation. The commander of a body of such troops may be compared with a man holding a box of matches in a conflagration. The only course for him is to scatter them far and wide to save those yet unaffected.

Another cause comes into play upon landing: it is the local climate of the place. As I will show in my further letters, there is no such entity as a "tropical climate." Tropical countries have all kinds of climates, with but few general characters not dependent on latitude. The problem before the sanitary officers in charge is to select such places of the country as will suit the newcomer the best, and require the minimum efforts for acclimation. In a tropical country this problem is reduced to a few elementary principles: to provide unquestionably pure drinking-water; to avoid large settlements; to avoid low elevations in general and swampy, undrained plains in particular; to choose localities away from all resources of stagnant water and malaria.

None of these precautions are taken upon landing troops in Honolulu. They stay where they land, viz., in the town and its suburbs. The very military hospital is located in the so-called "Independence Park," the least fit locality on account of its bad malarial reputation, surrounded as it is with morasses, ponds, rice and banana fields. The town of Honolulu represents an old settlement with about thirty thousand inhabitants, and is located upon a vast plain between the sea and the adjoining mountains. This plain is a coral field partly covered with alluvial soil washed down from the neighboring hills. On account of its low elevation and of the mountain waters draining into its soil it is practically a morass whose ground water fluctuates with the ocean tides. There is no drainage whatever, either natural or artificial. There is no sewerage, the ground having been soiled with animal products for a century, since the time of Captain Cook, notwithstanding hundreds of millions of dollars made on the place or rather from the place by its inhabitants. Drinking-water is supplied partly from a shallow artesian well sunk in the middle of the town, immediately under the filthy Portuguese quarters and cemeteries, from which water is pumped into an elevated reservoir; the principal supply comes from some ponds in a neighboring valley, at about one thousand feet altitude. Those ponds are fed by a stream which owes its existence to the rain-water of the surrounding mountain slopes, which are utilized as cattle pastures.

These are the general facts concerning the local climate of Honolulu, where both malaria and typhoid fever are endemic. There are no pernicious forms that could be compared with those of other tropical countries, but malarial influence is generally felt as a chronic condition by everybody who does not possess a strong natural immunity. Objectively this influence is manifested in the loss of weight, all the symptoms of tropical anæmia, a pale, sick, sallow complexion, etc.; subjectively it is felt as nervous and muscular debility, rendering long and steady exertion difficult. It is not the temperature but these miasmatic influences that render the local Honolulu climate debilitating and make every pathological process assume asthenic characters. In its pure and acute manifestations this malaria is but seldom intermittent; mostly it is remittent and accompanied by certain typhoid features, on account of which it is called "typhoid malaria." It is unaffected by quinine, but proves very seldom fatal, though it may last several weeks.

The sporadic cases of the real typhoid fever, due to the lack of sewerage in town and to the use of animal fertilizers in the country, are far from being so common. In fact, it is not any more frequent here than in any part of the American continent under similar conditions. The asthenic character due to the unabating influence of malaria is the only peculiarity it possesses. The question whether the epidemic among the United States troops is real typhoid fever or "typhoid malaria" is not yet settled between the military and local sanitary authorities. It is not settled because in reality it is both malaria and typhoid fever, or rather typhoid fever whose course is affected by local malaria.

In short, the diagnosis of this epidemic runs thus: The germs are imported by the troops themselves and probably are more virulent than those we usually have to deal with in this country. Their virulence is still increased through the debilitated condition of the troops as well as by the asthenic influence of local malaria. Inferring from causes, we may say that this and other similar epidemics might have been prevented: (1) By paying more attention to the character of the former occupations of volunteers. (2) By a better organization of the supply service and the adoption of more hygiene in camps and especially on transports. (3) By the immediate scattering of troops upon landing in foreign ports, in small detachments over the surrounding country, viz., upon the neighboring hills and plateaus, the sanitary reputation of which, at least for the Hawaiian Islands, is above all suspicion. (4) By providing camps with pure and healthy drinking-water. These are old truths; but the older they are, the more frequently they have to be repeated.

Medical Items.

German University Students have increased in numbers from 10,000 twenty-five years ago to 32,241 last year. The increase is out of all proportion to the population.—*Scientific American.*

The Coming Season in Cairo.—In spite of the absence of the German Emperor, the season promises to be exceptionally good. The principal hotels have already double the number of visitors which they had last November, and most of the dahabiyehs on the Nile have been engaged. Two new hotels will be opened next month, and several existing ones have enlarged their premises during the winter.—*London Lancet.*

Nurses and Women Doctors.—In an address given at the Royal Free Hospital in London a short time ago, Dr. I. Walter Carr made some exceedingly apt remarks in reference to the extraordinary development of nursing during the last generation, and expressed the fear that there was possibly a danger of its being carried too far in private work, and especially in the homes of the middle classes. The same speaker also touched upon the question of women doctors, and discussed their present position. He asked if they were a merely passing fancy, or were destined to take a permanent place in medicine. The question might seem superfluous, in view of the rapid progress they were making, but if the movement became fashionable, and unsuitable women were led to enter the profession, a reaction might easily arise and jeopardize the cause.
